Having a contaminant in the environment does not mean that all nearby organisms will have contact with it. For example, surface-dwelling animals may not have direct access to a contaminant buried under many centimeters of topsoil. However, certain organisms may be exposed by consuming earthworms or plants that bring the contaminants to the surface. In ecotoxicology, receptors generally refers to intact organisms. When pollutants and receptors co-occur, pathways of exposure, including dermal, ocular, oral (via water, diet, and grooming), inhalation, and/or gills, may be important. The bioavailability of a pollutant in the environment refers to the fraction of the substance that is absorbed across the gut, skin, or other portals to enter the bloodstream and other tissues where it can cause one or more pathophysiological reactions. Bioavailability can be influenced by the types and concentrations of toxicants in the environment, the nutritional status of the exposed organisms, the amounts of organic matter, pH, cation-exchange capacities of soils or sediments, and the presence of elements or other chemicals that antagonize uptake.

Environmental contaminants can be physically transformed into simpler, often less toxic forms, in several ways. Spontaneous oxidation, reduction, and hydrolysis reactions may be involved. By definition, photodegradation implies reduction in toxicity and, in the case of many complex molecules containing chlorine, bromine, or fluorine, can result from ultraviolet (UV)-induced dehalogenation. Although many man-made chemicals are rapidly photodegraded by sunlight, some chemicals become more toxic to organisms through

photoactivation. For example, dechlorination of hexachlorodibenzo-*p*-dioxin may produce lower chlorinated but more toxic dioxin congeners.

Biotransformation involves modifications of chemicals by physiological processes in living organisms (e.g., enzymes in the liver that catalyze hydrolysis, oxidation, reduction, or conjugation). Biotransformation occurs not only in animals and plants but also in soil microbes such as fungi and bacteria under aerobic or anerobic conditions. In vertebrates, microbes within digestive tracts can also greatly influence the biotransformation of environmental contaminants. Metabolism and conjugation of xenobiotics often reduces toxicity and enhances the ability of the animal to eliminate the agent from the body. By contrast, metabolic changes can also bioactivate chemicals to produce (by definition) metabolites that are more toxic than their parent compounds. For example, the organochlorine pesticide DDT is not itself highly toxic to birds, but its metabolite *p,p'*-DDE can cause thinning of eggshells due to disruption of calcium metabolism. Also, microbial metabolism in anaerobic sediments converts inorganic mercury to methylmercury, which is responsible for cognitive, motor, and visual-spatial disabilities, especially in the developing young of a wide array of animals including human beings. Efforts by organisms to detoxify exogenous compounds can sometimes produce temporary bioactivation manifested in reactive species such as singlet oxygen or hydroxy radicals. These free radicals or oxidants, as well as their depletion of natural antioxidants in the body (e.g., glutathione, ascorbic acid, and carotenoids), can lead to oxidative stress, damaging macromolecules, cells, and tissues. Such processes can culminate in overt tissue injury and also DNA damage leading to degenerative diseases, mutagenesis, carcinogenesis, and hereditary defects. To better understand what is happening to wildlife and ecosystems – as well as to domestic animals and humans – far more research is warranted on the fate and toxicity of mixtures of contaminants, as well as their metabolites, and their environmental degradation products.

### **Chemical disasters: ecological, economic, and societal factors**

The stewardship of chemically mediated disasters ranges from responsible and efficient to neglect and indifference. Localized disasters involving a single, acutely toxic, short-lived chemical (e.g., a volatile solvent released into a warm water body from a damaged tank car of a train) can be largely self-resolving. Ecological recovery after a chemical insult is also more likely when ecological resources (locally adapted microbes, plants, and animals) from the periphery are intact and able to recolonize the affected area; local emergency agencies

are well equipped, staffed, and responsive; funding is available from responsible parties or government to support containment, cleanup, and ecological rehabilitation; and the public is strongly engaged. Conversely, recovery is less likely when releases involve multiple long-lived chemicals spread over a wide area (e.g., complex, halogenated, higher molecular-weight wastes in a series of large lakes), ecological resources from the periphery are insufficient to support recolonization, responsible parties deny involvement, neither the responsible parties nor the governments involved put forth needed funds, and the public is largely disengaged. Accordingly, for the ecotoxicologist to be an effective member of a stewardship team, effective laws and policies and an informed and empowered public are often essential. Rather than tolerating or increasing releases of environmental pollutants that lead to downstream, downwind, or wider chemical disasters, enlightened leaders in industry and government are supporting harmonized global laws and regulations that impose industrywide stewardship so that they may produce and use chemicals responsibly without being at a competitive disadvantage.

### **ECOTOXICANTS IN CONCERT WITH OTHER MECHANISMS OF ECOSYSTEM DISEASE**

Prevention of ecotoxicological diseases is uniquely important because wild animals are less readily observed than people, domestic animals, exotic pets or zoo animals; toxic agents in ecosystems cause not only direct poisoning of observed organisms but also poisoning of other species on which they depend; treatment of free-ranging species is challenging if not impossible; and the survival of endangered species is commonly at risk.

Aquatic systems throughout the world are increasingly under stress from human activities. Wetlands, lakes, streams, rivers, and estuaries are being degraded due to hydrologic mismanagement, which directly stresses local aquatic life and may also aggravate chemical pollution problems. A vastly reduced sponge effect (which historically was provided by ubiquitous native plant debris), grading of land, hard surfaces, drainage of wetlands, stream channelization, and subsurface tiling of fields decrease groundwater recharge and increase the “flashiness” of streams, contributing to catastrophic and prolonged flooding. After significant rainfall, cropland (especially when largely barren in fall, winter, and spring), cleared forests, stockyards, lawns, roofs, roads, parking lots, demolition and construction sites, and poorly managed industrial and dump sites release pulses of complex pollutant mixtures to water bodies (Kolpin *et al.*, 2002). Such pulses

can carry high loads of nutrients, metals, salts, hydrocarbons, synthetic organic chemicals including pesticides, and combustion products into surface waters.

When wetlands and forests dry, essential carbon needed for water retention is oxidized, leaving the system as CO<sub>2</sub>. Also, without water recharge from wetlands, streams experience abnormally low flows during dry periods, which decrease dilution and thus increase concentrations of contaminants. Reduced volume in streams also results in increased water temperatures in summer, which greatly reduces the water's oxygen-holding capacity. Removal of tree canopies through logging, agriculture, and urban development further increases stream temperatures, harming aquatic species such as trout and salmon, which can survive only in cool, highly oxygenated waters.

In addition to being sources of toxicants, road and bridge construction, deforestation, agriculture, and mining erode soils and increase sedimentation of waterways. High suspended sediment loads increase turbidity, shading plants so that their primary productivity from photosynthesis and the dissolved oxygen, biomass, and structure that they provide are reduced. Excess suspended sediments in waterways can also degrade spawning habitat, produce lesions in gills, and modify animal behaviors, reducing fish productivity and disrupting fish community assemblages (Burkhead and Jelks, 2001).

Many of the world's coral reefs are being degraded by destructive fishing and collecting methods, eutrophication, and increasing water temperatures related to global climate change and especially runoff. Coral diseases have been attributed to thermal stress, viruses, bacteria, cyanobacteria, and fungi. Although the mechanisms of environmental degradation in producing coral disease remain poorly understood, the vast majority of impacted reefs in the Caribbean are near areas of human activity. For example, coral off the coast of the Netherlands Antilles where there are inputs of sewage have experienced black band disease, the lesions of which are characterized by changes in microbial communities. Understanding the complex relationships among black band and other coral diseases, their microbial co-inhabitants, and chemical contamination will undoubtedly require additional research (Green and Bruckner, 2000; Klaus *et al.*, 2007).

Many frontier areas of North America were initially converted to farms that consisted of a mosaic of small fields of vegetables, grains, and forage crops, interspersed with fencerows, woodlots, pastures, and wetlands. People learned to use crop rotations for both fertilization and pest control. By contrast, modern agricultural and forestry practices have produced vast monocultures of genetically similar plants that deplete nutrients and are susceptible to attack by plant pathogens such as fungi and herbivorous insects, triggering

applications of toxic fertilizers and pesticides, the effects of which are discussed later.

Modern agriculture and forestry, along with urbanization and suburban sprawl, have eliminated most natural habitat, leaving habitat islands in a largely inhospitable larger landscape. Biota trapped in such habitat remnants are prone to extirpation due to extreme weather, desiccation, inbreeding, competition with invasive and sometimes exotic species, starvation, predation, infectious diseases, and toxicoses. Individually and together, these forces can cause reduced breeding fitness and reproduction, as well as direct mortality. The resultant loss of species from habitat patches can culminate in local or regional extirpations and ultimately extinction events.

### **Wasting carbon, inducing climate change, and increasing toxic exposures**

Human-induced environmental contamination is not a new phenomenon; it is one that is becoming far more complex. In much of the midwestern United States prior to European settlement, wild habitats were burned by people to create lush grazing lands that could be used for hunting. This activity released not only smoke but also pulses of nutrients to local watersheds. Anthropogenic air pollution has been reported since 13th-century London, when smog from coal fires blanketed the city, and the situation worsened with the industrial revolution of the 1700s. An estimated 12,000 people died in London during the Great Smog of the winter of 1952. Today, climate change, flooding, fires, free nutrients, and low water flows are associated with increased toxicant exposures and ecotoxicological impacts. Excessive reliance on natural gas, petroleum, and coal for power generation releases a wide array of pollutants from tall stacks, potentially harming people, animals, and the environment both near and far from the source. Additional major anthropogenic sources of today's atmospheric pollutants include oil refinement, motor vehicles, waste incineration, industrial emissions, fires from slash-and-burn agriculture in previously forested areas, annual clearing of land by burning before planting of crops (common in much of the world), and large wildfires that follow misguided forest fire suppression. Widespread deforestation, especially in the tropics (the "lungs of the earth"), and coastal pollution that limits phytoplankton photosynthesis reduce the ability of the environment to remove CO<sub>2</sub> and clean the air. These various and pervasive activities are increasing CO<sub>2</sub> and methane levels, which are largely responsible for global climate change.

China recently became the global leader in emissions of CO<sub>2</sub>, and the United States is a close second. According to the Oak Ridge National Laboratory, of

North American releases of greenhouse emissions in 2002, approximately 92% were generated in the United States, and this was 26% of the world total (Marland *et al.*, 2005). A recent estimate indicates that half of the estimated 337 billion tons of CO<sub>2</sub> released globally due to human activities since 1751 has entered the environment since the mid-1970s (Boden *et al.*, 2010). The major source is fossil fuels, but cement production is becoming increasingly significant. During the 20th century, CO<sub>2</sub> emissions in the United States increased an estimated ninefold. According to the United Kingdom Department of Trade and Industry, China, which has a much higher human population and has been rapidly industrializing, has increased its CO<sub>2</sub> emissions in the same time frame by 6000-fold.

As ice caps melt due to the greater increases in temperature at the poles, more infrared is absorbed by the darker water and land, further aggravating warming. Additional methane is then released from lands previously covered with ice. Steady increases in average temperatures are also causing glacial retreat, and when the glaciers are finally depleted, downstream areas will dessicate. In addition, climate change has been linked to increasing extreme weather events (e.g., droughts, floods, and hurricanes) as well as to fires.

Rising global temperatures are also producing shifts in species distributions. Species, including arthropod vectors, that tolerate warmer temperatures are able to move farther from the equator and to higher elevations, commonly carrying diseases to previously unexposed and thus immunologically naïve wildlife. Climate change may also aggravate natural toxin problems, as noted later.

### DIRECT TOXICITY OF NUTRIENTS, STIMULATION OF HARMFUL ALGAL BLOOMS, AND FACILITATION OF LETHAL OUTBREAKS OF BOTULISM

Globally, the rate of transfer of atmospheric nitrogen (N) to the available nitrogen pool has doubled due to anthropogenic activities (Vitousek *et al.*, 1997). Nutrients, primarily N and phosphorus (P), enter environments from chemical fertilizers, manure, urine, sewage effluents, burning fossil fuels, fires, decay of plants and animals, and industrial processes such as pulp/paper milling and nitric acid production. Free nutrients are washed into water bodies and enter groundwater and aquifers, some of which feed streams, ponds, lakes, estuaries, bays, and oceans. Agricultural production of plants and animals is the primary source of excess nutrients in the environment. The lack of incentives and disincentives sufficient to substantially close the nutrient loop between

plants and animals is the heart of the problem. World consumption of fertilizers in 2005 and 2006 totaled 154 million tons. In 2003, the United States used 21 million tons of plant fertilizers, primarily as N, P, and potassium (K), which is approximately the same level as in 1976. Similarly, fertilizer use in other developed nations has plateaued, having reached a point where further inputs do not increase yields. However, as the human population and economic expansion increase, demand for animal protein, and thus production of animal feed, may prompt an expanded agricultural footprint with more extensive use of fertilizers, especially in developing countries.

Forms of inorganic N, including ammonia, ammonium, nitrate, and nitrite, are directly toxic to aquatic life, including invertebrates, fish, and amphibians. For example, ammonium nitrate fertilizer produced toxic effects in tadpoles of American toads (*Bufo americanus*), western chorus frogs (*Pseudacris triseriata*), northern leopard frogs (*Rana pipiens*), and green frogs (*Rana clamitans*) at concentrations found in the agricultural environment (Hecnar, 1995). Twenty percent of more than 8000 water samples collected from the Great Lakes watershed exceeded concentrations considered toxic to amphibians (Rouse *et al.*, 1999). High N concentrations contributed to lower amphibian reproductive success and reduced species richness in wetlands in agricultural areas (Knutson *et al.*, 2004).

Nutrient contamination can also set the stage for production of toxins by certain blue-green algae (cyanobacteria). Examples of cyanobacterial neurotoxins include anatoxin-A, anatoxin-A(s), saxitoxin, and neosaxitoxin. An as yet unidentified cyanobacterial neurotoxin is believed to account for avian vacuolar myelopathy (AVM). Evidence suggests that a cyanobacterium in the order Stigonematales produces a toxin as it grows on an exotic invasive macrophyte, *Hydrilla*, which is consumed by birds such as coots and ducks, resulting in AVM (Birrenkott *et al.*, 2004; Williams *et al.*, 2007). Eagles are subsequently exposed to the suspected toxin in poisoned prey.

In addition to producing neurotoxins, cyanobacteria may produce hepatotoxins, such as microcystins, nodularin, and cylindrospermopsin. Both neurotoxic and hepatotoxic cyanobacteria have been implicated in die-offs of lesser flamingos, an obligate algal feeder. However, additional research is needed before the importance of cyanobacterial toxins in long-term downward population trends of lesser flamingos can be deduced.

Although harmful marine algal blooms seem to be causing emerging toxicoses worldwide, and the causes are not adequately understood, the organisms require available nutrients. Among marine phycotoxin producers are diatoms that produce neurotoxic domoic acid and

different dinoflagellates that produce saxitoxins, ciguatera toxins, and brevetoxins. Brevetoxin exposures via aerosols and ingestion of sea grasses contaminated with the toxins seem to account for repeated major death losses in manatees along the southwest coast of Florida. Humans are also harmed by inhalation of brevetoxin-containing aerosols. Of great importance is that shellfish and finfish accumulate these various marine phycotoxins, and their ingestion leads to secondary poisoning in humans, cormorants, pinnipeds, and cetaceans (e.g., *Tursiops truncatus*) (Van Dolah, 2000; Flewelling *et al.*, 2005).

Free nutrients can also prompt growth of algae and cyanobacteria that smother and absorb essential UV needed by other photosynthetic species. Even nontoxic algal blooms can thereby cause massive alterations in ecosystems of lakes, estuaries, and coral reefs. Overgrowth of algae, cyanobacteria, and even macrophytes following nutrient pulses can result in decreased dissolved O<sub>2</sub> concentrations as a consequence of respiration of the photosynthetic organisms (e.g., at nighttime and during cloudy weather). Also, metabolism of dead algae, cyanobacteria, and macrophytes can greatly reduce dissolved oxygen concentrations and undermine nutrient storage.

According to the U.S. Geological Survey National Wildlife Health Center, more than 52,000 botulism-related avian deaths occurred on the Great Lakes during 2002–2006. Free nutrients made available in the tissues of dead animals and used by *Clostridium botulinum* to produce neurotoxins that are often conveyed by maggots to birds have long been incriminated in a vicious cycle causing major die-offs from botulism in waterfowl. A green alga and exotic species may be among additional factors that now contribute to initiation of avian botulism outbreaks. Increased water clarity and nutrient release due to inefficient feeding by invasive zebra mussels (*Dreissena polymorpha*) and quagga mussels (*Dreissena rostriformis bugensis*) have fueled dense growths of *Cladophora*, a filamentous green alga in the Great Lakes. When *Cladophora* ultimately dies, *C. botulinum* can thrive in the anaerobic mass (Byappanahalli and Whitman, 2009). The toxin can also accumulate in the mussels as well as in exotic round gobies (*Apollonia melanostoma* (*Neogobius melanostomus*)), and ingestion of the contaminated mussels or round gobies has been implicated in die-offs of common loons (*Gavia immer*) as well as in mergansers and other aquatic feeding birds.

Many phytoplankton and bacterial species have shorter generation times at warmer temperatures. Therefore, global climate change may lead to increased microbial diseases and harmful algal blooms. Other chapters of this book on nutrients, phycotoxins, and botulism should be consulted to learn more about the manifestations, diagnostic criteria, management, and prevention of the respective toxicoses.

## PETROLEUM DISASTERS, WILDLIFE TOXICOLOGY, AND HUMAN IMPACTS

Many of the effects of petroleum on wildlife are similar to those seen with domestic animals; therefore, readers who want to learn more about the impacts of petroleum on animal health should also examine the chapter on petroleum toxicity. Here, we provide examples of how petroleum can pose such extreme challenges to the health of wildlife and describe how some of its effects on wildlife are unique.

On March 24, 1989, the *Exxon Valdez* hit a reef, spewing almost 11 million gallons of crude oil into the largely pristine Prince William Sound in Alaska. Exxon Corporation (now Exxon Mobil), the ship's owner, the Alyeska Pipeline Service Company, a consortium of oil companies with interests in Alaska, as well as state and federal disaster response groups were criticized (and Exxon and Alyeska were eventually sued) as being wholly unprepared to provide a rapid and effective response for such a disaster as required by law. Confusion, poor communication, ineffective coordination, lack of sufficient personnel, inadequate equipment and supplies for a spill of that magnitude, and remoteness of the location hampered efforts to contain and begin effective cleanup for the first 2 days, and thereafter rough seas created further difficulties. The ecological and socioeconomic impacts were immense, and responses from conservation organizations and agencies, academic institutions, mass media, and the public were unprecedented. Frustrated by a lack of action on the part of industry and government, local citizens began to clean up what oil they could with resources at hand. Within hours of the spill, scientists arrived to begin documenting environmental impacts of the spill. Particularly sensitive environments were quickly identified and prioritized for protection and cleanup. Crews began to arrive from throughout the world to help clean oil-covered beaches, seabirds, and sea otters. Untold numbers of fish and wildlife died from direct impacts of oiling. An estimated 36,000 birds and 1000 sea otters were eventually treated for oil exposure. Approximately 25% of the Harlequin ducks in affected areas died after the spill, and the best estimate for time to recovery of the population was deemed to be 24 years (Iverson and Esler, 2010). Monson *et al.* (2000) detected reduced survival of sea otters in the 9 years following the incident, with some of the adverse effects noted in individuals born after the spill. According to the Exxon Valdez Oil Spill Trustee Council, the populations of only 4 of 11 bird species impacted were recovering or had recovered as of 2002. Spraying the oil with hot water caused penetration of sediments, prolonging effects. Impacts persist today (<http://www.evostc.state.ak.us/universal/documents/NEPA/Final%20SEIS%208-26.pdf>).

Populations of herring, a keystone species in the Prince William Sound's food chain and the crown jewel of the local commercial fishery, have not recovered. In addition to the economic losses to fisheries and tourism must be added nonmarket values (i.e., "replacement costs" of wildlife) as well as the costs of increases in cancers, respiratory illness, mental illness, and violence in the wake of the ecological and economic disaster. Although Exxon paid for some of the cleanup and lost earnings, the ecological and social impacts continue. In response to the *Exxon Valdez* disaster, the Oil Pollution Act of 1990 required increased spill preparedness and the phase-in of double-walled tanker ships, which greatly reduce chances of a spill when tankers run aground or hit an iceberg or reef. Unfortunately, the petroleum industry found loopholes in the law and effectively delayed the deadline for new or retrofitted tankers until 2015. Additional information on the history, current activities, and future plans surrounding this disaster is available at the *Exxon Valdez* Oil Spill Trustee Council's website (<http://www.evostc.state.ak.us>) and the U.S. EPA's *Exxon Valdez* Oil Spill Profile (<http://www.epa.gov/oilspill/exxon.htm>). Even now, surface and subsurface oil remain in some areas, poisoning aquatic life and slowing ecosystem recovery.

Although oil spills are preventable, they continue to occur, causing illnesses and mortality events in wildlife, which prompt extreme efforts by responders. Oil companies have sometimes paid out large sums to offset some of the impacts, but the costs to date have not triggered actions that reliably prevent spills from occurring.

Engineering flaws, poor preparedness for spill disasters, and delays and incoordination among responders were again evident during the British Petroleum Deepwater Horizon leak into the Gulf of Mexico in the spring and summer of 2010. In this case, areas of shoreline were partially protected by burning off oil, containment with booms, aspiration, physical removal on the land, and the offshore addition of dispersants of undefined composition in terms of specifics although they included solvents and detergents. Responders obtained and froze dead animals for necropsies, which continued 1 year after the spill. During and after the spill, rescue crews undertook triage including euthanasia of severely affected wildlife. Animals deemed to have reasonable prospects for survival were given diagnostic assessments, supportive care and time for acclimation and partial recovery, followed by extensive washing by well-trained crews and then more supportive care. Such efforts helped some of the affected wildlife, especially birds, to be returned to the wild. Although pelicans and other waterbirds were most often seen in media reports, among the more grave concerns were impacts to endangered sea turtles. Not only did the animals experience skin and respiratory irritation but also the dark-colored

oil coated their bodies and in the hot sun of the gulf area they became extremely hyperthermic. Some of the turtles were captured and treated, and death losses were somewhat curtailed. In addition, according to the National Oceanic and Atmospheric Administration, 274 sea turtle nests on the Gulf Coast were translocated to the east coast of Florida to avoid the impacts of oil pollution (<http://www.nmfs.noaa.gov/pr/health/oilspill/turtles.htm>).

Unfortunately, petroleum spills seem to receive far more attention from the media, corporations, and governments when they occur in developed countries compared to the developing world. A case in point is Nigeria, where, since the 1940s, the oil-rich Niger Delta has experienced oil spills that dwarf the 2010 Deepwater Horizon leak. With a corrupt government that has been unresponsive at best, oil companies that may be complicit in government violence against local peoples, native ethnic peoples receiving little if any compensation for oil extraction and related environmental degradation, associated unrest and protests that have turned violent, banning of public gatherings, and deaths including execution of leading activists for the Ogoni people of the Delta, the oil often seems to be more of a curse than a blessing to the Nigerian people. Currently, militant attacks on oil infrastructure have continued to aggravate spills, and the natural capital of the forests and waters continues to be replaced with pollution and oil infrastructure – leaving local people poor, sick, and discontented.

Waterbirds exposed to petroleum can lose the insulation and buoyancy of their feathers and, in cold water, can experience lethal hypothermia (Leighton, 1993). They can lose the ability to fly to feeding areas and sources of freshwater, resulting in starvation and dehydration. Petroleum toxicosis in birds can be associated with skin irritation, respiratory tract and ocular damage, neurologic dysfunction, and inhalation pneumonia. Birds with petroleum poisoning may also develop marked immunotoxicity with immunosuppression, and they often become progressively stressed and debilitated. They may experience digestive system irritation and even hemorrhagic gastroenteritis. They also may have renal failure, visceral gout, and hepatopathy with increased mixed function oxidase activities and associated alterations in the metabolism of endogenous and exogenous substrates – some of which result in further illness. Birds have repeatedly been found to develop hemolysis after exposure to petroleum. It has been suggested that certain polyaromatic hydrocarbons in a subset of petroleum sources may account for this effect. Consistent with oxidative injury, such birds may have elevated methemoglobin concentrations and Heinz body formation. Ultimately, such birds as well as fish may experience anemia and hemosiderosis (Khan and Nag,

1993). In fact, examinations of 560 common murres after the Apex Houston oil spill in February 1986 revealed packed cell volumes that were depressed by as much as 80%. As with other species, obtaining specimens of the oil from the animals and from the environment can be essential in ascribing liability.

Avian reproduction may be impacted by oil spills. Extremely small amounts of oil on eggshells can readily result in embryo mortality. Thus, oil transferred by minimally exposed parents to the eggs that they are incubating can be lethal to their offspring. Reproductive toxicity can also arise from exposure of adults to oil prior to egg laying because the eggs they lay may have reduced hatching and the surviving young may experience less than normal survival rates.

A current and growing concern pertains to placing oil fields in sensitive arctic and marine environments. A notable example is the Arctic Ocean off the north shore of Alaska. Oil spills in such areas may have immense adverse impacts on marine mammal populations and indigenous human communities.

It is clear that environmental and ecotoxicological problems related to petroleum including oil spills and global warming from CO<sub>2</sub> will continue for the foreseeable future. However, the problems do not stop there. Emissions during oil refining and polycyclic aromatics in the raw material and an array of products of combustion are also major concerns.

## AROMATIC HYDROCARBONS

Aromatic hydrocarbons have ring structures that confer the name to this group of toxicants. Included are both single ring and multiring (polyaromatic) structures. Petroleum includes a wide array of aliphatic as well as aromatic hydrocarbons. Aromatic hydrocarbons are also present at high concentrations in coal tar and are formed during incomplete combustion of coal, oil, gas, garbage, and other materials. Among the best known polycyclic aromatic hydrocarbons (PAHs) is benzo(*a*)pyrene, which is a component of cigarette smoke. Also of concern are volatile aromatic compounds such as benzene. Many of the aromatic hydrocarbons are oxidized by P450 enzymes in lung, liver, and other tissues to form reactive epoxide derivatives that form adducts to DNA, often resulting in mutations that have the potential to cause cancers as well as heritable defects. For example, both benzo(*a*)pyrene and benzene are known human carcinogens.

Another example of environmental contamination with aromatic hydrocarbons is that of the aluminum smelters of Quebec, Canada. Using the obsolete Soderberg method technologies, the smelting factories

released huge amounts of PAHs to the St. Lawrence estuary, where the compounds settled into sediments. Many species, including beluga whales, feed on benthic organisms. The PAHs, along with PCBs and other contaminants, were subsequently incriminated in digestive tract cancers of beluga whales as well as carcinogenesis in the local human population (Martineau *et al.*, 2002). After press coverage regarding the relationships among the contaminants and cancers, the aluminum industry of the area decommissioned the contaminating plants and installed cleaner technology ahead of their previously announced schedule.

The aryl hydrocarbon (Ah) receptor is a critical site of action of coplanar polychlorinated dibenzodioxins (PCDDs) and dibenzofurans (PCDFs) and PCBs. However, it should be kept in mind that the Ah receptor is activated not only by such compounds but also by unsubstituted aryl hydrocarbons. Accordingly, some of the impacts of the compounds discussed later are also catalyzed by PAHs.

## PERSISTENT ORGANIC POLLUTANTS

PCBs were marketed under the names Aroclor, Kanechlor, Clophen, and others throughout the world. The products consisted of mixtures containing more or less chlorine. PCBs came into widespread use in the 1930s and were banned in the 1970s. They were employed in electrical insulating, hydraulic and lubricating fluids, carbonless carbon paper, paints, and for many other uses. The array of structures of various PCB congeners in commercial mixtures influences their environmental and metabolic fate as well as their toxicity. Because of their widespread use, improper disposal, and semivolatile behavior, they have been released from equipment, soils, and sediments at contaminated locations and transported up to great distances in the atmosphere before condensation and deposition, often over cool surfaces such as large bodies of water. Thus, large lakes, seas, oceans, and glaciers have become repositories for such chemicals. This "global distillation" process largely accounts for the comparatively high concentration of persistent organochlorines in polar ocean food webs. Other semivolatile chemicals, such as organochlorine insecticides, the fungicide hexachlorobenzene, and PCDDs and PCDFs, which are toxic byproducts of organochlorine synthesis, manufacturing processes such as the Kraft paper bleaching process, and poorly controlled incineration, have similar environmental fates.

Most dioxin entering the environment today originates through incineration of products containing chlorine (Weber *et al.*, 2008). Today, Americans are exposed

primarily via consumption of beef and dairy products as a result of atmospheric deposition on foodstuffs. Fortunately, in developed nations such as the United States, efforts to limit emissions from municipal, medical, and commercial incinerators have substantially reduced atmospheric dioxin emissions.

PCBs, PCDDs, and PCDFs are uncharged molecules, and the more highly chlorinated congeners tend to be highly soluble in body lipids and difficult to metabolize and excrete. As a result, they are readily biomagnified in aquatic food webs, leaving top carnivores – especially in freshwater systems and contaminated harbors – at high risk of contamination and toxic impacts.

PCBs, PCDDs, and PCDFs can have serious effects on the immune, nervous, and reproductive systems, especially those of developing organisms. Such compounds can also reduce control of impulsive behaviors, impair learning, cause liver damage, and disrupt reproductive and thyroid hormone functions. For example, exposure of captive mink to PCBs in Great Lakes fish resulted in reproductive failure. Cleanup of “hot spots” of contamination and feeding the animals a much less contaminated diet enabled successful reproduction. Also, environmental exposures of Great Lakes fish-eating birds to organochlorines, including dioxins and dioxin-like compounds such as PCBs, resulted in embryo and chick mortality, growth retardation, and deformities associated with edema, hepatomegaly, gastroschisis, and other lesions – otherwise known as the Great Lakes embryo mortality, edema, and deformity syndrome, or GLEMEDS (Gilbertson *et al.*, 1991). Again, by curtailing emissions and cleaning up contaminated soils and sediments, this problem has been greatly reduced.

Whereas the concentrations of most organochlorine contaminants in the environment are decreasing, those of flame-retardant polybrominated diphenyl ethers (PBDEs) are increasing. These compounds are incorporated into foam cushions in furniture, fabrics, electronics cases, plastics, and other materials to reduce the risks of fires. Among the toxic effects of PBDEs are impairments in neurologic development, learning, attention, thyroid function, and spermatogenesis (Darnierud, 2003; Muirhead *et al.*, 2006). According to Environment Canada, concentrations of PBDEs in Great Lakes fish are showing marked and consistent increases ([http://www.on.ec.gc.ca/csl/fich/fich003\\_002\\_e.html](http://www.on.ec.gc.ca/csl/fich/fich003_002_e.html)). Also, killer whales (*Orcinus orca*) of the Pacific Northwest have body burdens well above those associated with toxic effects in other species (Ross, 2006). Although some of the most toxic congeners of PBDEs have been banned in areas of Europe and voluntarily withdrawn in the United States, environmental contamination continues on an upward trend due to uncontrolled disposal of highly contaminated products.

## CONTAMINANTS FROM E-WASTES

Since the advent of the personal computer and throw-away televisions and stereos, e-wastes (i.e., discarded electronics) have been an ever-growing environmental issue – one that transcends political boundaries and has great impact on the poor in developing nations. According to the U.S. EPA, in 2007, the United States generated 2.25 million short tons of e-waste, which represented 2% of municipal waste streams. Of this, 82% by weight of televisions and computer components went to landfills, and much of the remainder was shipped to developing nations, especially China, India, and Ghana, where men, women, and children dismantle and mine them for the metals in the circuit boards, wiring, and other components.

At uncontrolled e-waste recycling sites, mountains of discarded and burning components leach chemicals into the air, soil, and water, where they find their way into biota. PCBs and PBDEs have been detected in the serum of a large portion of samples from multiple species of birds and especially herons in an e-waste recycling region of China (Luo *et al.*, 2009). The city of Guiyu, China, has become a poster child for e-waste problems, with reportedly the largest volume of e-waste on Earth. Recovery of metals over open flames without personal protection or environmental safeguards exposes workers, the communities, and the nearby environments to cadmium, lead, nickel, and other metals. Toxic levels of heavy metals have been found in the city's children (Zheng *et al.*, 2008). Burning of circuit boards and other plastic components releases plasticizers including bisphenol A, triphenyl phosphate, palmitic and stearic acids, brominated flame retardants, and the highly chlorinated flame retardant Dechlorane Plus (Dechlorane A) into the air, soils, and tissues of resident people and animals near the recycling facilities, potentially causing oxidative stress, reproductive and developmental problems, and altered thyroid function.

In addition to causing human poisoning and environmental pollution, the current methods of e-waste recycling in developing countries squander both energy and other materials. Efforts are under way to stem such practices by increasing the recovery, recycling, repurposing, and refurbishment of more items in countries of origin and sale, as well as providing developing nations and communities with means to recover materials in a safe and efficient manner. Ultimately, designing products so that, when they lose their usefulness, their materials are readily reconverted into useful new materials (i.e., cradle-to-cradle technology) should resolve major e-waste-related and many other environmental contamination problems (McDonough and Braungart, 2002).

## PESTICIDES

World pesticide usage was approximately 5.1 billion pounds in 2005 and 2006. The United States alone used approximately 25% of the total herbicides, as well as 10% of the insecticides, 14% of the fungicides, and 26% of the other types of pesticides ([http://www.epa.gov/opp00001/pestsales/07pestsales/market\\_estimates2007.pdf](http://www.epa.gov/opp00001/pestsales/07pestsales/market_estimates2007.pdf)). Agriculture accounts for the largest proportion of total conventional pesticides applied (70–80%) in the United States, and the most highly used compounds include glyphosate, atrazine, metam sodium, metolachlor-S, acetachlor, dichloropropene, 2,4-D, methyl bromide, and chloropicrine. Many pesticides, including some no longer in use, have important ecotoxicological impacts. Given the numbers of pesticide products used, in this chapter, we can at best highlight some instructive examples. Other chapters in this book, as well as books devoted entirely to pesticide toxicology and ecotoxicology, the primary research literature, and government reports, should also be consulted.

### Organochlorine insecticides

As noted in part previously, the widespread use of organochlorine insecticides (OCIs), DDT, aldrin, chlordane, dieldrin, heptachlor, and others began after World War II. These compounds were initially considered a boon to agriculture and public health because they were both effective and persistent. However, because of their persistence, pests soon began to develop genetic resistance. The persistent OCIs also poisoned insect predators so that the pests had greater impacts than before. These phenomena triggered higher application rates and, eventually, the continual development of new compounds. As with other toxicants, the OCIs have different effects via actions at a range of types of molecular receptors in the body.

The insecticidal properties of OCIs relate mainly to neurotoxicity. The molecular receptors are highly conserved and thus both invertebrates and vertebrates are susceptible. DDT increases sodium conductance across nerve cell membranes, increasing excitability and resulting in tremors and the potential for seizures. The cyclodiene pesticides such as aldrin, chlordane, dieldrin, endrin, and heptachlor, the structures of which differ markedly from that of DDT, exert their influence most prominently at  $\gamma$ -aminobutyric acid (GABA) receptors in the brain, thereby reducing chloride conductance. In general, the cyclodienes are more acutely toxic than DDT. Consequently, cyclodienes such as aldrin and dieldrin have resulted in direct mortality in predatory birds,

such as sparrowhawks and kestrels (Newton *et al.*, 1992). This mortality, when combined with sublethal effects such as starvation and accidents due to neurological deficits and reduced productivity due to eggshell thinning caused by DDE exposure, soon led to population declines in these birds (Walker and Newton, 1998).

DDE often co-occurs in avian eggs with PCBs, and both are embryotoxic endocrine disruptors. Together, they may interact to contribute to decreased productivity in populations of waterbirds such as bald eagles (Bowerman *et al.*, 2003).

As with PCBs and dioxins, the slow biodegradation rate and high lipid solubility of many OCIs lead to biomagnification in food webs. Predatory animals thus often accumulate very high concentrations, and the nursing young of top predators feeding in contaminated aquatic ecosystems can be massively exposed. Among the species most at risk are marine mammals, the young of which may consume milk with extremely high fat content (e.g., up to 60% fat).

Fortunately, after decades since most of the compounds were banned, restricted, or voluntarily withdrawn, environmental concentrations of OCIs in most of the world have greatly declined. As a result, impacts of OCIs on wildlife have significantly, but not totally, abated.

### Concurrent exposures of frogs to DDT analogs and other persistent organochlorines

Reeder *et al.* (2005) suggested that populations of frogs may have been negatively impacted by DDT and PCBs. They examined spatial and temporal patterns of intersexuality in cricket frogs collected in Illinois from 1852 to 2001. In contrast to the preorganochlorine era (1852–1929), the percentage of intersex cricket frogs markedly increased during a time of industrialization and initial uses of PCBs (1930–1945), was highest during the peak of manufacture and use of DDT and PCBs (1946–1959), began declining with increased public concern and environmental regulation that led to restrictions and the eventual ban on the use of DDT in the United States (1960–1979), and continued to decline through the period of gradual reductions in environmental residues of OCIs and PCBs in the midwestern United States (1980–2001).

### Cholinesterase-inhibiting insecticides

Organophosphorous (OP) and carbamate insecticides such as diazinon, chlorpyrifos, malathion, and carbofuran are cholinesterase-inhibiting compounds. As such, they prevent breakdown of acetylcholine after transmission of a nerve impulse. The first OP cholinesterase

inhibitors were developed as chemical weapons during World War II. After the war, as pests developed resistance to OCIs and their use was restricted, the use of OP compounds increased. The OP compounds are not persistent in the environment compared to most OCIs, but they are broad-spectrum insecticides, and many exert potent acute toxicity. Human deaths from mishandling occur annually. Secondary poisonings can occur when predators consume invertebrates or vertebrate wildlife that were poisoned by OP and, less often, carbamate insecticides. In one of the best documented secondary poisoning events, approximately 6000 wintering Swainson's hawks (*Buteo swainsoni*) were poisoned in Argentina during 1995 and 1996 after they fed on grasshoppers that had been sprayed with the OP insecticide monocrotophos (Goldstein *et al.*, 1999). In another incident, hundreds of laughing gulls (*Larus atricilla*) were poisoned after consuming insects that were killed or debilitated by application of parathion to cotton fields (White *et al.*, 1979). The mortality included nestlings that died after being fed contaminated prey by adult gulls. It is likely that large numbers of individual poisonings of birds and other species by OP insecticides go unnoticed following the intended use of licensed products. Organophosphorous insecticides have also been used illegally as avicides to protect grain crops from bird depredation and as canicides to kill coyotes (*Canis latrans*) (White *et al.*, 1989; Wobeser *et al.*, 2004). Such misuse has resulted in additional mortalities in predatory birds and mammals that fed on the carcasses of the illegally poisoned species.

Two OP insecticides that were previously used very widely, diazinon and chlorpyrifos, are now severely restricted in the United States. Diazinon, which had been widely used on golf courses and lawns, was infamous for its lethality to birds. Chlorpyrifos had been routinely applied to homes, for termite and pest control, and in crop agricultural applications. The removal of diazinon and chlorpyrifos from household products was followed by almost immediate reductions in concentrations in umbilical cord blood and increased birth weights of babies of low-income families. As reviewed by Barrett (2007), the basis for withdrawal of the registration of chlorpyrifos from household use related to findings of lifelong neurotoxicity in laboratory animals exposed during development. Later, effects that were deemed consistent with the predictions from that research were noted in children. Whether such effects also occur in wildlife exposed under field conditions warrants concern.

Granular carbofuran pellets have been consumed by birds that apparently mistook them for seeds, and one pellet of this carbamate insecticide is enough to kill a bird (Balcomb *et al.*, 1984). In recent decades, carbofuran was the insecticide most commonly associated with

wildlife pesticide poisoning events (e.g., red-winged blackbirds (*Agelaius phoeniceus*), bald eagles (*Haliaeetus leucocephalus*), golden eagles (*Aquila chrysaetos*), coyotes, red foxes (*Vulpes vulpes*), red-tailed hawks (*Buteo jamaicensis*), buzzards (*Buteo buteo*), and herons), and it was implicated in declines of burrowing owls (*Athene cunicularia*) (Hunt *et al.*, 1995; Blus, 1996; Elliot *et al.*, 1996; Wobeser *et al.*, 2004). Fortunately for wildlife in the United States, a phaseout of the granular formulation of carbofuran began in 1991, and registrations for most solid forms were canceled. Ongoing concerns with regard to carbofuran include its availability in other countries and its misuse in malicious poisonings to kill wildlife in African nations.

### Other insecticides

Pyrethrins from chrysanthemums and structurally related synthetic insecticides (pyrethroids) bind to sodium channels, preventing closure, and/or to GABA-mediated chloride channels inhibiting chloride influx, resulting in excessive depolarizations culminating in tremors or seizures. These chemicals are generally of low toxicity to mammals and birds; however, they exert potent acute toxicity to arthropods, including non-target taxa such as spiders, parasitoids, and bees. Although early formulations had a short half-life, measured in hours in direct sunlight, newer compounds are designed to be more photostable, extending their effectiveness for up to 10 days outdoors, which increases environmental risks associated with their use. Synthetic pyrethroids often exhibit high acute toxicity to tadpoles and fish. For example, several pyrethroids have LC<sub>50</sub> values for fish of less than 1 µg/L in acute studies, and they can cause chronic toxicity at concentrations as low as 0.01 or even 0.001 µg/L (Bradbury and Coats, 1989).

A variety of other types of products are used for control of insects, arachnids (e.g., mites and ticks), and other "pests." Some are nerve poisons, and others inhibit energy production, chitin synthesis, metamorphosis, water balance, or growth. A number of lower risk pesticides include microbes (e.g., the soil bacterium *Bacillus thuringiensis* (*Bt*) for control of moths and mosquitoes), microbial products (e.g., spinosyn, which is a fermentation product of a soil actinomycete for control of caterpillars), a range of other "natural chemicals" (e.g., pheromones, florals, and sulfur), and "plant-incorporated protectants" (e.g., transgenic crops that may produce toxins originally synthesized in bacteria such as *Bt*). Many of these newer methods of pest control are more environmentally benign alternatives to traditional insecticides. Nevertheless, because they disrupt normal physiological processes of both target and

non-target species, each carries potential environmental risks that are only partially understood.

### Indirect effects of insecticides

In addition to direct toxic effects to avian wildlife, insecticides may reduce populations of non-target invertebrates used as food by birds, which may require increased foraging effort or prey switching by adults feeding their offspring (Morris *et al.*, 2005). Additional research in this topic area is needed.

Exposures to insecticides might also influence trematode infections in frogs by impacting populations of benthic and planktonic predators of motile stages of the parasites, including cercariae. Invertebrates, including hydra, copepods, daphnids, and especially damselfly larvae and dragonfly larvae, attacked, consumed, and digested trematode cercariae in a controlled setting (Schotthoefer *et al.*, 2007). Insecticide-mediated changes in invertebrate community structure might therefore release cercariae or other trematode life stages from this predation pressure. The overall importance of these “micropredators” as determinants of infective loads of cercariae in natural and human-altered aquatic environments, and their susceptibility relative to the parasites themselves and the other hosts involved in their life cycles, remains to be thoroughly investigated. Additional information on trematodes, amphibians, and toxicant interactions is presented later.

### Herbicides

During 2000, herbicides represented 36% of the world pesticide market, and in 2001, the agricultural sector accounted for 78% of herbicide use in the United States. Herbicides are often considered benign with regard to impacts on animals; however, many such compounds can reach concentrations in the environment that lead to direct toxicoses, and they can secondarily trigger other lethal mechanisms.

Atrazine is perhaps the world's most used agricultural herbicide. According to the U.S. EPA, an estimated 74–80 million pounds were applied in the United States alone in 2001. Atrazine and its degradation products have been found in air, rainwater, surface water, and groundwater.

Exposure of African clawed frogs (*Xenopus laevis*) to atrazine at 320 µg/L resulted in increased mortality. In different amphibian species exposed to a range of test concentrations found in the environment, atrazine has been associated with reduced survival of tadpoles, increased length of larval period, and reduced size at metamorphosis (Diana *et al.*, 2000; Sullivan and Spence, 2003; Storrs and Kiesecker, 2004). Atrazine and other

herbicides may exert such effects in part by reducing dissolved oxygen and algal food needed by tadpoles. Reduced size at metamorphosis is likely to be followed by reduced survival and impaired reproductive fitness.

The registration permitting the sale of atrazine was not renewed by several European Union countries. Among concerns regarding this herbicide is endocrine disruption. Reeder *et al.* (1998) associated detection of atrazine with intersex gonads in cricket frogs (*Acris crepitans*) in Illinois. Other workers subsequently found that low concentrations of atrazine affected gonadal development, produced hermaphroditism, and reduced the laryngeal muscle in males (needed for calling to attract females and to ward off competing males). At a range of test concentrations that can be found in the environment, atrazine was associated with gonadal dysgenesis, reduced spermatogenesis, impaired reproductive behaviors, and sex reversal (Tavera-Mendoza *et al.*, 2001; Hayes *et al.*, 2010). Although other workers have suggested that intersex is common in unexposed frogs, in some such reports, the animals in control groups or at reference sites were also exposed to low concentrations of atrazine (Coady *et al.*, 2004; Smith *et al.*, 2005).

Declines in amphibians in the wild have impacts on other species. Reducing tadpoles prevents them from consuming algal food, which leaves excess algae in waters, causing turbidity that can impact on a host of other species. Also, in some forest ecosystems, amphibian biomass in late summer can exceed that of all other vertebrate groups combined. In these and other types of ecosystems, tadpoles and frogs serve as a vital source of food for other amphibians, reptiles, birds, and mammals. Without the amphibians as a food source, other species can experience malnutrition and precipitous declines.

Glyphosate affects a broad spectrum of plants and has become the most used herbicide in the United States. Glyphosate has minimal toxicity to mammals, but surfactants added to some formulations to promote adherence to plant surfaces greatly increase product toxicity (Goldstein *et al.*, 2005). Thus, some formulations (those not intended for aquatic vegetation control) can result in direct mortality of larval and juvenile amphibians and subsequent loss of biodiversity. Glyphosate readily adsorbs to soil, is rapidly degraded by bacteria, and has limited bioavailability. Nevertheless, due to its high water solubility, runoff can result in detectable concentrations in surface waters. Of course, glyphosate is sold in formulations intended to control not only terrestrial but also aquatic vegetation. These and other herbicides kill both target and non-target plants, which alters ecosystem functioning. Also of concern is that a range of stressors may enhance the toxicity of pesticides, and predatory stress substantially increased the lethality of Roundup (a popular glyphosate product) to larval amphibians (Relyea, 2005).

## Interactions among pesticides, nutrients, and pathogens

Studies examining mixtures of pesticides have found additive, synergistic, or antagonistic effects on organisms, depending on the chemicals used, their concentrations, the test organisms, and the laboratory conditions. Nutrients may also interact with pesticides to produce interactive toxicity. Also, pesticides and nutrients can influence the incidence and intensity of infectious diseases in wild animals.

Nutrients and pesticides, coupled with habitat change, may help explain some of the recent outbreaks of supernumerary limbs and declines in frogs. Waterbirds are the definitive hosts of trematodes that rely on amphibians as intermediate hosts. In the life cycles of these parasites, sexual reproduction occurs in the birds and eggs are shed in their excreta. The first intermediate hosts are snails, in which massive asexual reproduction occurs. The second intermediate hosts are tadpoles, and when the amphibians are consumed by birds, the life cycle is completed. Because of ubiquitous drainage of aquatic habitats, waterbirds often crowd into remnant water bodies, providing potentially higher inputs of infective ova. Excess nutrient concentrations can increase algae and periphyton that comprise the main food of snails. Johnson *et al.* (2002) found positive relationships among nutrient pollution, snail populations, the frequency of limb malformations, and the intensity of infections of post-metamorphic frogs with *Ribeiroia* trematodes. While *Ribeiroia* infections may produce limb deformities, trematodes in the genus *Echinostoma* may cause potentially debilitating kidney infections in frogs (Fried *et al.*, 1997; Schotthoefer *et al.*, 2003a; Beasley *et al.*, 2005). Infections by either of these trematode groups in early stage tadpoles can cause nearly 100% death losses (Schotthoefer *et al.*, 2003a,b). Moreover, sublethal trematode infections may also make tadpoles less tolerant of other stressors.

Studies by our group suggested complex interactions among herbicides, nutrients, and trematode infections of amphibians in agricultural regions (Beasley *et al.*, 2005). In herbicide-impacted farm ponds, recruitment of juvenile cricket frogs was reduced, and trematode infections in the surviving frogs were greatly increased. Sousa and Grosholz (1991) suggested that more complex habitat structure impedes parasite transmission, and Beasley *et al.* (2005) hypothesized that severe trematode infections in frogs were due to interacting factors related to fewer plants in the water. In such simplified ecosystems, predation on amphibians by birds, reptiles, and fish would likely be facilitated, and motile cercariae might more readily find the surviving tadpoles so that they could receive a high infective load of trematodes. In a field study that examined more than 240 variables, atrazine and phosphate contamination was by far most closely

correlated with infections of leopard frogs (*R. pipiens*) with trematode infections. Also, studies of microcosms showed that atrazine removed phytoplankton, which increased the clarity of water; reduced macrophytes; increased periphyton and snails; immunosuppressed tadpoles; and increased their infection intensities with trematodes (Rohr *et al.*, 2008). Other research groups have also linked pesticide exposure to immunosuppression and increased susceptibility of amphibians to trematode infections (Kiesecker, 2002; Linzey *et al.*, 2003).

## Anticoagulant rodenticides

Anticoagulant rodenticides such as brodifacoum and bromadiolone inhibit blood clotting by inhibition of vitamin K epoxide reductase, an enzyme essential to the reuse of the vitamin in producing active forms of clotting proteins. Many such compounds are highly and acutely toxic. These rodenticides may directly impact non-target small mammal populations (Brakes and Smith, 2005). Also, secondary poisonings (relay toxicoses) have had impacts on birds of prey, such as buzzards, barn owls (*Tyto alba*), and red kites (*Milvus milvus*), as well as carnivorous mammals, such as mink (*Mustela vison*), polecats (*Mustela putorius*), and red foxes (Fournier-Chambrillon *et al.*, 2004; Ntampakis and Carter, 2005).

## Organotin biocides

Organotin biocides are widely used to coat pilings and ships to prevent the growth of barnacles, algae, and other organisms that deteriorate wood and/or create drag. Members of this environmentally persistent group of biocides are known for potent neurotoxicity as well as the capacity to induce “imposex” in mollusks, which may be manifested by sexual abnormalities and infertility in females (Ruiz *et al.*, 1998).

## ENDOCRINE-DISRUPTING MIXTURES IN SURFACE WATERS

Water bodies contaminated by persistent organic pollutants, detergents, plasticizers, pesticides, mercury, nitrate, other chemicals, sewage effluents, runoff from animal production systems, and ubiquitous cyanobacteria may induce apparent endocrine disruption in aquatic animals. Xenobiotics that influence hormone receptors include agents that (1) mimic effects of hormones at receptors (agonists), (2) interfere with normal hormonal activity at receptors (antagonists), (3) interfere with

synthesis of natural hormones, (4) accelerate metabolism or elimination of natural hormones, and/or (5) alter downstream biochemical processes that would otherwise follow normal receptor activity. Some agents can act through several of the previously mentioned mechanisms at different sites in the body. Also, agents that are weak agonists may have a net effect of receptor stimulation in immature animals and yet cause competitive inhibition of natural hormone activity in adults. In general, the developing young are most susceptible to the effects of endocrine disruptors, and effects on them often cause lifelong dysfunction.

A variety of endocrine-disrupting compounds have been detected in sewage effluent, including steroidal hormones, pesticides, breakdown products of surfactants and plasticizers, pharmaceuticals, and more (e.g., PCBs and dioxins). Kolpin *et al.* (2002) detected 82 compounds, 34 of which are known or suspected to have estrogenic activity, in 139 U.S. streams. In that study, 75% of the streams sampled had more than one of the compounds at detectable concentrations.

To our knowledge, the first study to establish a link between endocrine disruption and exposure to both sewage effluent and synthetic estrogens was that of Purdom *et al.* (1994). Following reports from fishermen of hermaphroditic fish in sewage lagoons, caged rainbow trout (*Salmo gairdneri*) and carp (*Cyprinus carpio*) were placed in sewage effluent in the field, and others were exposed to an oral contraceptive formulation in the laboratory. Marked increases in plasma vitellogenin (VTG) concentrations were observed, particularly in the trout. VTG is an egg-yolk precursor protein produced in the liver under control of estrogen. In adult fish, VTG is normally present in measurable amounts only in the blood or tissues of mature females. Thus, plasma VTG concentrations in males have been widely used as a marker of exposure to environmental estrogens. Induction of VTG, increased incidence of intersexuality (the presence of ova in testicular tissue), and reduced gamete production and quality have been observed in male fish collected below sewage outfalls. VTG responses are dose and time dependent: fish chronically exposed to low concentrations of effluent in river water had a lower threshold for VTG induction than did fish exposed for a shorter time period. Fish that are affected may show a sustained VTG response to estrogen exposure because plasma VTG concentrations in male fathead minnows remained elevated 21 days after exposure to estradiol (Panter *et al.*, 2000). Young male roach (*Rutilus rutilus*) exposed to graded dilutions of sewage effluent experienced VTG induction and feminization of reproductive ducts but no effects on germ cell development (Rodgers-Gray *et al.*, 2001). High levels of plasma VTG in male fish may be accompanied by kidney and liver damage. Increased liver mass, reduced gonad mass relative to body mass, testicular

damage, reduced gonopodium length (the modified male anal fin that is critical for sperm transfer in some species), and reduced serum testosterone concentrations have been observed in fish collected downstream of wastewater treatment plants (Panter *et al.*, 1998).

Natural estrogen (e.g., 17- $\beta$  estradiol) and ethinylestradiol (from birth control medications) are among the most commonly occurring and potent endocrine-disrupting compounds in effluents from treatment plants that receive domestic wastewater. However, sensitivity to estrogen exposure is species specific, highlighting the need for proper selection of species for monitoring purposes in regard to impacts on local fish communities (Purdum *et al.*, 1994; Thompson *et al.*, 2000). Increased VTG production has also been documented in mussels exposed to sewage effluent (Quinn *et al.*, 2004).

Research studies have documented a variety of endocrine-disrupting effects of steroidal hormones on fish, including reductions in (1) gonadosomatic indices (organ weights as a proportion of body weight), (2) the proportion of males with milt (seminal fluid containing sperm) and spawning tubercles, (3) gonopodium length, (4) courtship displays, (5) chasing/following behaviors, (6) copulation attempts, and (7) aggressiveness toward other males, and (8) fecundity (number of eggs) but not fertility (Doyle and Lim, 2002). Such effects would likely cause marked reductions in reproductive success.

Contaminants from livestock production are additional sources of environmental contamination with active hormones. Estradiol in ponds receiving water from cattle pastures was associated with increased VTG concentrations in female painted turtles (*Chrysemys picta*) (Irwin *et al.*, 2001). Also, cattle feedlots in Nebraska were found to cause endocrine disruption in both male and female fathead minnows (*Pimephales promelas*) in waters receiving runoff (Orlando *et al.*, 2004). In that study, males had reduced testicular size and testosterone synthesis, and they failed to develop normal secondary sex characteristics. Also, gonads of females had reduced *in vitro* estrogen:androgen ratios. Because of the complex mixtures of natural and synthetic hormones and their metabolites in the animal wastes, it was unclear what agents accounted for the masculinization of the fish, but the net changes were consistent with environmentally persistent and bioactive metabolites of the androgenic anabolic steroid trenbolone acetate, which is used widely in feedlot cattle.

Blooms of *Microcystis aeruginosa*, a common cyanobacterium in nutrient-enriched waters, could add yet another source of estrogenicity to water, as indicated by gene expression in exposed larval zebrafish (*Danio rerio*) (Rogers *et al.*, 2011). The estrogenic effects were not attributable to the often-encountered microcystin-LR contained in the cyanobacteria.

The long-term impacts of exposure to complex mixtures of endocrine-disrupting compounds on

populations of fish, frogs, and other aquatic life are not well understood. Grist *et al.* (2003) modeled the effects of ethynylestradiol exposure on populations of fathead minnows (*P. promelas*) and predicted that reduced fertility could impair population growth. Whether males with subtle intersex characters breed successfully in the wild and whether a population with fewer mature males can be sustained long term are areas of concern. With urbanization and a burgeoning human population, effluent-dominated streams (i.e., streams that contain mainly effluent from sewage treatment facilities) are becoming increasingly common. Accordingly, impacts of hormones and other substances that survive sewage treatment are a growing concern. Considering all of the endocrine disruptors as well as the many other pharmaceuticals, personal care products, and cleaning compounds that are resistant to biodegradation and thus pass through sewage treatment plants as parent compounds or active metabolites, there is a need for development and application of new technologies (Carballa *et al.*, 2004). The goal should be to ensure detoxification or physical removal of endocrine disruptors and other toxicants from sewage effluents. Similar attention is needed for animal production facilities.

## METALS, MINERALS, AND MINING

Other chapters of this book should also be examined to best gauge the impacts of metals, minerals, and mining on wildlife and ecosystems. Metals are electropositive elements that readily lose electrons to form cations. Some heavy metals, such as cadmium, lead, and mercury, have high atomic weights, have no known physiological role, and can produce toxic effects at low concentrations. Others, such as copper and zinc, are essential for life but are toxic at elevated concentrations. Metalloids are elements with properties intermediate between metals and nonmetals. Metalloids such as arsenic and nonmetals such as selenium can be toxic at relatively low doses. Of course, regular intake of low levels of selenium is essential for survival and good health.

Metals are usually complexed with other elements in the environment, and the form, or species, of a metal as well as its valence state are important determinants of toxicity. Trivalent chromium occurs naturally, and small amounts are thought to be necessary for optimal health. In contrast, hexavalent chromium is produced and used in industry and is highly toxic.

Irrigation, fertilizers, and pesticides can increase concentrations of toxic elements and salts in surface soils. Early pesticides included metal salts such as lead arsenate, and in some areas soils remain contaminated

from early use of these compounds. Also, mining and smelting, as well as processing and burning of pressure-treated wood have produced toxic environmental concentrations of metals and metalloids.

Because of persistence of mercury in the biosphere and because human and wildlife populations are already experiencing its toxic impacts, continued environmental loading, atmospheric transport, and deposition of this element are grave concerns. Mercury is a volatile metal that is released naturally into the biosphere from volcanic eruptions and exposed bedrock. Humans increase mercury exposures through ongoing use of obsolete technologies, in chloralkali plants that produce chlorine (being phased out in much of the world), coal burning, waste incineration, mining, smelting, and metal processing, as well as from reservoir development, dental wastes, and disposal of thermometers, barometers, electrical switches, and fluorescent lights.

In terms of wildlife impacts and long-term contamination of fisheries, an especially important source of mercury contamination is use of the liquid metal to capture gold from streambed deposits in artisanal gold production. Veiga and Baker (2004) reviewed human and environmental impacts of the artisanal uses of mercury for gold capture and estimated that approximately 1 or 2 g of mercury is lost for each gram of gold recovered. Poverty is a major driver of artisanal mining of gold, and poor and corrupt governments often fail to improve the plight of artisanal miners, their villages, and their regional environments. Among other locales, this is important in areas of South America, Southeast Asia, Indonesia, and Africa. Gold particles are brought up from the river sediments or dug from ore-laden soils that are washed and/or screened and added to liquid mercury to form an amalgam, but some mercury is lost during this process. The amalgam is then placed into a retort, or distillation vessel, that is heated to evaporate the mercury, leaving behind the gold. Often, these are open retorts, and little, if any, of the mercury is captured. The use of mercury to recover gold has resulted in the pollution of tributaries of large rivers such as the Amazon, Nile, Mekong, and Zambezi. Thus, mercury pollutes international waters that provide many people with water needed for drinking, bathing, washing, and food fish. Although the miners and their families may be exposed to dangerous levels of mercury during the recovery process, fish is the primary source of mercury exposure for human populations and wildlife along the rivers. Miners move on as gold becomes depleted, and the problem becomes more widespread. A great deal more needs to be done to prevent further mercury pollution and toxic impacts as a consequence of artisanal gold mining, including finding new sources of income for affected communities.

When mercuric salts and metallic mercury are metabolized by organisms in anaerobic sediments, they form

the more toxic methylmercury. The rate of conversion of other forms of mercury to methylmercury is much faster in certain warm climates that have favorable geochemistry (e.g., the Amazon basin and Florida) than in many areas more distant from the equator. Methylmercury bioaccumulates via the aquatic food chain, readily crosses the placenta and blood-brain barrier, and is highly toxic to the developing nervous system.

Methylmercury toxicoses in food chains of the Everglades were linked with high feather mercury concentrations, immunosuppression, same-sex pairing, and population declines in fish-eating birds (Sepulveda *et al.*, 1999; Spalding *et al.*, 2000; Adams and Frederick, 2008). Fortunately, removal of mercury from batteries and other sources entering a regional incinerator, that were the main source of mercury loading of the environment, resulted in rapid reductions in mercury contamination of fish and fish-eating birds, and this was followed by apparent improvement in their health and reproduction.

Cadmium is a toxic element used in Ni-Cd batteries and in certain pigments, plastic stabilizers, coatings, alloys, and electronics. It is also an impurity found in conjunction with and released during the processing of other metals such as copper, iron, and zinc. Cadmium also enters the environment from the manufacturing of steel, cement, and fertilizers, as well as the combustion of fossil fuels. The metal is readily taken up by some plants (e.g., leafy vegetables and rice) and is then ingested by humans and other animals in their food. Among the principal target organs of cadmium are bone and kidneys. Larison *et al.* (2000) monitored trace metals in the food web and tissues of white-tailed ptarmigan (*Lagopus leucurus*) in Colorado, and they concluded that trace amounts of cadmium can both undermine the health of individuals and alter the demographics and distributions of species.

Lead has been used in shotgun pellets, bullets, fishing sinkers, paint, batteries, gasoline, solder, water pipes, and other products. In the United States, one of the largest sources of lead in the atmosphere was alkylated lead added to gasoline to reduce engine preignition or “knocking.” To limit harmful emissions, beginning in 1975, passenger cars and light trucks manufactured in the United States included catalytic converters that required lead-free gas. The U.S. EPA therefore mandated a phase-down of lead concentrations from 2–3 to 1/10th g/gallon during 1977–1986. Prohibitions on lead in paint, water pipes, and tin cans were also enacted during this period. Leaded gasoline was still available for use in passenger automobiles in some areas of the United States until 1996, and it is still used in aviation, motorboat, farming, and racing vehicle gasoline. In the United States, reductions in lead use were reflected in a 37% decrease in mean blood lead concentrations of humans during 1976–1980 and a 41% reduction between

the periods 1988–1994 and 1999–2002 (Muntner *et al.*, 2005). However, lead exposures among children of some socioeconomic groups in the United States remain high due in part to contaminated dust, lead paint chips, lead dissolved from plumbing, and other sources. Worldwide, internal combustion engines are still a major source of environmental lead, although an increasing number of nations have banned or are beginning to restrict its usage in gasoline. Although lead shot to hunt waterfowl is now illegal in the United States and this has substantially reduced poisoning of waterfowl, lead used to hunt upland game has been a major cause of poisoning of scavengers, including highly endangered California condors. After the 22 remaining birds were brought into captivity and their offspring were eventually reintroduced to the wild, the birds were often poisoned by lead, leading to routine periodic capture and chelation, usually with calcium disodium EDTA (Church *et al.*, 2006). Ultimately, this resulted in regulatory and voluntary limits on the use of lead ammunition to hunt larger game in the range of California condors. Of course, scavengers and carnivores that feed on smaller species not protected by those measures, and scavengers and carnivores in other areas where lead ammunition continues to be used for all sizes of upland game, are still being poisoned by lead in carcasses and gut piles of game animals (Kelly and Johnson, 2011). Another important source of lead that affects wildlife is its continued use in fishing tackle, which poisons endangered loons, as well as pelicans, cormorants, and herons (Franson *et al.*, 2003). Concerned animal health professionals and others are urging a ban on lead in ammunition used in hunting as well as in fishing tackle.

Mining of metals and minerals often carries large environmental impacts. Not only do these activities leave the land degraded and scarred but also processes to remove the product of interest often result in the release of toxic elements or other chemicals into the environment. For example, sulfides released from newly exposed rock may combine with water and oxygen to form deadly sulfuric acid, which often makes its way into soils, groundwater, and streams. This acid has the added effect of leaching or dissolution of toxic elements such as arsenic, cadmium, lead, iron, and mercury from mine tailings or “waste” rock. The mining boom of the mid- to late 1800s in the American west left many miles of streams and rivers that are still contaminated with metals and sulfuric acid.

A long history of coal mining has also left a legacy of ecological degradation and toxicity. Concerns regarding the environmental and aesthetic effects of surface coal mining led to the Surface Mining Control and Reclamation Act of 1977. This law required mine owners to reduce impacts of surface mining by “reclaiming” surface mined lands – that is, follow guidelines “to conserve and develop soil, water, woodland, fish and wildlife, recreation sources and agricultural productivity.”

Although implementation of this law mitigated some of the environmental impacts of surface mining, such as soil erosion, water pollution, and losses of native biodiversity, the landscapes were still significantly degraded. Unfortunately, the legislation did not prohibit the immensely destructive and short-sighted coal extraction method known as mountaintop removal mining, in which the summit or top of a mountain is removed and the “overburden,” or removed vegetation, soils, and bedrock, is pushed into adjacent valleys. This approach to coal mining was used in many areas in the first decade of the 21st century in the United States. Portions of streams that were not completely buried were polluted with both metals and sulfates that leach from the overburden, degrading ecosystems, eliminating native species and harming nearby human inhabitants (Palmer *et al.*, 2010). Perhaps some lessons regarding the irrevocable damage of this method of coal extraction have been learned: the U.S. EPA recently revoked a permit that allowed expansion of one of the nation’s largest surface coal mines.

Mining has been responsible for transboundary pollution events. For example, in 2000, an accidental release of 100,000 cubic meters of heavy metal-laden cyanide solution, used to recover gold from mine tailings, escaped from a tailings dam at the Australian- and Romanian-owned Baia Mare gold mine in Romania. An estimated 40-km-long plume flowed into the Tisza River, a tributary of the Danube. Concentrations of cyanide in these rivers in Romania, Hungary, and Serbia were up to 700 times the allowable limit, killing much of the aquatic life and preventing use of river water by human residents. Both fish-eating wildlife and the local fishing industry were deprived of their essential catch. Fortunately, although cyanide is highly toxic, it does not persist very long in the environment. In addition, large volumes of copper, lead, and zinc were also released into the rivers. Unfortunately, the long history of environmental contamination of the rivers made it difficult to isolate the specific damage induced by the Baia Mare incident. Due to this incident, other mining disasters, and its lax environmental laws related to mining and the cyanide-extraction method, Romania was harshly criticized by its downstream neighbors.

Smelting, the process of removing metals from ore, results in deposition of aluminum, cadmium, fluoride, lead, zinc, and/or other elements that are highly toxic to plants, soil-dwelling invertebrates, and vertebrates. Such toxicity can reduce the diversity of flora and soil fauna, leaving only more tolerant species so that ecological function in contaminated landscapes is altered for centuries and likely millennia. An example is provided by two zinc smelters that operated near Palmerton in the mountains of eastern Pennsylvania for much of the 20th century. Approximately 485 ha of vegetation was severely degraded by the contaminants. Ecological

damage extended many kilometers downwind of the smelters, including well beyond the areas of obvious impact (Beyer and Storm, 1995). Areas that remained forested had fewer species of moss and lichen, and surviving trees were mainly species that resprouted from roots or stumps instead of seeds (Oyler, 1988). Retardation of decomposition due to greatly reduced populations of soil and litter macro- and microorganisms resulted in a buildup of plant litter on top of mineral soil (Strojan, 1978). Drought and fire, followed by erosion of as much as 30–60 cm of topsoil, exacerbated the damage to the mountainsides. These habitat changes and toxic levels of cadmium, lead, and zinc were associated with reduced populations of forest birds, small mammals, and salamanders, especially insectivorous species. Forest floor salamanders were extirpated. The sheer volume of contaminated soil, along with a cinder bank or “dross” pile containing an estimated 33 million tons of slag (waste ore), makes removal of contaminated material impractical. In the 1990s, to control the pH, prevent further erosion, and provide a medium for revegetation, mixtures of fly ash, sewage sludge, and limestone were applied to the barren mountainsides. Such efforts on the steep, rocky, highly contaminated slopes have been largely unsuccessful to date (Oyler, 1988).

Natural waters and soils can sometimes harbor toxic concentrations of salts and trace elements. For example, arsenic and selenium can be present at levels of concern in ancient groundwater, and pumping from wells for drinking and irrigation makes them available at the surface. Also, whereas most natural soils contain low concentrations of toxic elements, soils in some areas are naturally high enough to result in toxic effects in wildlife. Important examples exist in the western United States. Due to the marine origins of the adjacent mountains, the soils of the San Joaquin Valley in California are high in salts and certain trace elements, including selenium. Irrigation is necessary to leach and wash away salts from the soil to allow the production of vegetables and other crops. Agricultural wastewater is then carried away by a network of canals. In the past, the water was directed to a basin that formed 12 constructed wetlands on what became the Kesterson National Wildlife Refuge. These wetlands, located in an arid region with a diminished wetland base, provided an attractive habitat to a variety of breeding waterbirds. However, high concentrations of selenium in wastewater built up in the food webs of these wetlands, in part because of the rapid evaporation of water in the arid climate of central California. By 1983, selenium toxicosis had resulted in a high incidence of embryo mortality and deformities, including reduced or missing eyes and beaks, and clubbed limbs in wetland birds such as grebes, coots, stilts, and ducks (Ohlendorf and Hothem, 1995). Because of the severe impacts of selenium pollution, the ponds

were closed and filled. Subsequently, 12 other water reclamation projects in the arid western United States were also found to be contaminated by selenium from irrigation drainage water. Although this issue has received attention from planners and researchers, and some remediation has been undertaken, the underlying issues are socioeconomically, politically, and technically complex, and progress in finding solutions has been slow.

In addition to the impacts of effluents from mining related to a lack of, or poor enforcement of, environmental protection laws, the pursuit of minerals may also lead to armed conflicts and human rights abuses ([United Nations Department of Public Information, 2001](#)). For example, conflict diamonds (i.e., diamonds that “originate from areas controlled by forces or factions opposed to legitimate and internationally recognized governments, and are used to fund military action in opposition to those governments, or in contravention of the decisions of the United Nations Security Council”) have fueled prolonged civil wars, environmental devastation, and human suffering. Affected areas in West Africa include parts of Angola, Sierra Leone, and Liberia.

Throughout the world, mining companies have often been set up and operated in a manner so that they can, by design, go bankrupt when mineral deposits are depleted, thereby foregoing the costs of environmental rehabilitation. Recognizing the harm to human populations, wildlife, and ecosystems related to mismanaged mineral exploitation, not only by mining companies but also by small-scale artisanal workers, societies now have the option to educate their citizens and to alter laws, regulations, incentives, disincentives, and enforcement procedures to create safer and more productive environments. In an era of globalization of economies, the only rational course to protect people, animals, and ecosystems is to counter the “race-to-the-bottom” through globally enforced standards for coordinated environmental and human rights stewardship. Developing international standards to control problems associated with mining in the areas where the minerals are found throughout the world should be a top priority ([Hilson, 2003](#)).

## OXIDES OF NITROGEN AND SULFUR AND THEIR INTERACTIONS WITH METALS

The world is becoming more acidified ([Galloway, 2001](#)). In the anaerobic environments of sediments and geologic deposits, reducing chemistries and microbes, such as sulfate-reducing bacteria, have produced massive amounts of sulfides. However, mining and other forms of exposure of these deposits to air allow for oxidation to form

sulfur oxides and sulfates. Also, burning of coal rapidly converts sulfides to sulfur dioxide. Sulfur dioxide is also produced by refining and burning of oil and natural gas. Nitrogen, as  $N_2$  gas, comprises almost 80% of the Earth's atmosphere, and  $N_2$  is oxidized to form nitrogen oxides ( $NO_x$ ) during burning of gasoline, diesel fuel, and coal. When sulfur oxides ( $SO_x$ ) and  $NO_x$  combine with water vapor and precipitation, the resulting sulfuric, nitric, and nitrous acids can build up in the environment, leading to harmful reductions in the pH of soils and water bodies.

Coal-fired power plants in the United Kingdom have contaminated the environments of Sweden, Norway, and eastern Europe with acid deposition. Likewise, similar sources in the midwestern and eastern United States have fed air masses that delivered huge amounts of sulfur dioxide and acids to New England and Canada. Acidification is especially impactful in poorly buffered water bodies (e.g., water bodies with granite bottoms, in contrast to bottoms of limestone, which consists largely of the potent buffer calcium carbonate). Such granite bottom areas are common in the northeastern United States and areas of Europe. Adverse effects of acidification in lakes and forests in New England, eastern Canada, and Europe are well documented. One grave impact of acidification is the reduced capacity of invertebrates to precipitate calcium carbonate to form and harden their shells.

The acids also change soil and water chemistry, solubilizing ubiquitous aluminum (the third most abundant element in the Earth's crust). Then, when an acidified stream merges with a water body of a higher pH, the aluminum (as well as other metals such as iron) can readily precipitate on the gills of fishes as well as aquatic invertebrates, preventing gas exchange ([Glynn \*et al.\*, 1992](#); [Soucek, 2006](#)). Highly acidic waters with excess aluminum can also cause sludging of blood in aquatic organisms and reduced calcium uptake via gills. As a result, slowed growth, delayed development, and increased death losses are found in exposed aquatic vertebrates and invertebrates. Technologies to reduce contamination by  $SO_x$  and  $NO_x$  are widely used in the developed world, and acid deposition is less of a concern than in the past. However, considering the rapid exploitation of coal and other fossil fuels throughout the world, and especially in developing countries, a strong global effort to employ scrubbers and other technologies, and thus to prevent acidification and protect aquatic and terrestrial ecosystem resources, is needed.

## RADIATION/RADIONUCLIDES

The nuclear age began with the discovery of X-rays in 1895. Fission was first demonstrated in 1938 by German

scientists, which led to competition between Nazi Germany and the United States to develop an atomic weapon. The United States developed such a bomb in 1945 and then used two against Japan to end World War II. Nuclear weapons testing and the bombing of Hiroshima and Nagasaki, Japan, during the mid-20th century resulted in the global distribution of radioactive material.

The first reactor-produced radioisotopes for medical and industrial use were provided by the Oak Ridge National Laboratory in 1946. Since that time, nuclear medicine has been a boon for the diagnosis and treatment of many diseases.

By 1951, electricity was being produced via nuclear fission, and by July 1957, the first civilian reactor for power was online. However, in October 1957, the first accidental release of radiation from a reactor occurred. Theoretically, nuclear energy can provide cleaner and cheaper electricity than burning of fossil fuels. However, in addition to the high expense of construction and maintenance, and the small releases of radioactivity during normal operations as well as concerns regarding the transportation and storage of nuclear wastes, there have been accidental discharges of larger amounts of radiation, such as the incidents at Three Mile Island, Pennsylvania, in 1979 and most notably at Chernobyl, Ukraine, in 1986 and Fukushima, Japan, in 2011. The most recent incident was the consequence of a combination of poor choice of location, a poor design, and resultant flooding immediately after an earthquake and an immense tsunami. Currently, the Fukushima accident remains to be resolved, and retired employees are working and sacrificing their health to help alleviate great risks to younger workers, many of whom have already been heavily exposed to radiation.

In 1986, the explosion and fire at a poorly designed reactor at Chernobyl led to the hospitalization of 203 people and the death of 47 due to radiation poisoning. Also, as of 2000, 1800 cases of thyroid cancer in children of the area had been diagnosed and more were anticipated. Fallout containing short- and long-lived radioisotopes covered a wide area of northeastern Europe, and radiation from this incident ultimately was transported throughout the Northern Hemisphere. Residents of a 30-km radius were evacuated, and few have returned. One source estimated that there would be an eventual 4000 additional human deaths, driven by a 2% increase in cancer rates. Whereas the environmental half-life of radioactive iodine (I-131) from reactors is only approximately 8 days, that of strontium (Sr-90) is approximately 29 years and that of radiocesium (Cs-137) is approximately 30 years. Hence, in the area around Chernobyl, as of 2011, less than one half-life of the latter two radioactive isotopes has transpired.

In the 30-mile exclusion zone around Chernobyl, despite somatic and germ cell mutations in birds, small

mammals, and fish associated with increased aberrant phenotypic traits, native plants and wildlife have flourished, and invasive exotic species have declined. This has been touted as “proof” that effects of radiation from this nuclear disaster were not as long-lasting as feared. However, these animals could represent the immigration of dispersing animals from surrounding areas into unoccupied habitats that are now relatively undisturbed by humans. Few detailed, longitudinal studies of wildlife populations and their age structures have been conducted. Perhaps best studied in the Chernobyl area have been barn swallows, which are migratory insectivorous birds with a high degree of philopatry. Fourteen years after the incident, swallows nesting in the area around Chernobyl had a high prevalence of abnormal sperm and reductions in antioxidant levels compared to swallows from a reference area. The exposed birds also had a sustained high rate of partial albinism and germline mutation rates that were 2- to 10-fold higher than those of birds at distant reference sites. The mutations likely accounted for immune suppression, reduced carotenoid-based sexual coloration, and abnormal feather lengths (defective phenotypic secondary sexual traits), which may undermine reproductive success (Møller *et al.*, 2004). Small mammal populations in some areas near Chernobyl were reduced by as much as 90% following the reactor incident. Increases in populations the following spring were attributed to immigration from less contaminated adjacent areas and the cessation of tillage and crop harvest (Sokolov *et al.*, 1993). Voles collected from the Chernobyl area had the highest radiocesium burdens and dose rates ever recorded for mammals. Researchers have reported high genetic diversity in voles from the highly contaminated zone, which could be indicative of high mutation rates and/or immigration from less contaminated areas. Cytogenetic damage was also documented in voles in Belarus and Sweden, both of which were in the direction of prevailing winds in the first few days following the disaster (Goncharova and Ryabokon, 1995).

## THE FUTURE OF ECOTOXICOLOGY

Trends in wildlife numbers are telling. The World Wildlife Fund's Living Planet Index estimates that the number of free-ranging wild vertebrates on Earth declined by approximately 30% from 1970 to 2007 ([http://www.panda.org/about\\_our\\_earth/all\\_publications/living\\_planet\\_report/living\\_planet\\_report\\_graphics/lpi\\_interactive](http://www.panda.org/about_our_earth/all_publications/living_planet_report/living_planet_report_graphics/lpi_interactive)). Although gains were seen in temperate climates of the north, countries of the tropics and the Southern Hemisphere have shown overwhelming declines. Accordingly, across the globe, our vertebrate relatives are being devastated.

Unlike domestic animals and most people, many wild animals face extreme challenges daily and sometimes many times a day. Differences in milliseconds of response time can determine the likelihood of successful predation as well as whether animals avoid becoming prey. Also, females of many species will breed only with males that display ideal conformation and behaviors. Moreover, organisms in the wild are routinely confronted with a host of potential pathogens: their water is never filtered or disinfected, and their food is never dried, preserved, or cooked. Although a high plane of health is essential for wild animals to contribute to future generations in the wild, there is no disputing that their health is being undermined not only by habitat loss, climate change, exotic species introductions, overharvest and pathogen pollution, but also by a host of chemical contaminants – both man-made and produced by toxigenic microbes, plankton, and plants. If various forms of environmental mismanagement continue to place greater numbers of species at risk of extinction, as seems likely, attention to toxic effects on individuals will be increasingly necessary. Moreover, ethically consistent animal health professionals, manufacturers, the public, and the regulatory community cannot ignore the suffering and death losses of wild animals any more than they would ignore suffering and deaths in publically or privately held animals within laboratories, homes, or farms. Tolerating widespread poisoning of wildlife, when we know quite well how to prevent toxic exposures, is irresponsible.

In the view of the authors, ecotoxicology should always be a balance of ecological, biomedical, and chemical sciences. Ecotoxicology initially was focused largely on determining chemical residues in the environment, and later it focused more on mechanisms and effects of select groups of toxicants. To be most effective, ecotoxicological research should include both aspects. Ecotoxicology should also include assessment of effects on individuals, populations, biotic communities, and ecosystems. Now and in the future, ecotoxicology should strive to reach a point where it has been so successful that remediation of contaminated sites is no longer necessary. Thereafter, future efforts could relate almost exclusively to prevention of poisoning. Currently, achieving that goal is difficult, and it is becoming more so in much of the developing world.

Although diagnostic laboratories should become involved in forensic ecotoxicology on a daily basis, simply waiting for specimens to be brought in for studies will fail to provide adequate protection of wildlife and ecosystems. Thus, diagnostic and forensic ecotoxicology must become a routine, proactive, collaborative enterprise involving trips to the field for monitoring of community structure, population trends, exposures, and impacts; trips to the laboratory for exploratory and confirmatory research; and common interactions

with manufacturers, end users, wildlife managers, and regulatory agencies to ensure responsible chemical stewardship.

The authors believe that there is a need for better testing of products before marketing to ensure not only the health of humans but also that of pets, livestock, wildlife, plants, and the environment as a whole. Products already on the market but not thoroughly investigated to date should be reexamined. To enhance diagnostic and forensic capabilities, studies designed to identify causes and effects should examine test organisms via physical examinations; clinical pathology assays; gross and histologic pathology assessments; assessment of genomic, proteomic, and metabolomic impacts; and chemical analyses to determine residues. These endpoints should be evaluated at doses with no impact, threshold toxic reactions, marked toxic reactions, and overt lethal toxicity.

For most toxicants, detailed and comprehensive ecotoxicological information exists for only a relatively very few plant and animal species. Risk assessments rely on extrapolation from these surrogate species to the huge array of organisms that will ultimately be exposed when the product is used or the effluent is released. Without requirements for effective monitoring and reporting on the effects of exposures of a host of biota in the field under conditions after the introduction of contaminants to the environment, toxic effects are bound to be missed. Accordingly, postmarketing studies of impacts on native organisms should be a new priority.

Of concern is that much information from industry on testing of products is buried in reports to the U.S. EPA and difficult to obtain. We contend that upon granting of patents, industry scientists should be required to publish results of toxicity testing in the scientific literature and via the Internet so that the information is fully available to scientists and the interested public. Stakeholders aware of toxicological data should share in decision making with regard to risk management and longer term product registration. We are also of the view that considerable effort in regulatory ecotoxicology should be devoted to removal of problematic compounds and formulations, with replacement as warranted, with products unlikely to present undue ecological harm.

Because of the reality of modern-day exposures, far greater attention needs to be devoted to complex mixtures of chemicals, the fate and toxicity of chemical degradation products, the indirect effects of contaminants, and the validation of risk assessments. These deficits indicate a need for more integrative ecotoxicology research, including comprehensive, large-scale field studies examining interactions among biotic and abiotic factors, complemented by microcosm and mesocosm studies. Also, more research incorporating reproductive toxicology and multigenerational studies is needed. In addition, more studies should examine how contaminant

exposure affects animal behavior because subtle changes in behavior can have immense negative impacts on an animal's survival and reproductive fitness.

Because of the scale and complexity of challenges in ecotoxicology, filling critical data gaps and implementing adaptive management actions can most often be achieved as a member of a collaborative team. Single individuals in such teams may "wear more than one hat" in this process. In any case, expertise is often needed in ecology, wildlife biology, wildlife management, veterinary medicine, veterinary toxicology, ecotoxicology, analytical toxicology, epidemiology, pathology, immunology, environmental risk assessment, environmental law and policy, ecological rehabilitation, and other areas. To get under way and to help ensure a recognized positive impact, individual scientists and groups may choose to focus their attention by specializing in a particular toxicant group (e.g., metals, herbicides, or hazardous wastes), an animal species group (e.g., marine mammals, birds, or invertebrates), a given habitat type or biome (e.g., deserts, forests, mountains, tundras, estuaries, or coral reefs), or a given region (e.g., the midwestern United States, north Africa, tropical Asia, or Antarctica).

The prospects for a healthy environment for humans, domestic animals, and wild biota depend to a large extent on whether we learn to prevent poisoning and ecological disruption by naturally occurring and synthetic chemicals. In the world of tomorrow, rather than relying on more fertilizers, more pesticides, and more raw materials, food must be grown in new ways and in new places, with only benign chemical inputs and closure of nutrient loops. To conserve energy, production of food should be closer to consumers, but to reduce the adverse impacts of the agricultural footprint, production of food should also take place in what is currently unused space such as in open oceans and barren deserts in concert with astute forms of desalination of seawater. Other products and services must also be provided more efficiently and cleanly. Clean and renewable energy sources, cradle-to-cradle technologies, and other innovations offer the option to move strongly in the direction of rehabilitating ecosystems to achieve recoveries of biodiversity and improved health. These are not someone else's problems. They are our problems, and toxicologists, practitioners, and other health professionals of many stripes have unique and timely opportunities to lead.

## Avian toxicology

*Robert H. Poppenga and Snehal Tawde*

### INTRODUCTION

There are approximately 30 orders of birds in the Aves class, with approximately 2000 genera and 10,000 species. Obviously, such a large class of animals possesses a bewildering array of unique physiologic adaptations, behaviors, and ecologic niches. Thus, a discussion of a broad topic such as avian toxicology presents a daunting task. This chapter provides an overview of toxicologic hazards to three subsets of birds: pet and aviary birds, poultry and other farm-raised birds, and wild birds. Given the breadth of the topic, this chapter is not an exhaustive treatise but, it is hoped, provides an overview of major avian toxicologic hazards.

#### Pet and aviary birds

The popularity of birds as pets has increased substantially during the past several years. The increased popularity is due to a variety of factors, including the availability of species with a diversity of sizes, colors, and temperaments; the ability to house birds in a small area; and, in some cases, a long life span. The fact that most pet birds are confined to the home environment exposes them to toxicants that poultry and wild birds are unlikely to come into contact with, such as the pyrolysis products from Teflon-coated cookware. Alternatively, pet birds can be exposed to toxicants to which poultry and wild birds are also exposed but that are in different forms or from different sources. For example, pet birds can be intoxicated by lead, most often in the form of

lead-based paint or lead objects such as drapery weights or toys, whereas wild birds are frequently intoxicated following ingestion of lead ammunition or lead-containing fishing gear.

#### Wild birds

Obviously, wild birds exist in a much less well-controlled environment than do pet birds or poultry and are therefore exposed to a greater variety of potential toxicants. It is safe to say that avian toxicology had its origins in the 1950s and 1960s when the effects of organochlorine insecticides (OCs) such as dichlorodiphenyltrichloroethane (DDT) on a variety of bird species were first recognized. The rapid decline of a variety of high-profile avian species such as bald eagles, peregrine falcons, and pelicans during those years and, more recently, the declines of many songbird and waterfowl populations have resulted in significant government funding to more fully characterize the effects of toxicants on avian wildlife. In addition, regulatory requirements to obtain premarket toxicology information for pesticides using laboratory surrogates, such as quail and mallard ducks, have resulted in the generation of a substantial database of toxicologic information.

One unique aspect of wild bird toxicology is the potential exposure of wild birds to toxicants via their prey. Raptors and scavengers such as turkey vultures or condors are often poisoned as a result of feeding on animal carcasses contaminated with pesticides or lead. Thus, secondary or relay toxicosis is a more common occurrence in wild birds than in pet birds or poultry.

## Poultry

Most commercial poultry are raised in well-controlled environments and are provided quality feed and water. Thus, their potential for exposure to toxicants is more limited. However, poultry can become intoxicated following exposure to common feed additives such as organic arsenicals or ionophores if feed misformulations occur. Obviously, free-ranging poultry are potentially exposed to a greater variety of hazardous chemicals.

## Physiologic differences of birds relevant to toxicology

### Respiratory system

The unique physiology of bird respiration makes them more susceptible to some inhaled toxicants, such as carbon monoxide (CO) and pyrolysis products from overheated Teflon. The sensitivity of birds to inhaled toxicants brings to mind the image of the canary in the coal mine. Several physiologic differences of birds increase their sensitivity to inhaled toxicants, such as a higher mass specific minute ventilation, a higher mass specific ventilation of gas-exchange tissues, cross-current and countercurrent gas exchange mechanisms, and a gas diffusion barrier one-half the thickness of that of mammals (Brown *et al.*, 1997). Some of these physiologic adaptations are a result of high metabolic rates of birds and the concomitant need for a high ventilatory capacity.

### Metabolic system

A number of studies have examined the metabolism of xenobiotics in a variety of avian species and compared metabolic capabilities of birds and mammals (Pan, 1978; Dalvi *et al.*, 1987). Xenobiotic metabolism has been studied most extensively in chickens, pigeons, Japanese quail, and domestic ducks (Pan, 1978). As expected, there are substantial differences in metabolic pathways and capacities between birds and mammals that influence susceptibility to intoxication. Organophosphate (OP) insecticides are more toxic to birds than mammals, and the basis for this difference is primarily due to differences in OP metabolism. Dimethoate is 20 times more toxic for pheasants than for rats. Dimethoate is metabolized by pheasants to a toxic metabolite, whereas the toxic metabolite is detoxified by rats (Pan, 1978). In addition, there are differences between bird species and between sexes and ages. Geese, chickens, and turkeys had similar liver aniline hydroxylase activity compared with that of rats, whereas quail and ducks had lower activities (Dalvi *et al.*, 1987). Conjugating capabilities also differ. For example, glucuronidation of *p*-nitrophenol was greater in ducks than in chickens or turkeys.

### Excretion

Birds have several unique excretory pathways for xenobiotics. Many metals are incorporated into feathers, which are subsequently molted. In addition, incorporation of lipophilic toxicants into eggs provides a significant excretory pathway for female birds.

## GENERAL COMMENTS ABOUT DIAGNOSING AVIAN INTOXICATIONS

Although most diagnostic approaches for documenting intoxication in mammals are applicable to birds, there are several unique aspects that bear mentioning. Given the small size of many birds, obtaining a sufficient amount of sample for testing can sometimes present a challenge. For example, it is not unusual to be able to obtain only 100  $\mu$ L (sometimes less) of whole blood or serum antemortem for lead and zinc testing, respectively. Quantities of gastrointestinal contents or tissues such as liver are sometimes limiting, especially if multiple tests are desired. The availability of less than optimal sample sizes often decreases the sensitivity of toxicologic testing, so it is possible that low toxicant concentrations are not detected. In the case of wild bird die-offs, pooling of samples from several dead birds is often required.

Investigation of wild bird die-offs is often a challenge from the standpoint that frequently birds are not discovered until significant postmortem autolysis and/or predation has occurred. Postmortem autolysis often precludes thorough pathologic, microbiologic, and virologic testing. However, for the vast majority of toxicologic tests, the condition of the tissue or fluid sample is of less concern, and severely autolyzed samples may be perfectly suitable for toxicologic testing.

Antemortem, whole blood is most often requested from mammals for cholinesterase activity determinations. However, in birds, there is little cholinesterase activity that is associated with the red blood cell. Therefore, for avian species, plasma is preferred. Feathers and egg samples are sometimes useful for diagnosing either exposure to or intoxication from toxicants.

As is the case for any suspected intoxication related to feed, it is critical to obtain a representative feed sample. For example, feed-related mycotoxicoses are common concerns in poultry. However, the distribution and concentration of a mycotoxin in a feed can be quite variable. Therefore, it is important to obtain a number of samples that can then be pooled and subsampled. Other toxicants for which obtaining representative feed samples are critical include drugs; growth promotants such as ionophores; sodium chloride; and nutritionally important minerals such as copper, zinc, and selenium.

Because malicious poisonings of wild birds are common and some poisoned birds are protected by state or federal laws, the potential for litigation should always be of concern. Therefore, it may be critical to obtain and submit samples following chain-of-custody procedures.

## NATURAL TOXICANTS

### Algal toxins

Wild bird species are more likely to be intoxicated by cyanobacterial toxins than are pet birds or poultry given their most common water sources. However, it is possible that zoo birds or production birds such as poultry, game birds, or waterfowl can be exposed via their water depending on its source and if conditions conducive to algal blooms are present. There are few documented instances of intoxication of birds, although cyanobacterial toxins are often found in lakes, reservoirs, and rivers used by wild birds. A survey of the saline Salton Sea in California detected microcystins in 85% of the samples tested (Carmichael and Li, 2006). Analyses of liver samples of eared grebe (*Podiceps nigricollis*) found microcystins at concentrations believed to be clinically significant. However, the role that microcystins play, if any, in documented large eared grebe die-offs remains to be determined. A bloom of *Microcystis aeruginosa* in a pond in Japan was believed to have played a role in the death of approximately 20 spot-billed ducks (Matsunaga *et al.*, 1999). Although analysis for microcystins was not done, hepatic necrosis was noted in the one bird necropsied.

Anatoxin-a(s) was believed to have been the cause of bird mortality in several Danish lakes. *Anabaena lemmermannii* dominated the blooms, and anatoxin-a(s) was detected and bloom material was shown to be toxic to mice (Henriksen *et al.*, 1997; Onodera *et al.*, 1997). Both anatoxin-a and microcystins (LR and RR) were implicated in the mass mortalities of flamingos in Kenya (Krienitz *et al.*, 2003).

### Avian vacuolar myelinopathy

Avian vacuolar myelinopathy (AVM) is a disease of birds that has sporadically caused mortality of bald eagles (*Haliaeetus leucocephalus*), American coots (*Fulica americana*), and other waterbirds in several reservoirs in the southeastern United States. AVM is characterized by widespread, bilaterally symmetrical vacuolation of the white matter of the brain and spinal cord. Work has demonstrated an association between bird mortality and the presence of the invasive plant hydrilla (*Hydrilla verticillata*) (Wilde *et al.*, 2005). An unknown cyanobacterial species belonging to *Stigonematales* has been found to be

associated with the plant. AVM was reproduced using mallard ducks exposed to *Stigonematales* blooms. It is believed that a currently uncharacterized algal neurotoxin is the cause of AVM.

### Plants

A number of plants are recognized for their toxicity for birds (Table 67.1). Plants contain a large variety of biologically active constituents, including volatile oils, resins, alkaloids, polysaccharides, phenols, glycosides, and fixed oils. Free-flying companion birds are likely to encounter and eat household plants. Free-ranging production birds encounter plants in their outdoor environment. Both companion birds and production birds can be exposed to potentially toxic plants via their feed. Generally, wild birds are adapted to their environments and are unlikely to inadvertently ingest toxic plants.

The susceptibility of different bird species to specific toxic plants is variable. In addition, birds may be unaffected by plants that are toxic to other animals such as mammals. For example, cedar waxwings and house finches can consume fruit from the pepper tree (*Capsicum annuum*) that is toxic to mammals (Navarro, 1992).

Feeding behaviors also influence the susceptibility to intoxication. For example, it has been suggested that parrots can consume otherwise toxic plants because they remove the outer covering of fruits and seeds, which can contain high concentrations of toxins, before consumption.

There are few documented cases of bird intoxication following plant ingestion. However, there are several experimental studies of the susceptibility of small companion birds such as budgerigars and canaries along with numerous feeding studies using chickens and turkeys. There are published and anecdotal reports of fruit-eating birds being intoxicated by ethanol as a result of eating fermented fruit (Fitzgerald *et al.*, 1990).

### Mycotoxins

Independent chapters pertaining to mycotoxins are presented elsewhere in this book; therefore, select information pertaining to avian mycotoxicoses is presented in this section.

### Aflatoxins

Economic losses attributed to aflatoxin exposure in poultry often stem from reductions in growth rate, hatchability, feed efficiency, and immunocompetence. These naturally occurring mycotoxins are secondary metabolites produced by *Aspergillus flavus*, *A. parasiticus*, and

TABLE 67.1 Plants reported to be toxic to birds

Common name	Scientific name	Toxin	Plant part demonstrated to be toxic	Mechanism of toxic action	Primary organ system affected	Species/bird type reported to be affected	References
Avocado	<i>Persea americana</i>	Persin	Fruit, leaves	Unknown	Cardiovascular system	Budgerigars ( <i>Melopsittacus undulates</i> ), canaries ( <i>Serinus canaria</i> ), cockatiels, ostriches ( <i>Struthio camelus</i> )	Hargis <i>et al.</i> (1989), Shropshire <i>et al.</i> (1992), Burger <i>et al.</i> (1994), Burrows and Tyrll (2001)
Black locust	<i>Robinia pseudoacacia</i>	Unknown; possibly glycoprotein lectins, proteins	Leaves, bark	Unknown	Cardiovascular system, gastrointestinal tract	Budgerigars ( <i>Melopsittacus undulates</i> )	Shropshire <i>et al.</i> (1992), Burrows and Tyrll (2001)
Bladder pod, rattlebox, coffeeweed, daubentonia, others	<i>Sesbania</i> spp.	Saponins, others	Seeds	Smooth muscle inhibition, vasodilation	Nervous system, gastrointestinal tract, kidneys	Chickens	Flory and Hebert (1984), Burrows and Tyrll (2001)
Cacao	<i>Theobroma cacao</i>	Theobromine, caffeine	Seeds	Adenosine receptor antagonism, increased intracellular Ca <sup>2+</sup> concentrations	Nervous system, cardiovascular system	Chickens	Day and Dilworth (1984)
Canola (also referred to as rapeseed), mustards	<i>Brassica</i> spp.	Glucosinolates, others	Seeds	Accumulation of trimethylamine affects eggs (odor and taste); liver and muscle damage due to unknown mechanism	Eggs, liver, muscle, cardiovascular system	Chickens, turkeys, ducks	Ratanasethkul <i>et al.</i> (1976), Wight <i>et al.</i> (1987), Burrows and Tyrll (2001)
Cassava	<i>Manihot</i> spp.	Cyanide	Root	See section on cyanide			
Castor bean	<i>Ricinus communis</i>	Ricin	Seeds	Protein synthesis inhibition	Gastrointestinal tract, liver	Ducks	Jensen and Allen (1981)
Coffee senna, sickle pod, coffeeweed, others	<i>Senna</i> spp. (previously <i>Cassia</i> spp.)	Anthraquinones	Fruit, seeds	Irritation, mitochondrial myopathy	Gastrointestinal tract, skeletal muscle	Chickens	Cavaliere <i>et al.</i> (1997), Burrows and Tyrll (2001), Haraguchi <i>et al.</i> (2003)
Corn cockle	<i>Agrostemma githago</i>	Saponins	Seeds	Irritation	Gastrointestinal tract	Chickens	Heuser and Schumacher (1942), Burrows and Tyrll (2001)
Cottonseed	<i>Gossypium</i> spp.	Gossypol	Seeds	Unknown	Gastrointestinal tract, kidneys, liver, egg production	Poultry	Brown and Julian (2003)
Coyotillo	<i>Karwinskia humboldtiana</i>	Anthracenones	Seeds	Uncoupling of oxidative phosphorylation, inhibition of axoplasmal transport	Nervous system	Poultry	Burrows and Tyrll (2001)
Day jessamine, day cestrum, wild jasmine, Chinese inkberry	<i>Cestrum diurnum</i>	Analog of 1,25-dihydroxycholecalciferol	Leaves	Hypercalcemia, dystrophic tissue calcification	Cardiovascular system, kidneys	Chickens	Sarkar <i>et al.</i> (1981)

(Continued)

TABLE 67.1 (Continued)

Common name	Scientific name	Toxin	Plant part demonstrated to be toxic	Mechanism of toxic action	Primary organ system affected	Species/bird type reported to be affected	References
Death camas, others	<i>Zygadenus</i> spp.	Alkaloids	Seeds, stems, roots	Increase reflex activity, stimulate afferent pathway receptors, increase and extend negative afterpotentials	Nervous system	Poultry	Burrows and Tyrl (2001)
Dieffenbachia	<i>Dieffenbachia</i> spp.	Insoluble oxalates	Leaves	Physical irritation	Gastrointestinal tract	Canaries ( <i>Serinus canaria</i> )	Arai <i>et al.</i> (1992)
Digitalis	<i>Digitalis purpurea</i>	Cardiac glycosides	Leaves	Inhibit $\text{Na}^+ - \text{K}^+$ ATPase	Cardiovascular system	Canaries ( <i>Serinus canaria</i> )	Arai <i>et al.</i> (1992)
Eucalyptus	<i>Eucalyptus cladocalyx</i>	Cyanide	Leaves	Inhibit cytochrome oxidase <i>c</i>	Multiorgan	Poultry	Brown and Julian (2003)
Jimsonweed, thorn apple	<i>Datura</i> spp.	Tropane alkaloids	Seeds	Cholinergic (muscarinic) receptor antagonism	Nervous system	Chickens	Day and Dilworth (1984), Kovatsis <i>et al.</i> (1994), Burrows and Tyrl (2001)
Joboba	<i>Simmondsia chinensis</i>	Simmondsin	Seeds	Inhibition of appetite via unknown mechanism	Overall growth rate	Chickens	Arnouts <i>et al.</i> (1993)
White popinac, lead tree, guacis, jumby bean	<i>Leucaena leucocephala</i>	Mimosine	Seeds	Inhibit reactions requiring pyridoxine, inhibit DNA and RNA synthesis	Bone, depressed growth	Poultry	Kamada <i>et al.</i> (1998), Burrows and Tyrl (2001)
Lily of the valley	<i>Convallaria majalis</i>	Cardenolides	Leaves, rhizomes, roots	Inhibit $\text{Na}^+ - \text{K}^+$ ATPase	Cardiovascular system	Poultry	Burrows and Tyrl (2001)
Lupine	<i>Lupinus</i> spp.	Quinolizidine alkaloids	Leaves	Cholinergic receptor agonists	Nervous system	Canaries ( <i>Serinus canaria</i> )	Arai <i>et al.</i> (1992), Burrows and Tyrl (2001)
Milkweed	<i>Asclepias</i> spp.	Cardenolides, uncharacterized neurotoxin	Entire plant, latex sap	Inhibit $\text{Na}^+ - \text{K}^+$ ATPase, uncertain for neurotoxic effect	Cardiovascular system, nervous system		Burrows and Tyrl (2001)
Nightshades, potato	<i>Solanum</i> spp.	Steroidal glycosides (chaconine, solanine, others)	Immature seeds, foliage	Saponin-induced irritation, AChE inhibition	Gastrointestinal tract, nervous system	Chickens	Temperton (1944), Burrows and Tyrl (2001)
Oak	<i>Quercus</i> spp.	Tannins	Leaves, early buds	Astringent effect (protein precipitation), direct cell damage	Gastrointestinal tract, kidneys ( <i>Casuaris casuaris</i> )	Double-wattled cassowary	Kinde (1988), Burrows and Tyrl (2001)
Oleander	<i>Nerium oleander</i>	Oleandrin	Leaves	Inhibit $\text{Na}^+ - \text{K}^+$ ATPase	Cardiovascular system	Budgerigars ( <i>Melopsittacus undulates</i> ), canaries ( <i>Serinus canaria</i> ), geese (species not identified)	Arai <i>et al.</i> (1992), Shropshire <i>et al.</i> (1992), Alfonso <i>et al.</i> (1994)

Oxalates, soluble	Many plants ( <i>Halogeton</i> spp., <i>Sarcobatus</i> spp., others)	Calcium or potassium oxalates	Leaves, stems	Hypocalcemia, calcium oxalate precipitation in renal tubules	Cardiovascular system, kidneys	Poultry	Burrows and Tyrl (2001)
Parsley	<i>Ammi majus</i>	Furanocoumarins	Seeds, leaves	Primary photosensitization, other (calcium channel inhibition)	Skin, liver, kidneys	Ducks, geese; chickens and turkeys are less sensitive	Shlosberg <i>et al.</i> (1974), Burrows and Tyrl (2001)
Poison hemlock	<i>Conium maculatum</i>	Pyridine alkaloids including coniine, <i>N</i> -methylconiine, $\gamma$ -coniceine	Seeds	Nicotinic receptor agonist	Nervous system	Range turkeys (species not identified)	Frank and Reed (1987), Burrows and Tyrl (2001)
Pokeberry	<i>Phytolacca americana</i>	Saponins, oxalates	Berries	Irritation	Gastrointestinal tract	Turkeys	Cattley and Barnett (1977), Burrows and Tyrl (2001)
Rattlebox, others	<i>Crotalaria</i> spp.	Pyrrolizidine alkaloids	Seeds, leaves, stems	Inhibition of protein and RNA synthesis, alkylate DNA, inhibit mitosis	Liver	Chickens, geese	Gopinath and Ford (1977), Alfonso and Sanchez (1993), Burrows and Tyrl (2001)
Ragwort, groundsel	<i>Senecio</i> spp.	Amino acids, nitriles, $\beta$ -aminopropionitrile	Seeds	Glutamate receptor agonism, inhibition of lysyl oxidase	Nervous system, reproduction (decrease ovarian activity), eggs	Chickens, turkeys	Chowdhury (1988), Burrows and Tyrl (2001)
Sweet pea	<i>Lathyrus</i> spp.						
Tobacco	<i>Nicotiana</i> spp.	Nicotine, nornicotine, anabasine	Leaves and stems	Nicotinic receptor stimulation, teratogen	Nervous system, embryo development	Poultry	Burrows and Tyrl (2001)
Velvetweed	<i>Abutilon theophrasti</i>	Cyanogenic glycosides (probably not toxic), $\beta$ -cyano-L-alanine	Seeds	Affects egg yolks due to unknown mechanism	Eggs	Poultry	Brown and Julian (2003)
Vetch	<i>Vicia</i> spp.			Cyanide inhibits cytochrome oxidase <i>c</i> ; signs similar to pyridoxine deficiency	Nervous system	Chickens	Harper and Arscott (1962), Burrows and Tyrl (2001)
Virginia creeper	<i>Parthenocissus quinquefolia</i>		Leaves	Unknown	Gastrointestinal system	Budgerigars ( <i>Melopsittacus undulatus</i> )	Shropshire <i>et al.</i> (1992), Burrows and Tyrl (2001)
Yew	<i>Taxus</i> spp.	Taxine	Leaves, seeds	Alter atrioventricular conduction via inhibition of $\text{Na}^+ - \text{Ca}^{2+}$ fluxes and possible $\text{K}^+$ channel effects	Cardiovascular system	Budgerigars ( <i>Melopsittacus undulatus</i> ), canaries ( <i>Serinus canaria</i> ), emus ( <i>Dromaius novaehollandiae</i> )	Shropshire <i>et al.</i> (1992), Fiedler and Perron (1994), Burrows and Tyrl (2001)

*A. nomius*. In 1959, the infamous turkey "X" disease, involving the deaths more than 100,000 turkey poults and ducklings in England, was determined to be due to multiple aflatoxins, including cyclopiazonic acid, in imported Brazilian peanut meal fed to affected birds (Cole, 1986). Structurally, aflatoxins (AFs) are difurocoumarin derivatives that fluoresce under ultraviolet light. Depending on the color of the fluorescence, AFs are divided into aflatoxin B<sub>1</sub> (AFB<sub>1</sub>) and AFB<sub>2</sub> for blue and AFG<sub>1</sub> and AFG<sub>2</sub> for green (Dalvi, 1986). Although peanuts and corn are commonly known substrates for the growth of aflatoxin-producing fungi, other grains and nuts have been implicated as well. The U.S. Food and Drug Administration (USFDA) has set a current guidance level for AFB<sub>1</sub> concentrations in corn and peanut products intended for immature and mature poultry at 20 and 100 parts per billion (ppb), respectively. Moisture content greater than 14%, relative humidity greater than 70%, and temperature greater than 70°F are often conducive for the growth of *Aspergillus* sp. fungi in improperly stored grain. Fungal invasion of field crops, especially during drought stress or when there is insect or mechanical damage, can occur.

Mortality in cranes and waterfowl due to consumption of waste grain in standing crops containing acutely toxic aflatoxin concentrations has been reported, coinciding with migration and wintering. Contaminated grain offered at bird feeding stations, however, can lead to clinical signs at any time of the year. Exposure to aflatoxins and subsequent mortality events have been reported in free-ranging birds, including a variety of duck species (mallard, black duck, lesser scaup, gadwall, and blue- and green-winged teal), Canada geese, snow geese, and sandhill cranes (Friend and Franson, 1999).

Poultry, especially turkeys, are extremely sensitive to the toxic effects of AFB<sub>1</sub>, with quails being intermediate and chickens being comparatively resistant (Lozano and Diaz, 2006). AFB<sub>1</sub> at 0.7 mg/kg reduced the growth rate of turkey poults but had no effect in quails and chickens (Arafa *et al.*, 1981). Significant reduction in weight gain and feed consumption was observed in day-old broiler chicks fed 10 ppm AFB<sub>1</sub> for 8 weeks, especially after the third week (Dalvi and Ademoyero, 1984). In day-old ducklings, the acute toxicity for AFB<sub>1</sub> has been estimated to be 12 µg/duckling (Purchase, 1967).

Clinical signs in birds include lethargy, depression, blindness, inability to fly, tremors, and wing flapping, although birds can also simply be found dead. Lethal aflatoxicoses in ducklings occurred as inappetence, reduced growth, abnormal vocalization, feather picking, purple discoloration of leg and feet, and lameness. Ataxia, convulsions, and opisthotonus preceded death (Asplin and Carnaghan, 1961). Turkeys develop inappetence, reduced spontaneous activity, unsteady gait, recumbency, anemia, and death (Wannop, 1961). Aflatoxicosis in chickens closely resembles the clinical signs in ducks and turkeys.

Chronic effects, which include appetite loss, weight loss, and general ill health, can be more insidious and difficult to definitively relate to aflatoxin exposure. Chronic exposure can also produce a shrunken, fibrous liver with regenerative nodules or tumors. Chronic low-level aflatoxin exposure is also known to suppress the immune system, which may predispose animals to infectious diseases.

It is well recognized that several mycotoxins may act in combination to cause lesions previously considered to be consistent with aflatoxicoses; cyclopiazonic acid, sterigmatocystin, and possibly others play a role in the development of this disease. Acute exposures over a relatively short period lead to pale, swollen, and enlarged livers (and kidneys), occasionally accompanied by gallbladder distension. Hemorrhages in internal organs may be accompanied by generalized edema. The crop and proventricular mucosa shows thickening (Kumar and Balachandran, 2009). Inflammation and bleeding of the gastrointestinal (GI) tract lining, which may cause the intestines to appear blackish-red throughout their entire length, can also be observed. Microscopically, the hepatocytes show fatty changes, proliferation of bile ductules, and extensive fibrosis, accompanied by vascular and degenerative lesions in pancreas and kidney (Hoerr, 1997).

Measurement of aflatoxin concentrations in suspected feed, ingesta, or the liver is crucial for confirming the diagnosis. Representative sampling and adequate precautions (e.g., freezing samples) to avoid fungal growth and toxin production secondary to improper post-collection storage and shipping are necessary.

Suspected feed sources should be removed from the diet. Selenium supplementation has been suggested to have some protective action in Japanese quail fed 1 ppm (mg/kg) AFB<sub>1</sub>. Field crops frequented by avian wildlife for seasonal feeding may be monitored for aflatoxins, especially during hot and humid weather. At concentrations of 100 ppb and higher, deep plowing of fields containing the contaminated grains is recommended by the U.S. Geological Survey National Wildlife Health Center (Friend and Franson, 1999). If that is not possible, hazing the birds away may be another strategy.

Aflatoxin contamination of feedstuff is nearly universal, and chemopreventive and/or enterosorptive approaches have been attempted. Synthetic zeolites incorporated at 1% in diet were observed to be protective against 2.5 mg/kg AFB<sub>1</sub> in feed (Miazzo *et al.*, 2000). Hydrated sodium calcium aluminosilicate, fed at dietary levels ranging from 0.25 to 1%, has been shown to diminish the deleterious effects of AFs (up to 5 mg/kg in diet) in broiler chicks (Kubena *et al.*, 1998; Ledoux *et al.*, 1999). Silymarin, a hepatoprotective agent used in humans, may be useful in the treatment of aflatoxicosis due to promotion of cellular synthesis of macromolecules, antioxidant activity, and stabilization of cell membranes (Tedesco *et al.*, 2004). Dietary

inclusion of the food antioxidant butylated hydroxytolouene at a level of 0.39% ameliorated weight loss in chickens consuming AFB<sub>1</sub> at 3 mg/kg in their diet (Larsen *et al.*, 1985) due to an inhibitory effect on the activity of Cyt P450 1A enzymes, suggesting reduced bioactivation of AFB<sub>1</sub> to the AFBO (Klein *et al.*, 2003). *Lactobacillus rhamnosus* GG was able to bind AFB<sub>1</sub> in adapted Caco-2 cells and thereby reduce its transport, metabolism, and toxicity, suggesting the possible usefulness of this and other probiotics in protection against aflatoxicosis (El-Nezami *et al.*, 2002; Gratz *et al.*, 2007). Various non-nutritive sequestering agents, such as polymers, chlorophyll, and yeast-derived products, and silicate minerals and activated charcoal products minimize the toxicological effects of mycotoxins and reduce the potential carryover into the human food chain. They have been reviewed for their potential as additives in livestock feed and make for further in-depth reading (Diaz, 2008).

## Fusariotoxins

Fungi belonging to *Fusarium* spp. and several other genera produce chemically distinct mycotoxins in feed grains and nuts. Type A and type B trichothecenes, zearealenone (ZEN), and fumonisins are fusariotoxins of relatively greater importance from a poultry production and health perspective (Girgis and Smith, 2010). Type A trichothecenes include T-2 toxin, HT-2 toxin, and diacetoxyscirpenol; type B trichothecenes include deoxynivalenol (DON, vomitoxin), 3- and 15-acetyl-DON, nivalenol, and fusarenon-X (D'Mello *et al.*, 1997). Of these, DON is the most commonly encountered fusariotoxin; 15-acetyl-DON is more prevalent in North America, often at levels of 10–20% of DON compared to 3-acetyl-DON prevalent in Europe (Scientific Committee on Food and European Commission, 1999). 15-Acetyl-DON is considered less toxic than DON, whereas 3-acetyl-DON is similarly toxic to DON (U.S. Wheat and Barley Scab Initiative, 2007). ZEN commonly co-occurs with trichothecenes (Placinta *et al.*, 1999). A descending order of sensitivity to fusariotoxins has been noted in turkeys, layers, breeders, broilers, and ducks (Girgis and Smith, 2010). Fusariotoxins differ from other mycotoxins in that they tend to be produced during the colder seasons of the year. Common substrates involved in fusariotoxin production include corn, wheat, barley, oats, peanuts, and, sometimes, forages (Friend and Franson, 1999). The effect of multiple fusariotoxins (DON, 15-acetyl-DON, ZEN, and fusaric acid) in blends of naturally contaminated wheat and corn was evaluated in broiler breeder chicken and other species. Reduced egg production and eggshell thickness accompanied with a significant increase in early embryonic mortality was observed, although the fertility of roosters was not affected (Smith *et al.*, 2008). More studies are needed

to better understand toxicological interactions of fusariotoxins under field conditions. ZEN often occurs with DON in naturally contaminated cereals, and it is responsible for reproductive disorders due to its estrogenic effect at suitable concentrations in susceptible livestock and avian populations. However, in general, ZEA has limited toxicity to birds. Commonly observed symptoms are vent enlargement and enhanced secondary sex characteristics. ZEN may be an indicator of the presence of other mycotoxins and therefore may be of some value as a diagnostic marker. Identification and measurement of suspect mycotoxins are crucial to accomplish a confirmatory diagnosis.

## T-2 toxin

Compared to DON, T-2 toxin occurs less frequently in grain and other agricultural products (Murphy *et al.*, 2006). Weather conditions, grain defects, and moisture contents (13–22%) influence T-2 production, with maximum production at temperatures below 15°C (Mateo *et al.*, 2002). In 7-day-old broilers, the LD<sub>50</sub> of T-2 toxin is 4.97 mg/kg, and it is therefore more toxic than aflatoxin (LD<sub>50</sub> = 6.8 mg/kg), HT-2 toxin (LD<sub>50</sub> = 7.22 mg/kg), and DON (LD<sub>50</sub> = 140 mg/kg) (Leeson *et al.*, 1995). In poultry, toxicological and immunomodulatory effects of T-2 are observed on the liver and digestive system, nervous system, and skin due to its cytotoxic and genotoxic potential, leading to impairment of performance. Type A trichothecenes (especially T-2) are significantly less immunotoxic than type B trichothecenes (Sharma, 1993). However, T-2 toxin can induce necrosis and depletion of lymphoid cells in the thymus, spleen, and lymph nodes of chicken and pullets (Wyatt *et al.*, 1973; Hoerr, 2003). In the digestive system, necrotic damage characterized by white-yellowish bulges containing caseous-necrotic material is observed in various areas of the mouth, gizzard, intestinal mucosa, and liver (Wyatt *et al.*, 1972; Ademoyero and Hamilton, 1991; Konjevic *et al.*, 2004). Frequently, long-term feeding with contaminated feed (1–5 mg/kg) for at least 1 week or even a single application (5 mg/kg) of T-2 can lead to oral lesions and decreased weight gain (Brake *et al.*, 2000). Other type-A trichothecenes, such as HT-2 toxin, diacetoxyscirpenol, monoacetoxyscirpenol, and scirpentriol, can also cause similar lesions (Hoerr, 2003).

The primary toxic effects of T-2 are on the liver, by virtue of inhibition of protein synthesis and reduced enzymatic activity leading to lipid peroxidation and cellular damage (Smith, 1992). Incoordination, hysteroid seizures, and loss of appetite are some central nervous system (CNS) symptoms recorded in birds fed trichothecenes-contaminated feed. Consumption of feed containing elevated concentrations of T-2 (4–16 mg/kg) was correlated with very low feather quality and

wing abnormalities (Wyatt *et al.*, 1975). Comb cyanosis, skin depigmentation of the legs, and necrohemorrhagic dermatitis have been recorded as well. Eggshell thinning, reduced egg production, decreased feed intake and weight gain, and growth retardation are commonly observed signs.

Diagnosis is based on history, clinicopathological findings including necrotic lesions in the digestive system, and detection of T-2 at significant concentrations in the suspected feed. Total amount of all trichothecenes including T-2 toxin in poultry feed should preferably not exceed 0.5 mg/kg, based on a compilation of data including occurrence, toxicity, and clinical signs in poultry (Eriksen and Pettersson, 2004).

### Deoxynivalenol (vomitoxin)

Diversion of DON-infected cereals to poultry feed is commonly believed to be a significant route of exposure. DON is the least acutely toxic but a more commonly occurring grain contaminant (Rotter *et al.*, 1996). Most poultry experimental studies have revealed a highly variable effect on performance, and there is major interest in the effect of chronic low-level exposure. Direct effects on hematology and clinicochemical parameters are poorly defined, although reduced feed intake and weight gain have been established.

Dietary concentrations greater than 5 mg/kg are necessary to cause detrimental effects in broilers (Dänicke *et al.*, 2001), and even higher concentrations did not consistently induce ill-effects. Reduced weight gain and feed refusal were observed at 16–20 mg/kg concentrations of DON. The USFDA has established a 10 mg/kg advisory concentration for DON in grain or grain byproducts destined for chicken, with the added recommendation that such feed may not exceed 50% of the total diet. Erosions in the mucosa of the gizzard, corrugations in the gastric mucosa, duodenitis, jejunitis, intestinal bleeding, and necrosis have been associated with DON exposure. Decreased absorption of glucose and amino acids in the chicken small intestine has been recorded as well. A reduced immune response to Newcastle disease vaccine has been measured in chicken fed 50 mg/kg DON (Harvey *et al.*, 1991), and decreased serum antibody titers against infectious bronchitis virus and Newcastle disease virus have been observed in laying hens and broilers due to feeding DON-contaminated grain.

### Fumonisin

As a commonly occurring contaminant of corn and other agricultural products, fumonisins exert their toxic effects in poultry at relatively higher concentrations compared

to those in pigs. Fumonisin in excess of 100 mg/kg in the diet have been shown to reduce poultry performance. FB<sub>1</sub> incorporation at 251 mg/kg in broiler feed caused a 5% reduction in growth rate, whereas pigs showed a similar growth reduction at 21 mg/kg (Dersjant-Li *et al.*, 2003). In day-old broiler chicks fed 0–400 mg/kg FB<sub>1</sub> for 21 days and 30 mg/kg for 14 days, reduction in weight gain, hepatic necrosis, biliary hyperplasia, and thymic cortical atrophy were noted (Brown *et al.*, 1992). Elevated sphinganine (Sa)/sphingosine (So) ratios were observed in young chicks treated with FB<sub>1</sub> containing culture material (Weibking *et al.*, 1993). Abnormal erythrocyte formation and cytotoxic effects on lymphocytes have been noted as well (Dombrink-Kurtzman *et al.*, 1993). FB<sub>1</sub> incorporated at 50 mg/kg in the diet led to reduced feed intake in turkey poults but not in broiler chicks up to market age; Sa/So ratios were elevated in both, although neither hematologic parameters were affected, nor were any microscopic lesions observed in organs (Broomhead *et al.*, 2002). The USFDA guidance concentration for fumonisins in poultry feed is set at 50 ppm in the total ration. Feed containing elevated fumonisin concentrations may be disposed or diluted with suitable feed sources.

### Ochratoxin and citrinin

These nephron- and hepatotoxic mycotoxins are produced by multiple species of *Aspergillus* and *Penicillium*, and they occur in grains and feedstuff produced worldwide. Ochratoxin A (OTA) is comparatively more toxic than citrinin and has been studied extensively (Gupta, 2011), although both may co-occur. OTA inhibits protein biosynthesis, accelerates lipid peroxidation, causes oxidative stress, and reacts with enzymes-utilizing phenylalanine as a substrate, thereby exerting its toxic effects. The nephrotoxic effect of OTA is due to its action on the organic anion transport system, located in basolateral and brush border membranes of the proximal tubule cells of the nephron and also involved in the absorption/reabsorption and excretion of OTA in the kidney. The middle (S2) and terminal (S3) segments of the proximal tubule of isolated nephrons have been found to be most sensitive to the toxic effect of OTA (Ringot and Chango, 2010). Field outbreaks of ochratoxicosis typically result in decreased feed consumption, efficiency, and growth rate (Hamilton *et al.*, 1982), along with increased mortality (Elaroussi *et al.*, 2006). Avian species vary in their sensitivity to OTA; the LD<sub>50</sub> in chicken is reported to be 2–4 mg/kg, whereas ducks and Japanese quail are susceptible to 0.5–16.5 mg/kg body weight (BW) (Peckham *et al.*, 1971). Young broiler chickens were fed four treatments of feed containing 0, 1, 2, and 4 mg OTA/kg of feed and sequentially euthanized and necropsied up to 21 days of age. At 4 mg/kg (ppm) feed concentrations,

significant growth depression occurred, as early as 6 days of age. Dietary OTA significantly increased the relative weights of liver, kidney, spleen, pancreas, and gizzard. Anemia, characterized by a significant decrease in packed cell volume and hemoglobin levels, was present. Hepatotoxicity was inferred through a significant reduction in serum levels of total protein, albumin, globulin, cholesterol, triglyceride, and blood urea nitrogen and a significant increase in the serum activities of  $\gamma$ -glutamyl transferase. A significant increase in serum uric acid and creatinine concentrations was considered to be indicative of nephrotoxicity (Huff *et al.*, 1988). Dietary OTA at or above 400  $\mu\text{g}/\text{kg}$  (ppb) *ad libitum* feed was fed to broiler chickens for 5 weeks, leading to marked degenerative changes in the kidney and bursa, accompanied by mononuclear infiltration in the liver. Significant increases in the weights of kidney and liver were observed, along with increases in serum glutamic oxaloacetic transaminase, glutamic pyruvic transaminase, uric acid, and creatinine concentrations. Serum total protein, albumin, and globulin were significantly decreased (Elaroussi *et al.*, 2008). Microscopically, pathological changes in the kidney consistent with acute, subacute, and chronic ochratoxicosis have been well characterized and presented in several avian pathology texts.

Broiler chicks fed 300  $\text{mg}/\text{kg}$  (ppm) citrinin displayed severe enlargement of the kidneys, pale livers, and pinpoint cardiac hemorrhages. Histologically, severe tubular nephrosis, vacuolar degeneration of hepatocytes, catarrhal enteritis, degeneration, and mononuclear infiltration in the myocardium were observed (Ahmad *et al.*, 2009). Comparisons between the previously mentioned reports illustrate the difference between toxic doses of OTA and citrinin necessary to cause intoxication.

## Zootoxins

There are few reports of bird intoxication resulting from exposure to zootoxins. Snakebite was believed to have been responsible for the deaths of two red-tailed hawks (*Buteo jamaicensis*) and a Cooper's hawk (*Accipiter cooperii*) based on the carcasses being found in the vicinity of venomous snakes and gross findings of hemorrhages, muscle degeneration, and gangrenous necrosis of a limb (Heckel *et al.*, 1994). Chickens, turkeys, and ducks have also reportedly been killed by snakes based on bite sites being identified on postmortem examination along with the occurrence of compatible gross organ lesions (Lawal *et al.*, 1992).

## Bacterial toxins

### *Botulinum toxin*

Avian botulism results from the ingestion of botulinum toxin produced by *Clostridium botulinum*. There are eight

antigenically distinct toxin types, which are designated A, B, C alpha, C beta, D, E, F, and G; the type designations reflect their order of discovery. Type C alpha cultures produce three toxins designated C1–C3 and small amounts of type D. *Clostridium botulinum* is an anaerobic bacterium that persists in the form of dormant spores when environmental conditions are not conducive for bacterial growth. The spores are quite resistant to destruction and can remain viable for years. Spores of type C toxin are widely distributed in wetland sediments and in tissue of wetland organisms. A number of factors play a role in the occurrence of an outbreak of botulism, including optimal environmental conditions for spore germination and bacterial growth, availability of suitable material to support bacterial replication, and a means for toxin transfer to birds (Friend and Franson, 1999). Most outbreaks occur during summer and fall months when ambient temperatures are relatively high. Bacterial replication requires substrates that are high in protein; decomposing carcasses are good bacterial substrates. Types C1 and D are produced by clostridia containing pseudolysogenic *tox+* phages encoding for the respective toxin genes (Zechmeister *et al.*, 2004; Sakaguchi *et al.*, 2005). Genes encoding for C1 toxin are ubiquitous in wetlands inhabited by bird populations (Zechmeister *et al.*, 2004).

Botulinum toxin is one of the most toxic chemicals known, although for any given species, toxicity varies by toxin type and age (Barnes, 2003). For example, chickens, turkeys, pheasants, and peafowl are susceptible to types A, B, C, and E but not to types D or F (Gross and Smith, 1971). As broiler chickens age, they become less susceptible to type C toxin (Barnes, 2003). Most outbreaks of botulism in birds are due to exposure to type C1 toxin. Less frequently, exposure to type E has caused mortality of fish-eating birds (Friend and Franson, 1999). Domestic chickens have been intoxicated by type A. A mosaic neurotoxin (two-thirds type C and one-third type D) has been characterized that is believed to have been responsible for some forms of avian botulism (Takeda *et al.*, 2005).

Avian botulism is one of the most important diseases of migratory birds (Friend and Franson, 1999). Filter feeding and dabbling waterfowl are among the species most at risk. Raptors have been intoxicated by feeding on poultry carcasses that have not been disposed of properly. Waterfowl are exposed to botulinum toxin via ingestion of contaminated substrates or via contaminated invertebrates such as maggots that feed on decaying carcasses or other organisms such as zooplankton that are inadvertently contaminated. As few as two maggots can be lethal if ingested. Outbreaks of botulism in avian wildlife result in losses that are quite variable, ranging from a few hundred birds to more than 1 million.

Poultry and other production birds can be affected. Game farm pheasants have been intoxicated by feeding on maggots (Foreyt and Abinanti, 1980). Wound contamination by spores of *C. botulinum* was hypothesized to have contributed to the deaths of caponized chickens (Trampel *et al.*, 2005).

Vultures and other carrion eaters are resistant to botulinum toxin, perhaps, in part, due to the production of antibodies to botulinum toxin, which does not occur in sensitive species such as chickens and ducks (Gross and Smith, 1971; Ohishi *et al.*, 1979; Friend and Franson, 1999).

Clinical signs are consistent with neuromuscular paralysis. Early, affected waterfowl are unable to sustain flight (Friend and Franson, 1999). Leg paralysis in waterfowl causes birds to propel themselves using their wings. Paralysis of the nictitating membrane and neck muscles follows, resulting in an inability to hold the head erect (thus the term limberneck). In chickens, an ascending flaccid paralysis is noted (Barnes, 2003). Initially, affected birds are reluctant to walk and, when forced, appear lame. Similar to waterfowl, the wings droop and the neck becomes weak, followed by eyelid paralysis. Waterfowl often drown; affected terrestrial birds die from respiratory and cardiac failure. The time between the onset of clinical signs and death can be as short as a few hours. Postmortem lesions are generally not observed; in affected waterfowl, lesions may be consistent with drowning.

A presumptive diagnosis is based on characteristic clinical signs and environmental conditions conducive to bacterial growth and toxin production. Confirmation of botulism is most often made by using the mouse bioassay to detect the presence of the toxin. Toxin specificity is determined by protecting inoculated mice with specific antitoxins. Enzyme-linked immunosorbent assay and liquid chromatography–mass spectrometry methods have been developed to confirm the presence of toxin (Zechmesiter *et al.*, 2004; Barr *et al.*, 2005). The mouse bioassay is still considered to be the “gold standard” assay due to the sensitivity of the mouse to botulinum toxin. However, newer methods will likely replace the mouse bioassay in the future.

Treatment of individual affected birds with antitoxin can result in recovery, especially in waterfowl. Other affected species, such as coots, shorebirds, gulls, and grebes, rarely recover (Friend and Franson, 1999). Difficult logistics, limited availability of antitoxin, and cost of treatment preclude effective intervention in large outbreaks.

Prevention and control of outbreaks are critical to minimize losses. In wetlands, the amount of organic and decaying material should be limited. Prompt removal and disposal via burial or burning of animal carcasses is important during outbreaks to interrupt bacterial growth and toxin production. Immunization with inactivated

bacterin-toxoids is protective, but vaccination of large poultry flocks or waterfowl is expensive and, in the case of waterfowl, logistically difficult.

#### *Biogenic amines*

Biogenic amines, such as gizzerosine, histamine, histidine, cadaverine, spermine, and putrescine, result from the heating or bacterial spoilage of fish and animal byproducts (Barnes *et al.*, 2001; Brown and Julian, 2003). Poultry are potentially exposed to the amines when fish or meat meal is incorporated into their diets. Toxic concentrations vary depending on the specific amine. Dietary histamine at 0.1% is associated with reduced feed conversion and body weights in broiler chickens (Barnes *et al.*, 2001). Dietary spermine is toxic to 120-week-old chicks at 0.2% (Sousadias and Smith, 1995). Putrescine is toxic at concentrations of 0.05% (Chowdhury, 2001). Interestingly, a dietary concentration of putrescine of 0.05% has been associated with improved eggshell quality (Chowdhury, 2001). The improvement was hypothesized to be due to increased calcium transport.

Biogenic amines at toxic concentrations cause digestive disturbances. Gizzerosine causes gizzard erosion and hemorrhage. A dietary histamine concentration of 4ppm results in localized gizzard lesions and reduced growth rates in chicks (Harry and Tucker, 1976). In addition to gastrointestinal effects, toxic biogenic amine concentrations cause a malabsorption syndrome in chickens characterized by reduced feed efficiency and enlargement of the proventriculus (Barnes *et al.*, 2001).

## Feed additives

### *Arsenicals*

Arsenic exists in a variety of inorganic and organic forms and valences. Arsenic trioxide was used as an herbicide. Pentavalent and trivalent sodium, potassium, and calcium salts of arsenic have been used as insecticides, especially for ants. Trivalent organic forms of arsenic include the herbicides monosodium methanarsonate and disodium methanarsonate and thiacetarsamide, previously used for treating dogs with heartworm. Pentavalent arsenicals used as feed additives include arsanilic acid, sodium arsanilate, 3-nitro-4-hydroxyphenylarsonic acid (3-nitro and roxarsone), and 4-nitrophenylarsonic acid. Arsanilic acid and 3-nitro are the most commonly used organic arsenicals in poultry production (Feed Additive Compendium, 2005). They are used to increase feed efficiency, promote growth, improve pigmentation, and prevent coccidiosis. Although exposure of birds to inorganic arsenic salts can occur, most avian arsenic intoxications involve exposure of poultry to pentavalent organic arsenicals.

Pentavalent organic arsenicals are believed to substitute for phosphate in oxidative phosphorylation. Uncoupling of oxidative phosphorylation results in cellular energy deficits (Ensley, 2004). Intoxication occurs most commonly due to feed mixing errors. Clinical signs have occurred in turkeys exposed to dietary concentrations of 3-nitro approximately twice the recommended dose. Clinical signs in affected birds include stunting, depression, apparent lameness, and ataxia. Gross lesions are typically absent, but histopathologically, Wallerian degeneration of the optic and peripheral nerves occurs. Wallerian degeneration can also occur in the spinal cord (Ensley, 2004). Ulcerative cholecystitis has been reported in turkey poultlets intoxicated by 3-nitro (Brown *et al.*, 1991).

Diagnosis of organic arsenical intoxication in poultry depends on detection of potentially toxic concentrations in representative feed samples and the occurrence of compatible clinical signs and postmortem lesions. Treatment consists of removing the offending feed and providing accessible feed and water.

Arsenic has been detected at relatively high concentrations in some seabirds, including albatrosses and gulls (Kubota *et al.*, 2003). It is present in tissues primarily as the organic arsenical, arsenobetaine, which is relatively nontoxic.

A significant percentage of the human tolerable daily intake of arsenic can come from arsenic residues in poultry meat (Taylor, 2004). Measurable increases in soil arsenic concentrations can occur as a result of using litter from arsenic-treated poultry as fertilizer (Garbarino *et al.*, 2003; Rutherford *et al.*, 2003).

## Sodium

Sodium ion intoxication is a significant problem in poultry production. Intoxication can result from excessive sodium in the feed, water deprivation, or ingestion of saline waters (Brown and Julian, 2003). The most common form of sodium associated with intoxication is sodium chloride. Sodium sesquicarbonate, used as a buffering agent in ruminant feeds containing high concentrations of urea, was responsible for high mortality in broiler chickens as a result of a feed misformulation (Sander *et al.*, 1998). High dietary sodium can be well tolerated if access to water is not restricted. For example, 15-day-old turkey poultlets tolerated up to 10% sodium chloride in their mash for 14–16 days when drinking water was not restricted (Gitter *et al.*, 1979). However, young chicks and poultlets can be intoxicated from sodium in feed despite adequate water intake. Sodium concentrations in both the feed and the water need to be considered in assessing sodium exposure.

A number of factors influence the toxicity of the sodium ion, including bird age, bird species, dietary factors, and water quality and accessibility. Young birds are

more sensitive to sodium ion toxicity, most likely due to less developed renal function. Turkeys are more susceptible to intoxication than are chickens (Berger, 1993). In addition, birds have less ability to excrete salts in excess of water, so their ability to reduce high-plasma osmolality is limited (Barnes, 2003). Some waterfowl have nasal salt glands that provide an additional excretory route. In general, the addition of 1% salt (as sodium chloride) to poultry rations is safe, even for very young birds. A level of 0.25% salt in drinking water is considered to be safe (Berger, 1993).

At high sodium intakes, birds develop acute, severe diarrhea and dehydration, lose weight, and die. Renal function is often impaired, especially if sodium bicarbonate is the source for exposure (Barnes, 2003). Lower, but still toxic, sodium intakes primarily cause cardiac overload, ascites, dyspnea, and edema. Loose droppings, decreased feed intake, and poor growth are often observed. Thirteen-week-old tom turkeys affected by high dietary sodium chloride concentrations (~8%) exhibited polydipsia, diarrhea, ataxia, tremors, depression, sternal and lateral recumbency, torticollis, and death (Wages *et al.*, 1995).

Ascites, edema, fluid in the lungs, hydropericardium, cardiac hypertrophy (right-sided in chickens and bilateral in poultlets), and dilatory cardiomyopathy (poultlets) are found on postmortem examination. Most microscopic lesions are secondary to cardiac failure, although bilaterally symmetrical areas of cerebral necrosis, vascular congestion, and edema were noted in intoxicated tom turkeys (Wages *et al.*, 1995).

Sodium intoxication in waterfowl has been associated with the ingestion of hypersaline water or salt that has precipitated on feathers (Windingstad *et al.*, 1987; Meteyer *et al.*, 1997; Gordus *et al.*, 2002; Stolley and Meteyer, 2004). Significant gross and microscopic lesions in ruddy ducks intoxicated by sodium include conjunctivitis; lens opacity; cataract formation; vascular congestion in multiple organs, especially in the meninges; and myocardial and skeletal muscle degeneration (Gordus *et al.*, 2002).

The use of sodium chloride as a deicing agent on roads is believed to intoxicate passerine birds. Experimentally, sodium chloride was lethal to house sparrows dosed with a concentrated sodium chloride solution providing 8000 mg/kg (0.8%) (Bollinger *et al.*, 2005).

A diagnosis of sodium ion intoxication relies on detection of high dietary and/or water, serum, and/or brain sodium concentrations. The significance of detected dietary and water sodium concentrations needs to be assessed in conjunction with other historical, clinical, and postmortem findings. Serum sodium concentrations greater than 150 mEq/L are elevated, and brain sodium concentrations greater than 2000 ppm wet weight are highly suggestive of intoxication (Puls, 1994).

### Vitamin A

Vitamin A is an essential micronutrient that plays a role in normal vision, reproduction, immunity, membrane integrity, growth, and embryogenesis. Vitamin A intoxication has been produced experimentally in poultry and cockatiels (Tang *et al.*, 1985; Koutsos *et al.*, 2003). Osteodystrophy occurred in broiler and leghorn chicks exposed to 330–660 IU vitamin A per day for 21 days (Tang *et al.*, 1985). Skeletal development was affected in growing chickens given 200 mg retinyl acetate per kilogram (Baker *et al.*, 1967). Anorexia, conjunctivitis, eyelid adhesions, and encrustations around the mouth were also noted by Tang *et al.*, 1985. Cockatiels fed approximately 30,000 µg/kg of vitamin A (as retinol) for 269 days exhibited intensified vocalization patterns, pancreatitis, multifocal accumulation of lymphocytes in the lamina propria of the duodenum, and reduced body condition (Koutsos *et al.*, 2003). Intakes of 3000 µg/kg of vitamin A also caused clinical signs, but they were less severe. A diagnosis of vitamin A intoxication can be made based on measurement of high vitamin A concentrations in representative feed samples and in serum or liver tissue along with the occurrence of compatible clinical signs.

### Vitamin D

Vitamin D is required for normal calcium and phosphorus homeostasis, which in turn is important for normal bone, beak, claw, and eggshell formation. Poultry diets are commonly supplemented with vitamin D in the form of cholecalciferol (D<sub>3</sub>) (Barnes, 2003). Vitamin D stimulates the absorption of calcium from the GI tract, influences osteoblast and osteoclast activity, and increases renal tubular reabsorption of calcium. Exposure to excessive vitamin D results in increases in calcium absorption from the GI tract and renal tubules and also calcium mobilization from bone. High blood and tissue calcium concentrations cause metastatic tissue calcification. In broiler chicks, dietary concentrations of 30,000 IU/kg are toxic when fed during growth. Much higher doses of vitamin D can rapidly cause renal calcification and damage. Aortic and arterial calcification can also occur. Postmortem lesions include parathyroid gland atrophy, renal tubular and aortic calcification, and calcification of blood vessel walls in the brain. Older birds are less sensitive than younger, actively growing birds to vitamin D. Other forms of vitamin D are also potentially toxic. Relative toxicity is vitamin D<sub>2</sub> < vitamin D<sub>3</sub> < 25-mono-hydroxycholecalciferol < 1,25-dihydroxycholecalciferol (Barnes, 2003). Nephrocalcinosis was experimentally produced in chicks by feeding powdered leaves from *Cestrum diurnum*, which contains an analog of 1,25-dihydroxycholecalciferol (Sarkar *et al.*, 1981).

### Ionophores

Monensin, lasalocid, salinomycin, narasin, maduramicin, and semduramicin are the major, approved ionophore antibiotics used in poultry. Accidental or intentional off-label use has resulted in adverse reactions in adult poultry (laying hens), ostriches, and ornamental or game birds. In addition, interactions with other drugs used in target and non-target species can occur (Dorne *et al.*, 2011).

Salinomycin toxicity in turkeys has been reported extensively. A case report describing the death of 4287 (34.5%) 19-week-old heavy hybrid turkey hens in a flock in Manitoba ascribed the mortality to the accidental feeding of a broiler premix containing salinomycin sodium at 60 ppm concentrations along with 50 ppm of bacitracin methylene disalicylate. Affected birds showed signs of dyspnea, drowsiness, sternal recumbency with legs extended posteriorly, inability to stand, stiffness, and weakness. Histological muscle sections revealed extensive fragmentation and necrosis of muscle fibers. Myocardial fibers were eosinophilic and undergoing fragmentation. No other lesions were found. Salinomycin toxicity increases with age in turkeys. In one study, when turkeys at 27 or 32 weeks of age were fed diets containing 44–66 ppm salinomycin, 13 of 20 birds died. In contrast, 7-week-old turkeys fed the same concentrations showed a mortality of only 1 of 84 (Potter *et al.*, 1986).

Another case report of monensin intoxication on a commercial ostrich farm in northern Greece described clinical signs in 7 adult birds from a flock of 24 African black breeding ostriches. A locally manufactured vitamin and mineral supplement was used to replace a previously used premix, leading to the development of clinical signs of depressed appetite, sternal recumbency, dehydration, dyspnea, and diarrhea. Monensin was detected at 3790 ppm in the supplement and at 190 ppm in the feed concentrate (Dedoussi *et al.*, 2007). Extremely elevated concentrations of serum aspartate aminotransferase, creatine kinase, and lactate dehydrogenase were suggested to be caused by acute muscle myopathy and, in addition to the clinical signs and age of birds, were utilized to differentiate the toxicosis from botulism, salt poisoning, mycotoxicoses, vitamin E–selenium deficiency, and toxic plant ingestion. There are no indications for the therapeutic use of ionophores in ostriches, and no data are available on the safe levels of inclusion of these drugs in ostrich feed.

Various antibiotics have been reported to potentiate ionophore toxicity (Novilla, 2007). The most frequently reported drug interaction is with the pleuromotilin derivative, tiamulin. This antibiotic interferes with the metabolic degradation of monensin in the liver, causing accumulation at toxic concentrations. In another study, concurrent administration of tiamulin with semduramicin was evaluated in grower broilers. A temporary growth depression and transiently reduced feed efficiency was observed during the third week of the trial in the group receiving both antibiotics

simultaneously. However, by the fourth and the fifth (final) week, no adverse effects were observed and the feed conversion was found to be improved. Histopathological and hematological parameters were unaffected at the end of the trial (Schuhmacher *et al.*, 2006).

## Drugs

A number of chemotherapeutic agents have caused intoxications in birds, primarily in poultry and pet birds. In most cases, intoxication results from inappropriate

or overuse of a drug. Table 67.2 lists chemotherapeutic agents associated with adverse effects in birds. Two drugs have been documented to intoxicate birds of prey as a result of feeding on carcasses from animals administered the drugs prior to death. Carcass residues of the nonsteroidal anti-inflammatory diclofenac have been shown to cause renal failure, visceral gout, and death in oriental white-backed vultures (*Gyps bengalensis*) and long-billed vultures (*G. indicus*) in the Indian subcontinent (Oaks *et al.*, 2004; Shultz *et al.*, 2004). Diclofenac has been a widely used veterinary drug in regions with affected birds. In the United States, use of pentobarbital for euthanasia

TABLE 67.2 Drug intoxications in birds

Drug	Effects	Clinical signs	Pathologic lesions	References
Sulfonamides	Blood dyscrasias, bone marrow depression, anemia, thrombocytopenia, lymphoid depression, impaired immune function	Depression, pallor, weight loss, decreased egg production and quality, icterus, depigmentation of brown eggs	Widespread hemorrhage; pale bone marrow; swollen, pale red, or icteric liver; splenic enlargement; ulcers at proventricular–gizzard junction	Reece <i>et al.</i> (1985), Daft <i>et al.</i> (1989), Brown and Julian (2003)
Nitrofurans	Furazolidone causes dose-related biventricular cardiomyopathy; chronic exposure can delay sexual maturity in male broiler breeder chickens	Depression, incoordination, ruffled feathers, growth retardation, hyperexcitability, tremors, loud vocalization, opisthotonus, aimless running, seizures	Dilation of ventricles of the heart, thinning of right or left ventricular wall, passive congestion with lung edema, liver congestion, ascites	Reece <i>et al.</i> (1985), Brown and Julian (2003)
Aminoglycosides	Lysosomal dysfunction in renal tubular epithelial cells leading to necrosis; impaired synthesis of protective vasodilatory renal prostaglandins	Gentamicin causes depression, edema, injection site hemorrhages, large pale nephritic kidneys, weakness, and apnea	Increased number of lysosomes containing myelin figures in renal tubule cells	Bird <i>et al.</i> (1983), Boothe (2001), Woolley <i>et al.</i> (2001), Brown and Julian (2003)
	Apoptosis in cochlear sensory hair cells	Ototoxicity Egg inoculation associated with embryo deaths	Renal tubular cell necrosis Degeneration of the apical portion of cochlear hair cells	
		Streptomycin and dihydrostreptomycin sulfate associated with respiratory distress, paresis, mild convulsions		
Nicarbazin	Increases metabolic rate and heat production; increases lipoprotein lipase activity; acts as a Ca <sup>2+</sup> ionophore	Poor eggshell pigmentation, decreased egg weight, decreased egg hatchability, growth depression, increased susceptibility to heat stress	No diagnostic lesions	Reece <i>et al.</i> (1985), Hughes <i>et al.</i> (1991), Brown and Julian (2003), Yoder <i>et al.</i> (2006)
Dimetridazole (other nitroimidazoles)	Possible free radical damage to DNA and other molecules	Growth depression, decreased egg production, incoordination, inability to fly, aimless running, vocalization, tremors, seizures	No diagnostic lesions	Riddell (1984), Brown and Julian (2003)
3,5-Dinitro- <i>o</i> -toluamide	Purkinje cell dysfunction	Ataxia, torticollis, reduced growth	Necrosis and depletion of Purkinje cells of the cerebellar cortex	Reece and Hooper (1984), Brown and Julian (2003)
Ivermectin (and other macrolide endectocides)	GABA agonist	Somnolence, listlessness, ataxia, bradypnea, mydriasis	No diagnostic lesions	Kim and Crichlow (1995), Brown and Julian (2003)

has resulted in secondary intoxication of raptors feeding on carcasses from euthanized animals (O'Rourke, 2002). Intoxication has occurred from scavenging carcasses not disposed of properly on farms or landfills.

## Pesticides

A tabulation of the toxicity of a number of pesticides for birds is provided in Table 67.3.

### Insecticides

#### *Organochlorine insecticides*

Historically, OCs were widely used from the 1940s to the 1970s in agriculture and forestry and for mosquito control. The most widely used organochlorines included the dichlorodiphenylethanes (DDT, methoxychlor, and dieldrin), cyclodienes (aldrin, dieldrin, heptachlor, chlordane, and endosulfan), and hexachlorocyclohexanes (lindane and benzene hexachloride). Although these insecticides are no longer used in the United States, Canada, and Europe, they continue to be used in developing countries. These compounds are highly lipophilic and, in general, have long environmental and body half-lives. Because of their lipophilic and persistent nature, they biomagnify within food webs. They were banned due to their environmental persistence, concern about their impact on human health and wildlife health, and widespread insect resistance.

#### *Cholinesterase inhibitors (organophosphorus and carbamate insecticides)*

Due to their more rapid breakdown in the environment, OP and carbamate insecticides replaced the OC pesticides as the latter were banned for use in North America and Europe in the 1960s and 1970s. A number of different formulations are available for use either in the environment (e.g., agricultural or residential use) or on animals (e.g., livestock dips or sprays). OPs and carbamates are formulated as liquids, granules, and powders. The more toxic insecticides of each group are generally restricted to agricultural uses, whereas less toxic members are approved for use on animals or in residential environments. Although chemically distinct, the OPs and carbamates have a common mechanism of toxic action, namely the inhibition of cholinesterase enzymes.

Possible exposure scenarios are numerous. Pet birds can be exposed via their diets, via home or premise use, or via direct application. Inhalation exposure is also possible from the use of dichlorvos-impregnated pest strips or premise spraying or fogging. Poultry and other production birds can be exposed in similar ways. There are relatively few documented reports of acute pet or

production bird intoxication from the use of OPs or carbamates. However, acute OP and carbamate intoxications are common in wild birds, and although the number of affected birds is difficult to assess, losses are significant. For example, at the height of use of granular formulations of the carbamate insecticide carbofuran, 17–91 million birds were estimated to have died annually (Mineau, 2005).

Exposure of wild birds to these insecticides can occur via ingestion of treated seeds or vegetation (accidental, intentional, or misuse of a product), poisoned insects or animals (impaired live animals or carcasses), product (especially granular formulations), or contaminated water (Friend and Franson, 1999). Inhalation or dermal exposure is also possible from spraying or spills. With avian wildlife, there can be some degree of seasonality to OP or carbamate intoxications as a result of season patterns of insecticide use.

The acute oral toxicity of individual OPs and carbamates varies considerably within each of their classes. For example, within the carbamate insecticide class, the acute oral LD<sub>50</sub>s for carbofuran and carbaryl in mallard ducks are 0.5 and 0.2 mg/kg BW, respectively (Friend and Franson, 1999). Also, acute oral toxicities of specific OP or carbamate insecticides vary considerably between species. The acute oral LD<sub>50</sub>s of ethion range from 45 mg/kg for blackbirds to 0.2 mg/kg for mallard ducks. A number of other factors can influence toxicity, including age, sex, diet, body condition, and product formulation.

Some OPs, including insecticides such as leptophos, mipafox, and cyanofenphos and industrial chemicals such as tri-*ortho*-cresyl-phosphate, cause a delayed neurotoxic effect referred to as OP-induced delayed neuropathy (OPIDN). OPIDN occurs as a result of inhibition of neurotoxic esterase, an enzyme found in peripheral nerves. OP insecticides are tested for their ability to cause OPIDN in adult hens as a result of their unique sensitivity to this effect. Also, pheasants and mallard ducklings are highly susceptible to delayed neurotoxicity (Brown and Julian, 2003). Most OPIDN-inducing insecticides are no longer on the market (Hill, 2003).

As previously mentioned, OPs and carbamates inhibit cholinesterase enzymes. Inhibition of acetylcholinesterase (AChE) is primarily responsible for the clinical signs associated with intoxication. Enzyme inhibition prevents the breakdown of ACh at the synapses and neuromuscular junctions. As a result, ACh overstimulates muscarinic and nicotinic receptors in the central and peripheral nervous systems. Clinical signs include convulsions, hyperexcitability, opisthotonus, lethargy, miosis or mydriasis, apparent blindness, ataxia, muscular weakness, tachypnea, dyspnea, emesis, defecation/diarrhea, piloerection, lacrimation, ptosis, and epistaxis (Friend and Franson, 1999). The onset of clinical signs and death

TABLE 67.3 Rodenticides, avicides, and molluscicides toxic for avian species

Rodenticides/ avicides/ molluscicides	Uses	Formulations	Avian toxicity	Mechanism of toxic action	Clinical signs	Species affected	References
4-Aminopyridine (Avitrol)	Control red-winged blackbirds, blackbirds, grackles, pigeons, sparrows	Powder concentrate; 0.5–3.0% grain baits; 3% cracked corn bait for agricultural use diluted to 0.03% with untreated grain; 1% whole corn diluted to 0.1% for crows; 0.5% bait for pigeons	Highly toxic for most species, including birds; LD <sub>50</sub> s for birds range from 1.4 to 8.1 mg/kg	Blocks potassium ion channels and increases release of ACh	Distress cries, aerial distress displays, seizures, coma	Potentially all birds	Bischoff <i>et al.</i> (2001), Schell (2004a,b)
Bromethalin	Rodenticide	0.01% tan or green grain- based pellets in 16- to 42.5-g place packs	Not determined	Uncouples oxidative phosphorylation	Not described in birds; clinical signs in mammals dependent on ingested dose, with CNS excitation noted with high doses and paralysis noted with lower doses	Potentially all birds	Dorman (2004)
3-Chloro- <i>p</i> -toluidine hydrochloride (Starlicide)	Control ravens, starlings, crows, pigeons, cowbirds, grackles, magpies, certain gull species	98% powder used to prepare baits; 0.1% ready-to-use product	Highly toxic for most species including birds; LD <sub>50</sub> s for birds of 1.8–3.8 mg/kg BW	Unknown	Decreased activity, tachypnea, dyspnea, renal failure	Potentially all birds	Schell (2004a,b)
Fluoroacetate (1080)	Rodenticide, coyote control	Use restricted to livestock protection collars (LPCs); LPCs for sheep and goats contain 30 mL at 1%	Oral LD <sub>50</sub> s for magpies are 1.78–2.3 mg/kg BW	Blocks tricarboxylic acid cycle resulting in cell energy depletion	Vary depending on species; not well described in birds; CNS, gastrointestinal, and cardiovascular signs likely; skeletal muscle necrosis reported in mallard ducks	Potentially all birds; proper use of LPCs appears to present little or no intoxication risk to avian scavengers	Burns and Connolly (1995), Ataria <i>et al.</i> (2000), Parton (2004)
Metaldehyde	Control slugs and snails	Pelleted baits, granules, liquids, or wettable powders containing 5% metaldehyde	Minimum lethal doses for chickens and ducks are 500 and 300 mg/kg BW, respectively	Decreases GABA in the brain; alterations of other brain neurotransmitters	Restlessness, anxiety, tachypnea, seizures, hyperthermia	Potentially all birds; secondary poisoning not reported	Talcott (2004a,b)
Strychnine	Controlling ground squirrels, meadow and deer mice, prairie dogs, porcupines, chipmunks, rabbits, pigeons	Colored grain-based baits with 0.5–1.0% strychnine sulfate	Reported oral LD <sub>50</sub> s for golden eagles, sage grouse, and pheasants are 5–10, 42.5, and 8.5–24.7 mg/kg, respectively	Blocks inhibitory actions of glycine of spinal cord anterior horn cells and inhibits neurotransmitter release from Renshaw cells	Nervousness, apprehension, anxiety, tachypnea, muscle spasms, stiffness, tonic extensor muscle contractions, death due to respiratory impairment Secondary toxicity reported	Potentially all birds	Redig <i>et al.</i> (1982), Wobeser and Blakley, (1987), Warnock and Schwarzbach (1995), Talcott (2004a,b)
Zinc phosphide	Used to control rats, mice, voles, ground squirrels, prairie dogs, nutrias, muskrats, rabbits, opossums, gophers Aluminum phosphide used as a fumigant	Grain-based bait, scrap bait, paste, or tracking powder; baits generally contain 0.5–2.0% zinc phosphide; paste up to 10%	Oral LD <sub>50</sub> s for wild birds and ducks reported to be 23.7– 37.5 mg/kg; oral LD <sub>50</sub> in chickens reported to be 25 mg/kg	Phosphene released from zinc or aluminum phosphide blocks cytochrome oxidase	Often found dead; dullness, tachypnea, dyspnea, tremors, paralysis, seizures, death  Secondary toxicity unlikely	Potentially all birds	Shivanandappa <i>et al.</i> (1979), Albretson (2004), Poppenga <i>et al.</i> (2005), Tiwary <i>et al.</i> (2005)

can be rapid; birds are often found dead. Death is most often due to respiratory failure and hypoxia. Gross and histopathologic lesions in dead birds are usually minimal and nonspecific. Gastrointestinal contents should be examined carefully because the presence of granules or dye may suggest pesticide exposure. Often, given the rapidity of death, there is freshly ingested food in the upper GI tract. OP inhibition of AChE activity can be irreversible, thus necessitating synthesis of new enzyme before recovery can occur. Carbamates do not irreversibly inhibit AChE, and spontaneous regeneration of enzyme activity is rapid. Clinical signs can persist for days in OP intoxicated animals, whereas recovery from carbamate intoxication is generally completed within 2 or 3 days.

A diagnosis of intoxication is dependent on measuring reduced activity of cholinesterase along with identification of a specific insecticide in suitable antemortem or postmortem samples. In birds, plasma is suitable for cholinesterase activity determinations. Brain cholinesterase activity can be measured in dead birds. Cortex is the preferred specimen for cholinesterase analysis. It is important to note that because carbamate inhibition of cholinesterase activity is readily reversible, even after death, care must be taken when interpreting laboratory results. In general, cholinesterase activity less than 50% of normal suggests significant exposure to an OP or carbamate (activity is often <20% of normal following lethal exposures) (Hill, 2003). Normal plasma/whole blood and brain cholinesterase activities are quite variable among bird species, and interpretation of cholinesterase activity should be based on species-specific and, when possible, laboratory-specific reference ranges. Reference ranges for cholinesterase activity in plasma and brain from a variety of bird species have been published (Westlake *et al.*, 1983; Hill, 1988). Gastrointestinal contents and liver samples should be submitted for detection of a specific insecticide to confirm exposure. Urine should be submitted for detection of major metabolites of OPs (Jain, 2006).

Otherwise sublethal exposure to OPs or carbamates can result in mortality as a result of a variety of effects: increased vulnerability to trauma or predation, reduced ability to regulate body temperature and therefore increased susceptibility to hypothermia, and reduced activity leading to decreased feeding and weight loss (Friend and Franson, 1999; Hill, 2003). In addition, birds can be indirectly affected by reduced availability of food as a result of prey die-offs.

Fortunately, the overall adverse impact of agricultural pesticide use in general, and OPs and carbamate use more specifically, on avian wildlife has lessened during approximately the past decade. This is due primarily to the replacement of older, more toxic insecticides with

newer, less toxic ones such as pyrethrins/pyrethroids and neonicotinoids (Mineau and Whiteside, 2006).

#### *Pyrethrins/pyrethroids*

Naturally occurring pyrethrin (derived from chrysanthemum flowers) and synthetic pyrethroid insecticides are currently estimated to make up more than 25% of insecticide use worldwide. Their popularity is due to their lack of environmental persistence and relatively low toxicity for birds and mammals (they are highly toxic for fish). They are used to control a variety of agricultural, home, and animal pests and are available in a large number of formulations, including sprays, dusts, dips, shampoos, spot-ons, foggers, ear tags, wettable powders, granules, soluble powders, and emulsifiable concentrates. They are often combined with synergists such as piperonyl butoxide to enhance their insecticidal activity.

Pyrethrins and pyrethroids have low toxicity for birds. For example, the acute oral LD<sub>50</sub> of cypermethrin for mallard ducks is greater than 4640 mg/kg, and the dietary LC<sub>50</sub> for mallard ducks and bobwhite quail is greater than 20,000 ppm (EXTOXNET; <http://extoxnet.orst.edu>). The 8-day LC<sub>50</sub> of deltamethrin for ducks and quail is greater than 4650 and greater than 10,000 mg/kg, respectively. Permethrin is practically nontoxic to birds, with acute oral LD<sub>50</sub>s for one permethrin formulation (Praxem) of greater than 9900, greater than 13,500, and greater than 15,500 mg/kg for mallard ducks, pheasants, and Japanese quail, respectively (EXTOXNET).

Pyrethrins and pyrethroids are neurotoxic as a result of their ability to alter sodium channels and cause repetitive nervous discharges or membrane depolarization. Clinical signs associated with acute intoxication are related to nervous system stimulation. There does not appear to be any adverse behavioral effects on avian wildlife following sublethal exposures to pyrethrins/pyrethroids, similar to those reported for OPs or carbamates, which would cause mortality due to increased predation or inability to obtain food. However, this possibility should be further investigated.

#### *Boric acid*

Boric acid is used in poultry litter to control darkling beetles (Brown and Julian, 2003). Recommended litter treatment concentrations are between 0.4 and 0.9 kg per 9.3 m<sup>2</sup> (Dufour *et al.*, 1992). Boric acid has a relatively high acute oral LD<sub>50</sub> for 1-day-old chickens of 2.95 g/kg BW (Sander *et al.*, 1991). Exposure of 1-day-old chicks to litter treated with up to 7.2 kg boric acid per 9.3 m<sup>2</sup> of litter for 15 days exhibited a dose-related feathering abnormality, but no effect on productivity and no lesions were noted. Exposure of poultry to litter treated with recommended amounts of boric acid is unlikely to be toxic.

### Nicotine

Nicotine sulfate has been used to paint chicken roosts to control mites and has been given orally for internal parasites (Brown and Julian, 2003). Nicotine is a highly toxic alkaloid that stimulates nicotinic receptors at neuromuscular junctions. Initial receptor stimulation is followed by a depolarizing blockade. Death is due to hypoxia as a result of paralysis of the diaphragm and chest muscles. Currently, nicotine use as an insecticide is not common. Perhaps of more concern is the passive exposure of pet birds to cigarette, cigar, or pipe smoke. Chronic ocular, dermatologic, and respiratory diseases in pet birds have been associated with tobacco smoke exposure (Dumonceaux and Harrison, 1999).

Neonicotinoids, a new class of insecticide, are also nicotinic receptor agonists. They are considered to have low toxicity for vertebrates because of relatively low affinity for vertebrate nicotinic receptors compared to insect nicotinic receptors (Tomizawa and Casida, 2005, 2011). Neonicotinoids include acetamiprid, clothianidin, dinotefuran, imidacloprid, nitenpyram, thiacloprid, and thiamethoxam.

### Rodenticides

#### Anticoagulants

Anticoagulant rodenticides are the most widely available and used rodenticides. Available avian toxicity information is most often expressed as a median lethal concentration (LC<sub>50</sub>) of anticoagulant included in feed over a defined period of time (Petterino and Paolo, 2001). There are few toxicity data available for species such as raptors that are likely to be exposed to the anticoagulants following ingestion of exposed and/or intoxicated prey.

There are almost no reported cases of anticoagulant rodenticide intoxication in poultry. There is one case report of coumatyral toxicity in chickens 1 week of age (Munger *et al.*, 1993). Exposure occurred as a result of contaminated wood-straw mats used to ship the birds. The low incidence of intoxication most likely reflects the relatively controlled environments associated with most commercial poultry production. Exposure is more likely in free-roaming poultry.

There are several documented cases of anticoagulant intoxication in captive wild birds, including waterfowl, raptors, and bird-of-paradise. Fortunately, most institutions housing wild birds recognize risks associated with anticoagulant rodenticide use and either use alternative rodenticides or take precautions to avoid exposure.

Exposure of wild birds to anticoagulants either via bait ingestion or through ingestion of exposed and/or intoxicated prey is a major concern. The long half-lives of second-generation anticoagulants result in intoxication risks associated with repeated exposures to relatively low

doses of the compounds. Avian species that feed primarily on small rodents are at greatest risk. Soon after the introduction of second-generation anticoagulants, the potential for secondary intoxication of raptor species such as owls was investigated (Mendenhall and Pank, 1980; Townsend *et al.*, 1981). Residues have been measured in a number of bird species. Although anticoagulant intoxication has been documented in a number of individual birds, population impacts are less clear.

Diagnosis of intoxication is dependent on antemortem and/or postmortem evidence of a coagulopathy and the detection of an anticoagulant in blood, serum, or liver samples. Merely finding a residue of an anticoagulant in an animal is not sufficient for a diagnosis of intoxication because residues are often found in the absence of a coagulopathy.

Vitamin K<sub>1</sub> is antidotal treatment, although there is some delay before coagulopathy resolves. Dosing regimens have not been well defined in avian species, but vitamin K<sub>1</sub> at 0.2–2.2 mg/kg given intramuscularly or subcutaneously every 4–8 h until the bird is stabilized has been recommended. Once stabilized, vitamin K<sub>1</sub> given at similar doses once daily for 2 weeks or longer is indicated.

#### Avicides

Avicides are marketed primarily to control pest bird species such as blackbirds, pigeons, and grackles. They are designed to be placed on grain for baiting in such a way as to only affect a few individuals in a flock. The clinical signs exhibited by affected birds (distress cries and aerial distress displays) are such that unaffected birds are scared away. Two commonly used avicides are 4-aminopyridine and 3-chloro-*p*-toluidine hydrochloride. A number of chemicals have been investigated for their ability to repel birds (Clark, 1998; Dolbeer *et al.*, 1998; Stevens and Clark, 1998). Repellants such as methyl anthranilate are generally not associated with lethal intoxication.

## METALS

### Lead

Occurrences of lead exposure and intoxication in birds continue to be detected worldwide (Fisher *et al.*, 2006), along with increasing awareness and regulation. These occurrences are commonly due to mining and industrial activities, contaminated waste disposal, paint stripping/flaking, persistent lead-containing ammunition, and various household and hobby-based objects containing significant amounts of lead.

Clinical signs consistent with lead intoxication are related to nervous, GI, hematopoietic, and renal systems. Various species-specific and habitat-linked factors of lead exposure are unique to birds. Often, birds consume lead shot or other lead objects mistaken as seed or grit. The curious nature of pet birds leads them to ingest shiny objects easily. Temporal and spatial patterns of lead intoxication in California condors coinciding with anthropogenic activities such as big game hunting have been recorded (Cade, 2007; Strom *et al.*, 2009).

The amount and form of lead ingested, dietary factors, size of ingested lead particles, and amount of grit in the ventriculus are some factors that influence absorption and subsequent intoxication. In some species of raptors, rapid removal of lead particles can take place by regurgitation from the proventriculus (Locke and Thomas, 1996). Information pertaining to toxic doses is available for a limited number of avian species, although the large number of variables that affect toxicity of lead makes generalizations difficult (Smith *et al.*, 2009).

Inorganic lead salts and organic forms are more bioavailable than elemental lead; however, the acidic environment in the proventriculus and ventriculus increases the solubility of elemental lead. Lead is actively transported across the GI tract through the same transport mechanism used for calcium absorption. Irrespective of its form, ingested lead is mostly excreted in the feces without being absorbed. Red blood cells contain a majority of the absorbed lead, with smaller amounts being bound to albumin or existing as free lead in plasma.

Signs of intoxication can be nonspecific and limited to regurgitation, anorexia, weakness, and weight loss (Puschner and Poppenga, 2009). Lethargy, wing droop, leg paresis, changes in phonation, head tilt, ataxia, blindness, circling, head tremors, and seizures are notable signs related to the nervous system dysfunction. GI signs include regurgitation and decreased motility of the upper GI tract (esophagus, proventriculus, and ventriculus) resulting in impaction and greenish diarrhea that stains feathers around the vent (Dumonceaux and Harrison, 1994). Anemia as a result of increased erythrocyte fragility and delayed maturation is observed in affected birds. Whole blood lead concentration does not always correlate with the severity of clinical signs.

Emaciation and hydropericardium were the major gross lesions in experimentally dosed bald eagles (*H. leucocephalus*) (Pattee *et al.*, 1981). Pale musculature or viscera consistent with anemia, renal or visceral gout, air sacculitis, muscle and fat atrophy, and splenomegaly have been reported in various avian species (Locke and Thomas, 1996). Bile stasis leading to an engorged gallbladder, dark-green viscous bile, bile-stained gastric and intestinal mucosa, and a greenish appearance to the liver have been reported in raptors (Locke and Thomas, 1996).

Measurement of whole blood lead concentration in live birds or in the liver and kidney of dead birds is employed for diagnosis and is widely available. A whole blood lead concentration of 0.20 ppm (20 µg/dL) or greater is considered to be consistent with lead exposure and/or intoxication. Because lead associates with red blood cells, serum and plasma are not appropriate for testing. Generally, 4 ppm wet weight or greater lead concentration in the avian liver and kidney is likely to be significant (Puschner and Poppenga, 2009). Radiographic identification of metallic objects in the GI tract is helpful, but their absence does not preclude lead exposure because the source may not be radio-dense (e.g., contaminated soil). Other biomarkers of lead exposure, such as aminolevulinic dehydratase activity, blood zinc protoporphyrin concentration, and free erythrocyte protoporphyrin concentration, are used but not widely available.

Multiple decontamination approaches have been utilized, including saline lavage, administration of size-appropriate pieces of grit to promote excretion, use of laxatives such as mineral oil or psyllium, and use of cathartics such as sodium sulfate. Endoscopy can be used to remove lead particles entrapped in proventricular or ventricular folds (Samour and Naldo, 2005). Various chelation therapies are employed for the treatment of lead intoxication. Several chelators can effectively bind lead, including CaNa<sub>2</sub>EDTA, succimer, D-penicillamine, and British anti-lewisite (BAL). Succimer and CaNa<sub>2</sub>EDTA are currently the chelators of choice, although no veterinary-approved forms are available. Symptomatic and supportive care including seizure control, fluid and electrolyte therapy for birds experiencing diarrhea, and vitamin supplementation may further aid in patient stabilization and therapy.

## Zinc

Galvanized cage wires and accessories, pennies minted after 1982, and contaminated soil, water, and feed are some of the documented sources of zinc associated with avian toxicosis (Reece *et al.*, 1986; Howard, 1992; Lloyd, 1992; Romagnano *et al.*, 1995; Puschner and Poppenga, 2009). In immature chickens and turkeys, dietary concentrations between 800 and 4000 ppm (mg/kg) of zinc oxide, sulfate, or carbonate have been correlated with reduced growth and muscular dystrophy (Sell *et al.*, 1994).

Zinc is absorbed in the proventriculus and small intestine. The exact uptake mechanism is unknown; however, it is a carrier-mediated step of facilitated diffusion and is not energy dependent (Menard and Cousins, 1983). Intestinal zinc absorption is affected by dietary concentrations and form of zinc, the presence of other minerals in the intestinal lumen, the availability of zinc

chelating agents in the diet, and the synthesis of zinc carrier molecule(s) in the mucosal cells of small intestine (Song, 1987). Post-absorption, zinc is distributed in the pancreas, liver, kidneys, bones, muscles, brain, retinas, intestinal mucosa, and skin, where it binds to metallothionein, especially in the pancreas, liver, kidneys, intestinal mucosa, and brain. Turnover and secretion of zinc by the pancreas, bile, and gastroduodenal secretions leads to its excretion in feces.

Specific mechanisms underlying the toxic effects of zinc are not established; however, the direct and indirect toxic effects of zinc are observed on the GI tract, liver, kidneys, pancreas, red blood cells, and brain. The consequences of high intracellular zinc concentrations lead to increased cellular reactive oxygen species production, reduced cellular ATP concentrations, and loss of mitochondrial membrane potential (Dineley *et al.*, 2003).

Zinc intoxication has been reported in several avian species. In experimentally inoculated cockatiels, 32 mg/week of pure zinc powder or galvanized coating removed from welded wire mesh was observed to cause severe illness and death within 2 weeks. In addition, a dose of 2 mg/week for 6 weeks induced chronic signs marked by dullness, weight loss, and intermittent excretion of greenish droppings (Howard, 1992).

In acute cases, neurologic signs, corrosive lesions in the GI tract leading to associated disturbances, and injury to the liver, kidneys, and pancreas may be observed. In chronic cases, erythrocyte abnormalities and anemia may be commonly observed, and these have been thought to be a result of oxidative damage to the erythrocyte hemoglobin and cell membrane proteins (Luttgen *et al.*, 1990). Clinically affected birds may exhibit signs of lethargy, anorexia, polyuria, polydipsia, hematuria, hematochezia, regurgitation, pallor, dark or bright green diarrhea, foul-smelling feces, paresis, seizures, and sudden death (Howard, 1992; Lloyd, 1992; Romagnano *et al.*, 1995; Christopher *et al.*, 2004). Various degrees of dehydration and caudal staining of the vent with fecal/urate containing material as a result of diarrhea have been noted in some cases. Neurological signs such as intermittent head bobbing and ataxia may occasionally be observed as well. In ducks with severe zinc-induced hemolysis, a functional iron deficiency may impair the effectiveness of the erythropoietic response and contribute to death (Christopher *et al.*, 2004).

Common findings on gross examination of birds that have died from zinc toxicosis include greenish, mucoid feces in the ileum, colon, or cloaca and muscle wasting, especially of the pectoral muscles. Occasionally, the liver or kidneys are slightly enlarged. No other consistent lesions are usually noted on gross examination. Microscopically, pancreas may reveal severe apoptosis, characterized by cell remnants appearing as acidophilic bodies containing pyknotic nuclei accompanied by a

loss of normal acinar architecture, necrotizing pancreatitis, the presence of hyaline bodies and other electron-dense debris, cellular atrophy and necrosis of individual acinar cells, and interstitial fibrosis (Wight and Dewar, 1986; Zdziarski *et al.*, 1994). Hemosiderosis in the liver, accompanied by hepatic biliary retention and multifocal, necrotizing hepatitis, may be observed (Howard, 1992; Puschner and Poppenga, 2009). Lesions in the kidneys include varying degrees of acute tubular necrosis, occasionally with secondary renal or visceral gout, and moderate interstitial nephritis in addition to nephrosis. GI lesions include intestinal hemorrhage, hemorrhagic enteritis, hemorrhagic ventriculitis, and ventricular koilin degeneration (Puschner *et al.*, 1999).

Diagnosis of zinc intoxication can be challenging. The patient history may hold clues to exposure (e.g., exposure to a new cage, feeding and/or watering utensils, or metallic toys). Clinical signs may not always be specific; therefore, a thorough clinical examination, construction of a relevant list of differentials, radiography, diagnostic sampling of the serum/plasma in live birds, blood smear evaluation, and collection of the liver and kidney in the case of dead birds are vital. The absence of radiographically evident metal densities in the GI tract does not rule out zinc toxicosis in the differential diagnosis because some particles might not be dense enough to appear. A necropsy with complete histologic evaluation should be performed on all birds that have died of a potential metal toxicosis. In live birds showing clinical signs suggestive of zinc poisoning, serum and plasma samples are considered suitable for zinc determination (Kosman and Henkin, 1979). For most laboratories, sample volumes of 50–100  $\mu$ L are sufficient for analysis. Special care must be taken to avoid contact with rubber products that can be a source of zinc (e.g., rubber-topped tubes) and hemolysis, which may also increase zinc concentrations. In addition, zinc concentrations in plasma collected from psittacines show significant diurnal variation, with the highest concentrations detected in morning samples (Rosenthal *et al.*, 2005). For most psittacines, a physiologic, nontoxic zinc concentration in serum or plasma is 2 ppm (0.2 mg/dL) or less. Cockatoos and eclectus parrots tend to have higher physiologic concentrations of zinc in serum and plasma, with acceptable nontoxic concentrations of up to 3.5 ppm (0.35 mg/dL) for cockatoos and up to 2.5 ppm (0.25 mg/dL) for eclectus parrots (Puschner *et al.*, 1999). An assessment of erythrocyte morphology can aid in the diagnosis of zinc poisoning in birds. Observed abnormalities include a greater number of immature red blood cells; hypochromasia; poikilocytosis; and nuclear abnormalities such as fusiform, elongated, and irregular nuclei (Christopher *et al.*, 2004). Postmortem determination of liver or kidney zinc concentrations is useful. Most companion birds have acceptable liver zinc concentrations of 30–70 ppm (mg/kg) wet weight (Puschner *et al.*,

1999), and liver zinc concentrations of up to 100 ppm (mg/kg) expressed as wet weight are considered non-toxic. Toxic concentrations of zinc in liver tissue typically exceed 100 ppm (Smith, 1995).

If a radio-dense zinc object is identified by radiography, adequate treatment options such as lavage, use of emollient laxatives or cathartics, endoscopy, or surgery can be utilized. Removal of the zinc source results in the rapid decline of body concentrations. If immediate removal is not possible or delays are expected, reducing the further absorption of zinc in the GI tract may be achieved by administering antacids such as calcium carbonate (Van der Merwe and Tawde, 2009). Complete removal of the source of zinc in a timely manner may not always be possible. Financial considerations, very small particles not amenable to endoscopic removal, and uncooperative patients with weak physiological status hindering anesthesia may all potentially decrease treatment options. Chelation of zinc is possible with  $\text{CaNa}_2\text{EDTA}$ , although its efficacy and safety in the treatment of zinc intoxication in birds have not been evaluated.

## Mercury

Natural (e.g., volcanoes or weathering rocks) and anthropogenic sources such as coal combustion or industrial activities contribute to mercury accumulation in the environment. Methylmercury (MeHg) presents the most significant risk for intoxication in birds, particularly wild piscivorous species. Methylation of inorganic mercury by aquatic anaerobic organisms leads to biomagnification by microbes and plankton and subsequent accumulation in fish, which in turn can then be a significant source of exposure for fish-eating birds such as loons, mergansers, and bald eagles. Consumption of MeHg-containing diets at environmentally realistic concentrations has been demonstrated to cause behavioral, neurological, hormonal, and reproductive changes in birds, fish, and mammals (Scheuhammer *et al.*, 2007). Interestingly, subtle vocalization changes in selected mercury-exposed avian species have been noted by the analysis of spectrographic bird-songs, including a lower diversity of note types and lower tonal frequencies than in songs of birds at control sites (Hallinger *et al.*, 2010).

MeHg is metabolized and excreted more slowly than other organomercurials (Stickel *et al.*, 1977). The lipophilic nature of MeHg allows it to penetrate the blood-brain barrier, where the majority of toxic effects are expressed. Clinical signs due to mercury intoxication are similar in multiple species of birds and are characterized by reduced food intake, weakness in wings and legs, with difficulty flying, walking, and standing (Borg *et al.*, 1970; Fimreite and Karstad, 1971). Affected birds are unable to coordinate muscle movements (Tejning,

1967). Appearance of these symptoms typically leads to death, even if the source of exposure is removed. Feeding MeHg-contaminated seed at 2 or 3 ppm for 12 weeks to adult breeding pheasants (*Phasianus colchicus*) produced a significant increase in the laying of shell-less eggs and a decrease in mean egg weight. Decreased hatchability due to early embryonic mortality and an increased number of unfertilized eggs were observed compared to controls. Mating behavior, egg production, and mortality were not affected, nor was any effect on food consumption or the nervous system observed. Unhatched eggs contained 0.5–1.5 ppm mercury, and the livers of experimental birds contained approximately 2 ppm mercury (Fimreite, 1971). Spinal cord degeneration due to MeHg toxicity has been noted in birds (Scheuhammer, 1987); however, there are considerable differences in sensitivity to toxic effects of MeHg. Concurrent administration/exposure to selenium may act to form stable, nontoxic mercury-selenium complexes, preventing the attachment of mercury with sulfhydryl groups of enzymes and other bioligands (Sugiura *et al.*, 1976), thereby acting as a modifying factor in the toxicity of MeHg. Mercury exposures that might otherwise produce toxic effects are therefore counteracted by selenium, particularly when Se:Hg molar ratios approach or exceed 1 in marine or freshwater fish (Ganter *et al.*, 1972; Luten *et al.*, 1980).

Kidney MeHg concentrations of 40 ppm and higher have been associated with mortality in a number of bird species (Finley *et al.*, 1979); however, elevated tissue concentrations without overt signs of toxicity have been observed in experimental birds. The diagnosis of mercury intoxication therefore should not be based on tissue concentrations of mercury alone and should necessarily address corresponding selenium concentrations, the presence or absence of compatible clinical signs and necropsy findings, and the absence of other infectious or noninfectious causes. Selected chelators such as dimercaprol (BAL) and D-penicillamine (Dumonceaux and Harrison, 1994) can be used in birds to chelate Hg. Selenium and vitamin E supplementation can additionally be utilized to reduce the toxic potential of mercury before the appearance of expected signs.

## Iron

An increasing incidence of hepatic iron storage disease has been recorded in captive birds during approximately the past four decades, particularly associated with frugivorous species of the families Paradisaeidae (birds-of-paradise), Ramphastidae (toucans), and Sturnidae (starlings) (Sheppard and Dierenfeld, 2002). Often described as hemosiderosis due to the deposition of a ferritin-containing iron complex (hemosiderin), these elevated iron stores in

the liver and other organs may sometimes lead to icterus, ascites, and accompanying liver pathology. However, non-symptomatic hemosiderosis has been reported as well (Taylor, 1984; Ward *et al.*, 1988; Borch-Johnsen *et al.*, 1991). Dietary factors affecting iron metabolism and/or genetically regulated increased iron uptake in sensitive species may lead to drastically increased iron concentrations in the liver, sometimes as high as 5517 mg/kg mean wet weight ( $N=22$ ,  $SD=3797$ ) in captive Paradisidae (Dierenfeld *et al.*, 1994). In captive birds, evolutionary physiological mechanisms compensating for low bioavailability of iron and the supplementation of iron in formulated diets may contribute to excessive storage (Sheppard and Dierenfeld, 2002). In addition, nutritional interactions in mixed diets and greater bioavailability of dietary iron further complicate the issue. Dietary iron requirements of many sensitive avian species are not known, which makes the formulation of a low-risk diet especially challenging. A study found a significant correlation between hepatic hemosiderosis with age and time in captivity, suggesting a careful revision of commercial diets for sensitive and endangered species in captivity (Pereira *et al.*, 2010).

Although hemosiderosis has been reported in Galliformes, iron storage disease has not been reported. Many commercial diets intended for captive birds have been formulated using the nutritional requirements of poultry. These do not take into account the primarily fruit- and insect-based low-iron-containing diet of other sensitive avian species. In addition, the mineral, carbohydrate, and sugar profiles, vitamin concentrations, polyphenolic contents, and the use of animal byproducts significantly affect the nutritional interactions and bioavailability of iron. Absorption of iron from animal byproducts (heme-based iron sources) may be three times higher than that from non-heme products containing equivalent iron concentrations. Thus, higher dietary iron concentrations, increased bioavailability, and absorption in sensitive species form the major etiological factors of iron storage disease. A diet containing 50–100 mg/kg iron on a dry matter basis has been recommended for sensitive avian species (Sheppard and Dierenfeld, 2002).

Increasing cellular iron concentrations leads to lysosomal injury and release of ionic iron, causing oxidative damage to membranes and proteins. Liver, heart, and spleen are most commonly affected (Randell *et al.*, 1981; Gosselin and Kramer, 1983; Kincaid and Stoskopf, 1987). Fibrotic changes in the liver affect its function, commonly leading to ascites, hypoalbuminemia, and icteric symptoms. Clinically, dyspnea, abdominal distension, weight loss, and depression are major signs. Radiographically, the enlargement of liver, heart, and spleen may often be observed. Hematology and serum biochemistry are reportedly of less value, although elevations in liver enzymes may be noted. Serum ferritin reference ranges are not available, although transferrin

concentrations have been used. Various inflammatory, infectious, hemolytic, and hepatic diseases may elevate ferritin concentrations. Serum iron and total iron binding capacity are poor indicators of body or liver iron stores. A liver biopsy is often needed to confirm iron storage disease antemortem.

Treatment for iron storage disease relies on multiple approaches. In valuable birds, chelation therapy using deferoxamine (100 mg/kg, q24h, subcutaneously) (Cornelissen *et al.*, 1995) can be utilized, along with low-iron-containing diets. CaEDTA and BAL will chelate iron as well. Although stressful, phlebotomy of affected birds will force the body to use stored iron. If sufficient damage has occurred to internal organs, these interventions may be of little therapeutic value. Prophylactically, intermittent feeding of very low iron-containing diet may be useful; however, caution has to be exercised not to induce iron-deficiency anemia in birds. The addition of natural chelators such as phytates, fiber, and tannins may be of value, and the addition of tea leaves has been experimentally found to be useful (Seibels *et al.*, 2003). However, questionable consistency of chelation and the potential of chelating multiple minerals in the diet make this approach somewhat risky, and it needs further investigation and refinement.

## Selenium

Although rare, avian selenium toxicosis typically manifests as decreased egg production and hatchability, reduced weight gain and feed efficiency, embryonic deformities, and death. Consumption of water from irrigation drains containing excess selenium by aquatic birds and accidental inclusion of excess selenium in feed have been reported to cause selenium intoxication in avian populations (Ohlendorf *et al.*, 1986).

The bioavailability and relative toxicity of selenium depend on its chemical form and solubility. Elemental selenium is far less soluble and toxic than the selenite and selenate forms. Organic selenium forms (e.g., selenomethionine) are more effective in raising tissue selenium concentrations than are the inorganic selenite or selenate salts; although selenite was found to depress growth performance in chicks more than selenomethionine fed at equal concentrations of 15 mg/kg BW (Lowry and Baker, 1989). In mallard ducklings, both D and L forms of purified selenomethionine were more toxic than selenized yeast (containing approximately 65% L-selenomethionine) (Heinz *et al.*, 1996). Many trace elements, including mercury, arsenic, antimony, bismuth, cadmium, silver, and tungsten, can affect selenium metabolism and toxicity (Rahim *et al.*, 1986; Sell *et al.*, 1994).

A detailed case report of selenium intoxication in breeding ring-necked pheasants describes 12% mortality in the

first week of feeding selenium-containing feed (9.3 mg/kg feed). Necropsy of dead birds revealed colorless fluid around the heart and friable livers. Histologically, degenerative cardiomyopathy, vacuolar degeneration of hepatocytes, and centrilobular hepatic necrosis were noted. Feed replacement returned egg production to normal in 10 days. Post-exposure, 10% of the chicks that hatched had deformed beaks and abnormal eyes. Fifty percent of all embryos that developed in eggs had deformities and died within shells. Another case report involving consumption of irrigation drain water by aquatic birds described heart defects, hydrocephaly, abnormal legs and wings, and size variations in the liver (Ohlendorf *et al.*, 1986). In controlled studies, mallards (*Anas platyrhynchos*) fed selenomethionine and increasing concentrations of sodium selenite developed comparable lesions as described previously. In addition, selenomethionine was concluded to be considerably more teratogenic and embryotoxic than sodium selenite, possibly due to higher uptake (Hoffman and Heinz, 1988).

## ENVIRONMENTAL TOXICANTS

### Pentachlorophenol

Pentachlorophenol (PCP) is used primarily as a wood preservative. Poultry have been exposed to sawdust and shavings from PCP-treated wood (Brown *et al.*, 1997). Adverse effects associated with PCP include reductions in growth rates, kidney hypertrophy, and decreased humoral immune response (Stedman *et al.*, 1980; Prescott *et al.*, 1982). PCP exposure can also result in an off-taste to eggs and meat as a result of degradation of chlorophenols to chloroanisols (Frank *et al.*, 1983).

### Petroleum

Exposure of avian wildlife to crude oil is a significant cause of morbidity and mortality. Although oil spills involving large tanker accidents such as the grounding of the *Exxon Valdez* in Alaska receive most of the public's attention, other scenarios related to oil drilling and production, off-loading of oil from tankers, production, processing, and refining of oil, road transport, and improper disposal of waste oil and petroleum products result in considerable wildlife exposure (Jessup and Leighton, 1996). Because oil floats on the surface of water, birds that live on water or dive through water for food are more likely to be exposed in water spills. Marine birds and bird species that utilize environments near to shore are also likely to be exposed to oil if spills reach shorelines. Raptors such as peregrine falcons that feed on

other birds can be exposed to oil from contaminated prey (Zuberogoitia *et al.*, 2006).

Crude oil and petroleum products are complex mixtures of chemicals, including a variety of aromatic and aliphatic compounds. The toxicity of crude oils and petroleum products varies depending on their chemical compositions. Another complicating factor in assessing the toxicity of crude oil is the fact that soon after environmental release, the process of "weathering" occurs, which changes its chemical and physical properties.

Crude oil and other petroleum products affect birds in several ways. First, loss of insulating properties of the feathers results in rapid hypothermia. Oiled birds lose their ability to fly, and they frequently die from starvation, exhaustion, or drowning (Friend and Franson, 1999). Second, crude oil and other petroleum products are irritating to skin, mucous membranes, and the respiratory tract. Aspiration of oil into the respiratory tract and lungs can cause aspiration pneumonia. Third, systemic absorption of chemicals found in crude oil or petroleum products causes adverse effects on several organ systems, including reproductive, hematopoietic, nervous, immune, and hepatobiliary systems. Lastly, petroleum is extremely toxic to bird embryos.

Diagnosing petroleum intoxication as a cause of death can be challenging. There are no characteristic gross or histopathologic lesions specific to petroleum intoxication. A diagnosis is based on a history or evidence of exposure and compatible clinical and postmortem findings. Exposed birds, especially those with white or light-colored feathers, are easily identified because of the persistence of oil on feathers and skin. Birds are often emaciated, oil may be present in the respiratory or GI tracts, there may be congestion along the intestines, and the salt glands may be swollen (Friend and Franson, 1999). Feathers, skin, or organs of birds that do not have external evidence of exposure can be analyzed for the presence of chemicals typically found in crude oil or petroleum products (Jessup and Leighton, 1996).

### Cyanide

Cyanide (hydrocyanic acid) is a rapidly acting cellular poison. Poisoning most often occurs following ingestion of a cyanide salt or inhalation of hydrogen cyanide gas. Avian wildlife intoxications have occurred following exposure to cyanide used in heap leach and carbon-in-pulp mill gold or silver mining processes (Friend and Franson, 1999). Birds are most often intoxicated by ingesting cyanide-contaminated water. Between 1986 and 1995, 3000 cyanide-related mortalities involving 75 species of birds were reported to the National Wildlife Health Center (Friend and Franson, 1999). Most mortality events occur in the spring and fall as migratory birds

pass through mining areas. Large-scale cyanide spills have caused widespread contamination of rivers in Europe and South America (Koenig, 2000).

Cyanide binds to ferric ( $\text{Fe}^{+3}$ ) iron of mitochondrial cytochrome oxidase. This enzyme mediates the transfer of electrons to molecular oxygen, which is the last step in oxidative phosphorylation (Delaney, 2001). Cells are unable to use oxygen, resulting in tissue anoxia, increased anaerobic metabolism, and rapid development of lactic acidosis.

The acute oral toxicity of sodium cyanide has been studied in several bird species.  $\text{LD}_{50}$ s ranged from 4.0 to 21 mg/kg BW (Wiemeyer *et al.*, 1986).

Cyanide is a rapidly acting toxicant; most intoxicated birds are found dead. Grossly, dead animals often have bright red blood and multiorgan congestion. A diagnosis is based on the history of exposure and measurement of cyanide in blood, heart, liver, or brain. Samples should be stored and shipped frozen to avoid the loss of cyanide before analysis. Denying birds access to cyanide-contaminated water is the best preventive approach.

## TOXIC GASES

### Ammonia

High ambient air concentrations of ammonia (50–75 ppm) reduce feed consumption, growth rate, and egg production in poultry (Deaton *et al.*, 1986). Ammonia readily dissolves in water to form ammonium hydroxide, which is an alkaline irritant. Thus, contact with the moist mucous membranes of the eyes and respiratory tract results in corneal and epithelial cell damage. Toxic air concentrations cause keratoconjunctivitis, corneal ulceration, blindness, photophobia, tracheitis, tachypnea, and dyspnea. Prolonged exposure can result in increased mucous secretion and hyperplasia of the bronchiolar and alveolar epithelium. Ambient ammonia air concentrations should be greater than 25 ppm for poultry (Brown and Julian, 2003).

### Carbon monoxide

CO is an odorless, colorless, lighter-than-air gas that can reach toxic concentrations as a result of incomplete combustion of hydrocarbon-based fuels. Toxic concentrations of CO most often result from use of defective gas catalytic or open-flame brooders and furnaces or internal combustion engines in poorly or unventilated spaces. CO acts by competing with oxygen for a number of proteins, including hemoglobin. The affinity of hemoglobin for CO is approximately 250 times greater than that for oxygen.

Formation of carboxyhemoglobin reduces the ability of red blood cells to carry oxygen, and the oxygen dissociation curve is shifted to the left, resulting in tissue hypoxia. Affected birds exhibit drowsiness, labored breathing, weakness, and ataxia, with seizures occurring before death (Brown and Julian, 2003). Birds may be found dead. Carboxyhemoglobin causes the blood to have a bright red appearance. Carboxyhemoglobin concentrations of 20% are associated with some motor impairment; death occurs when blood carboxyhemoglobin concentrations approach 60–70% (Osweiler *et al.*, 1985). Ambient CO concentrations of 600 ppm for 30 min cause clinical signs in chickens; concentrations of 2000 ppm or greater are lethal within 1.5–2 h (Brown and Julian, 2003). Sublethal exposure to CO in poultry causes stunting.

Diagnosis of CO intoxication is based on a history compatible with CO production, compatible clinical signs, and measurement of ambient air CO and blood carboxyhemoglobin concentrations. Treatment is generally limited to provision of fresh air or oxygen; pet birds can be placed in oxygen cages.

Other gases, such as hydrogen sulfide and carbon dioxide, generally do not present significant intoxication risks for birds. Interestingly, chickens are less sensitive to hydrogen sulfide than are humans or dogs (Brown *et al.*, 1997).

### Polytetrafluoroethylene: Teflon

Polytetrafluoroethylene (PTFE) is a synthetic polymer that is widely used as a nonstick surface in cookware. It is also used in self-cleaning ovens and as a coating on heat lamp bulbs. Heated to high temperatures ( $\geq 280^\circ\text{C}$ ), PTFE releases toxic pyrolysis products that can cause rapid death of birds. There are no reported toxicities associated with the proper use of coated cookware because temperatures do not reach levels at which pyrolysis occurs. However, cookware without contents can reach critical temperatures within minutes.

Although all birds are likely to be susceptible to intoxication, most spontaneous cases involve pet birds such as cockatiels, parrots, finches, and budgerigars (Blandford *et al.*, 1975; Wells, 1983; Stoltz *et al.*, 1992). There is one case report in which broiler chicks were intoxicated from heat lamp bulbs coated with PTFE (Boucher *et al.*, 2000) and another suspected intoxication of wild birds associated with industrial activity (Pennycott and Middleton, 1997). Quail have been exposed experimentally (Griffith *et al.*, 1973).

PTFE pyrolysis products contain particulates of respirable size ( $<1\ \mu\text{m}$  diameter) that can penetrate to the alveoli (Wells *et al.*, 1982). The particulates are themselves toxic, but they also serve as a vehicle for other potentially damaging chemicals, including hydrogen fluoride,

carbonyl fluoride, and perfluoroisobutylene (Wells and Slocombe, 1982). The fumes are acidic and cause direct damage to cell membranes of the lungs. However, it appears that the particles are necessary for intoxication to occur because the gas phase of PTFE fumes alone does not cause damage (Seidel *et al.*, 1991). Lung damage is believed to be due to direct irritation and oxidative damage (Wells *et al.*, 1982; Johnston *et al.*, 1996).

Precise toxicity information is not available. Exposure of budgerigars to PTFE pyrolysis products for 9 min or longer resulted in severe clinical signs, death, and significant pulmonary lesions in 31 of 32 birds (Wells *et al.*, 1982). Although there is little comparative toxicity information among avian species, budgerigars were more sensitive than quail in one experimental study (Griffith *et al.*, 1973).

After exposure, the onset of clinical signs is rapid. Eyelid blinking is an early sign and may be related to a direct irritant effect on the conjunctiva and cornea (Wells *et al.*, 1982). Eyelid movements could also be secondary to hypoxia-induced somnolence. Tachypnea, dyspnea, anxiety, cage wire biting, incoordination, and inability to stand may be due to hypoxia secondary to lung damage. In many cases, the bird may be found dead with no other clinical signs noted.

Grossly, the lungs are severely congested and hemorrhagic (Wells and Slocombe, 1982). Histologically, there is extensive, severe, necrotizing, and hemorrhagic pneumonitis. Amorphous, elongate particles may also be noted (Wells and Slocombe, 1982).

A diagnosis is generally based on a history of exposure and characteristic postmortem lesions. Currently, there is no analytical test available to confirm exposure to the pyrolysis products. The rapidity of onset of severe signs and subsequent death most often precludes treatment. Awareness of the hazard and avoiding housing birds near PTFE coatings is the best prevention.

## CONCLUDING REMARKS AND FUTURE DIRECTIONS

Given the number and diversity of avian species and their environments and the diversity of chemicals to which they are exposed, assessing the impact of toxicants on individuals and populations is a daunting task. Toxicants can have direct toxic effects or, more subtly, indirect effects on the availability of important prey items. In addition, birds are commonly exposed to toxicants that accumulate in their prey (e.g., mercury, lead, and anticoagulant rodenticides). Although the diagnosis of acute intoxication is frequently straightforward, the challenge in avian toxicology is twofold. First, it is

sometimes difficult to determine the sublethal impact of more chronic exposure to toxicants on bird health. For example, does exposure to methylmercury predispose susceptible birds to sublethal effects on reproduction or altered fledgling success? Second, although the impact of toxicant exposure on individuals might be easily determined, it is more difficult to assess whether individual effects translate into adverse effects on populations. There is no doubt that many raptor species are exposed to anticoagulant rodenticides. However, the population impacts of such exposures are largely unknown. Better defining the effects of chronic, low-level toxicant exposures and toxicant effects on the long-term stability of avian populations are future challenges.

# Aquatic toxicology

Robert W. Coppock and P.N. Nation

## INTRODUCTION

Aquaculture is the production of aquatic animals for human food. In aquaculture, aquatic animals are grown immersed in the aquatic environment. The water may be a sheltered oceanic bay containing pens of aquatic organisms, or the aquatic organisms may be raised in inland ponds or in a tank system. In colder climates, a recirculation tank system in a heated building may be used. The more contained the aquatic rearing system, the more diligent must be monitoring and control of the artificial ecosystem.

Intoxication of fish can be acute, subacute, or chronic. Chemical causes of disease in aquatic organisms are generally linked to ambient water and food because these are the primary pathways of toxic substances to animals in aquaculture systems. Chemical-linked food safety issues can occur if chemical contamination of edible aquatic organisms occurs. The toxicity of a specific substance can vary between fish species and can change with water temperature, water pH, and ion composition (Wlasow *et al.*, 2010). In recirculation systems, waste materials and microbial degradation products can reach toxic levels. The interactions between infectious diseases and chemically induced disease are complex (Morley, 2010). Chemical intoxication and other environmental stressors can increase the susceptibility of aquatic organisms to infectious diseases. The predisposing causes of infectious disease can be overlooked because they may be subtle or unrecognized. The toxicology of the water column can be different from that of the sediment, and these variations in the aquatic environment present different issues to various segments of the aquaculture industry (Rudolph *et al.*, 2009).

This chapter focuses on aquatic toxicology as it relates to the culture of fish. However, the principles and many of the specifics that are discussed apply to most aquatic organisms, cultured or not.

## BACKGROUND

Aquaculture is an expanding and continually developing industry. Fish are cultured in some form of confinement such as a pen, pond, or tank. Cultured fish are usually dependent on humans for part or all of their feed and can be entirely dependent on humans for maintenance of their ecosystem. Commercial feed is generally presented in a granular or pelleted form and contains a binding agent. Inland aquaculture often requires at least some mechanical management of the aquatic environment. Large capital investment and high operational costs are incentives to maximize stocking densities in aquaculture systems. Increased stocking densities increase the degree of sophistication required for water management. Upstream users can contaminate the source of water for aquaculture, as can floods and chemical spills that find their way into water bodies.

## WATER SAFETY

Water safety is a particular concern with large commercial rearing operations. Unsafe water kills more fish in

tanks and ponds than all other causes of disease. In the wild, fish generally seek water that meets their needs for pH, dissolved oxygen, and other necessities. Fish in confinement are unable to do this. Fish can also directly affect safety of the water in which they live, and their metabolic activity can move water parameters from safe to unsafe. Sensitivity to parameters affecting water safety in aquaculture varies with age of the fish and stage of development (Finn, 2007). The factors in water safety for both wild and captive-reared fish are interactive, and changing one parameter always affects other factors. The pH of water is important in affecting the solubility of metals (Finn, 2007). Lowering the pH generally decreases the bioavailability of metals by increasing complexes with organic matter in the water. Temperature of the water is important, and the ideal temperature can vary with life stage and genera.

## Nitrogen cycle

The nitrogen cycle in aquatic systems is important (Boyd and Tucker, 1998). An excellent review on the geobiochemistry of the nitrogen cycle has been written (Hargreaves, 1998). The nitrogen cycle transforms organic nitrogen, ammonia, and other forms of nitrogen to nitrogen gas. The most common ionic forms of nitrogen are ammonium ( $\text{NH}_4^+$ ), nitrite ( $\text{NO}_2^-$ ), and nitrate ( $\text{NO}_3^-$ ) (Camargo *et al.*, 2005). Sources of these ions are atmospheric deposition, presence in surface and groundwater, nitrogen fixation, and degradation of organic matter. Important sources of nitrogen in the aquatic system are feedstuff residues, feces, and ammonia excreted from aquatic animals. The nitrogen cycle in an aquatic system is primarily regulated by biota. The organisms regulating the different steps in the aquatic nitrogen cycle are remarkably independent, and the products from the different steps can accumulate in the system. Species of *Nitrosomonas* and *Nitrobacter* oxidize ammonia to nitrite. Following this, oxidation of  $\text{NO}_2^-$  to  $\text{NO}_3^-$  occurs, and species of *Nitrobacter* are the primary organisms that accomplish this. Species of *Nitrosomonas* and *Nitrobacter* are dissimilarly affected by oxygen tension, pH, temperature, etc. Species of *Nitrobacter* are the most sensitive, and when they are disadvantaged, the level of  $\text{NO}_2^-$  increases. The end step in the nitrogen cycle is reduction, with production of nitrogen gas ( $\text{N}_2$ ) released into the atmosphere. The most toxic compounds in the aquatic nitrogen cycle are ammonia and  $\text{NO}_2^-$ . Changes in the nitrogen cycle can also be seasonal and/or related to weather conditions. For example, nitrate poisoning (brown blood disease) in the southern United States is more common in the fall and spring (Durborow *et al.*, 1997). When the concentration of nitrite is less than  $1\text{ }\mu\text{mol}$ , the water is generally considered unpolluted (Jensen, 2003).

## Ammonia

The economics of tank-rearing of fish requires high stocking densities. Recirculation systems have densities as high as 0.3 kg of fish/kg of water. Estimated ammonia production by fish is 0.02 kg of ammonia nitrogen produced for each kilogram of feed fed (Masser *et al.*, 1999). Total ammonia nitrogen should be monitored in the aquatic system because ammonia is the primary nitrogen waste excreted by freshwater fish and is the most toxic form. At a given pH of the water, ammonia ( $\text{NH}_3$ ) is in equilibrium with  $\text{NH}_4^+$ . The unionized ammonia can radially diffuse across cell membranes. The toxicity of ammonia is dependent on the pH of the water, water temperature, and the species of aquatic animal. The best measurement to predict water safety is total ammonia nitrogen (TA-N), which is the sum of  $\text{NH}_3$  +  $\text{NH}_4^+$  forms. The pK of ammonia is approximately 9.2. At a pH of approximately 9.2,  $\text{NH}_3$  is in equilibrium with  $\text{NH}_4^+$  +  $\text{OH}^-$ . Lowering pH below the pK increases the concentration of ionized  $\text{NH}_4^+$ .

Fish excrete 40–60% of ingested nitrogen within 24 h (Ip and Chew, 2010). The liver is responsible for the majority of ammonia production. Most of the ammonia comes from catabolism of  $\alpha$ -amino acids that are channeled into gluconeogenesis and the citric acid cycle. Ammonia can be converted to less toxic forms, such as urea and uric acid, but requires energy. Most fish species excrete excess nitrogen from deamination of amino acids as ammonia (Wilkie, 2002). Magadi tilapia (*Tilapia grahami*) excrete excess nitrogen as urea by using the ornithine urea cycle. Fish metabolize excess purines through uricolysis and excrete the nitrogen as urea. The gills excrete ammonia down a concentration gradient. The excretion of ammonia varies between freshwater and saltwater fish, and the mechanisms are not well established. Saltwater fish are more sensitive to ammonia toxicity than are freshwater fish (Randall and Tsui, 2002). There is evidence that minimal energy is used in the ammonia secretion process and transporter proteins facilitate the diffusion process. Increasing pH of the ambient water decreases excretion of ammonia. Most of the ammonia in fish blood exists as ammonium ion because the pH of blood is approximately 2 pH units below the pK of ammonia (~9.5). Increased ammonium in fish increases glycolysis in cytosol and decreases the TCA cycle in the mitochondria. The ammonium ( $\text{NH}_4^+$ ) ion at high concentrations can substitute for  $\text{K}^+$  in ion transporters and disrupt electrochemical gradients. Physical activity, feeding, and stress due to increased cortisol levels increase blood ammonia (Randall and Tsui, 2002). Increased blood ammonia reduces physical activity. The mechanisms of ammonia toxicity in fish have not been elucidated. Amino acid metabolism is disrupted (Ariello *et al.*, 1984; Smutna *et al.*, 2002). There

appear to be metabolic dysfunctions in the liver and links to disruption of neurotransmitters and electrochemistry in skeletal muscle (Randall and Tsui, 2002). Increasing water ammonia decreases swimming ability (Wicks *et al.*, 2002). The decrease in swimming ability was linked to depolarization of white muscles, and increasing water calcium ions ameliorated ammonia toxicity. Feeding fish appears to provide some protection from ammonia toxicity (Wicks and Randall, 2002). Increasing ammonia in ambient water increases oxidative stress in the gills and disrupts ion transport (Ip and Chew, 2010). The chronic toxicity of ammonia at a pH of approximately 7.93 and  $\text{NH}_3$  concentrations of 0.0,  $0.215 \pm 0.03$ , and  $0.423 \pm 0.163$  ppm, respectively, was studied in rainbow trout (*Oncorhynchus mykiss*) fingerlings (Daoust and Ferguson, 1984). Increased blood ammonia can interfere with neurotransmitters. Clinical signs of intoxication were not observed in fish exposed to 0.0 and 0.215 ppm  $\text{NH}_3$ . The water was maintained at optimal oxygen level. In fish exposed to approximately 0.4 ppm  $\text{NH}_3$ , clinical signs of erratic swimming, lying on their sides on the bottom of the tank, and varying degrees of anorexia were observed. The clinical signs decreased with time, and by day 55 the only clinical sign observed was erratic and frantic swimming. Appetite improved across study days and compared to that of control fish was considered to be fair or good. No mortalities were observed, but fish with clinical signs were removed for pathologic examination. On study day 60, fish from the tank receiving the approximately 0.4 ppm  $\text{NH}_3$  treatment had increased numbers of acidophilic droplets in the proximal tubular epithelial cells. Other studies have reported changes in gill epithelium. Most fish species are considered to be resistant to blood ammonia-induced neuropathy (Ip and Chew, 2010).

Studies have been done on the toxicity of  $\text{NH}_3$  in Atlantic salmon (*Salmo salar*) (Knoph and Thorud, 1996). In a subacute study, fish weighing  $369 \pm 70$  g were exposed to  $\text{NH}_3\text{-N} + \text{NH}_4\text{-N}$  to give TA-N at 0.5 (control), 3, 22, 40, 112, and 255 ppb and 0.05–25.3 ppm TA-N. The exposure was done in a running seawater system maintained at 8 or 9°C, 33–35‰ salinity, pH 7.8 or 7.9, and 6.3–9.7 ppm  $\text{O}_2$ . Parameters monitored were plasma TA; urea, glucose, osmolality ( $\text{OM}_p$ ), and ion levels; and the hematology parameters hematocrit (Hct), erythrocyte osmotic fragility (EOF), red blood cell numbers (RBCN), and the mean corpuscular volume (MCV). These parameters were measured after 2 or 3 and 14 or 15 days of exposure. It was found that plasma TA increased linearly with the water TA-N levels, and plasma urea generally decreased with increasing water TA-N levels, except for fish at the 25.3 ppm TA-N. At the 25.3 ppm TA-N level, there were large increases in  $\text{OM}_p$ ,  $\text{Na}^+$ ,  $\text{Cl}^-$ ,  $\text{Mg}^{+2}$ , urea, and TA levels, whereas glucose and  $\text{Ca}^{+2}$  were moderately increased and Hct decreased. All fish were dead by

day 6. At the 22 ppb TA-N exposure level, glucose,  $\text{OM}_p$ , and plasma ion levels and Hct, RBCN, EOF, and MCV were not affected at day 15. The authors concluded that the NOEC of 2.40 ppm TA-N should be safe for Atlantic salmon. Another study showed that cortisol levels were increased by exposure to approximately 13 ppm TA-N (Knoph and Olsen, 1994). The effect of 6 weeks of elevated ambient TA-N in Nile tilapia (*Oreochromis niloticus*) was studied by Benli *et al.* (2008). The TA-N concentrations were background, 1, 2, 5, and 10 ppm TA-N. Fish exposed to elevated TA-N had histopathologic lesions in the gills consisting of hyperemia, chloride cell proliferation, fusion of the secondary lamellae, and telangiectasis. Cloudy swelling and hydropic degeneration were observed in the liver, and hyperemia and glomerulonephritis were observed in the kidney.

### Nitrite

Nitrite ( $\text{NO}_2^-$ ) has a physiological endogenous existence in fish as an oxidate metabolite of the gaseous messenger nitric oxide (Jensen and Hansen, 2011). The presence of nitrite in ambient water can be toxic to aquatic animals (Camargo *et al.*, 2005). Aquatic animals, especially freshwater fish and crustacea, are more at risk for  $\text{NO}_2^-$  poisoning than are terrestrial organisms (Boyd, 1982; Boyd and Tucker, 1998; Camargo *et al.*, 2005). Nitrite values for human water safety generally do not apply to aquatic organisms. Nitrite intoxication of aquatic animals can occur when conditions exist for imbalance in the nitrogen cycle. Freshwater fish are more susceptible to  $\text{NO}_2^-$  than are saltwater fish. In freshwater fish,  $\text{NO}_2^-$  is rapidly absorbed across the gills. The generally accepted mechanism for  $\text{NO}_2^-$  absorption is by competing for  $\text{Cl}^-$  uptake across the gills. The chloride ion is exchanged for bicarbonate ( $\text{HCO}_3^-$ ), and this exchange occurs in the apical part of the gill epithelial cell. Nitrite has affinity for the  $\text{Cl}^-/\text{HCO}_3^-$  exchange protein and replaces  $\text{Cl}^-$  in the exchange process. Increasing the water concentration of Cl reduces the toxicity of  $\text{NO}_2^-$ . Fish with high  $\text{Cl}^-$  uptake, such as rainbow trout, perch (family Percidae), and Northern pike (*Esox lucius*), are more susceptible to  $\text{NO}_2^-$ . Millimolar  $\text{NO}_2^-$  levels in such fish, especially if  $\text{Cl}^-$  in the water is low, can result from micromolar levels of  $\text{NO}_2^-$  exposure from water. Nitrite causes a net loss of  $\text{Cl}^-$  because there is a reduction in the influx of  $\text{Cl}^-$ , and it stimulates a net loss of potassium ions from muscle, causing an extracellular hyperkalemia and increased excretion of potassium. Nitrite also enters red blood cells and oxidizes  $\text{Fe}^{+2}$  to  $\text{Fe}^{+3}$ , forming methemoglobin (metHb) (Grabda *et al.*, 1974). The metHb cannot carry oxygen, and oxygen tensions in blood approach the values for dissolved oxygen in the water. The oxidation of iron changes oxygen affinity of hemoglobin (Hb). Changes in oxygen affinity and blood

pH increase movement of oxygen to the swim bladder, thus affecting buoyancy. The stress response in teleost (bony) fish is  $\text{NO}_2^-$ -mediated disruption of the  $\text{Na}^+/\text{H}^+$  exchange mechanism in the red blood cell. This can further decrease the affinity of Hb for oxygen. Decreased oxygen tensions increase anaerobic metabolism and acidosis occurs. Exposure of rainbow trout to 1 mmol  $\text{NO}_2^-$  causes vasodilation and an increased cardiac workload (Aggergaard and Jensen, 2001; Jensen and Agnisola, 2005). The fish died when the metHg was greater than 70% and plasma  $\text{NO}_2^-$  level was 2.9 mmol at the time of death. Liver cell damage linked to mitochondrial pathology occurs, and hepatic stores of glycogen are depleted. Necrosis of the retina can occur. Hepatocytes from rainbow trout have been shown to detoxify  $\text{NO}_2^-$  by converting  $\text{NO}_2^-$  to considerably less toxic nitrate ( $\text{NO}_3^-$ ) (Doblender and Lackner, 1996). Recovery from nitrite poisoning appears to take several weeks, and compensatory gain may or may not occur.

Species susceptibility to  $\text{NO}_2^-$  is variable and is linked to  $\text{Cl}^-$  uptake by the gills (Durborow *et al.*, 1997; Jensen, 2003). Largemouth (*Micropterus salmoides*) and smallmouth bass (*Micropterus dolomieu*), bluegill (*Lepomis macrochirus*), and green sunfish (*Lepomis cyanellus*) are resistant to high concentrations of  $\text{NO}_2^-$ . Catfish (order Siluriformes), goldfish (*Carassius auratus auratus*), fat-head minnows (*Pimephales promelas*), and tilapia (genus *Tilapia*) are sensitive to  $\text{NO}_2^-$ , whereas cold-water fish such as rainbow trout are highly sensitive to  $\text{NO}_2^-$ .

Nitrite poisoning (brown blood disease) can be prevented by adding  $\text{Cl}^-$  to the water (Durborow *et al.*, 1997). The most common option is to add  $\text{Cl}^-$  to the water to achieve a ratio of  $\text{Cl}^-$  to  $\text{NO}_2^-$  of 10:1. Decreased feeding rates and increased throughput of non-recycled water are alternative methods of controlling  $\text{NO}_2^-$ . Bacterial and parasitic disease increases the sensitivity of fish to  $\text{NO}_2^-$  poisoning. The presence of concurrent infectious disease requires increasing the concentration of ambient  $\text{Cl}^-$ . Catfish producers commonly maintain 100 ppm  $\text{Cl}^-$  in the pond or tank water as insurance against an increase in  $\text{NO}_2^-$  levels or to counteract the effects of concurrent infectious disease. Adult carp were exposed to 1 mM nitrite in ambient water for 48 h (Jensen *et al.*, 1987). Nitrite uptake and changes in blood respiratory properties, extracellular electrolyte composition, and acid-base status were examined. Nitrate in plasma increased to 5.4 mM within 48 h. Methemoglobin increased to 83% as plasma  $\text{NO}_2^{1-}$  increased, and arterial oxygen content decreased to very low values. Plasma  $\text{Cl}^{1-}$  decreased as plasma  $\text{NO}_2^{1-}$  increased.

### Nitrate

Chronic  $\text{NO}_3^-$  poisoning in rainbow trout was studied using 26.2 ppm  $\text{NO}_3^-$  and a static tank system (Grabda *et al.*, 1974). Fish were observed to gather around the

aeration system. Liver pathology was observed, and the hemopoietic centers were considered to be abnormal.

## Metals

### Copper

Copper (Cu) is an essential trace nutrient for fish. There are many sources of copper ions that can potentially enter aquaculture systems, including surface water. Runoff from lands receiving swine and poultry manure can be a source of Cu. Copper compounds are commonly used in aquaculture as an algicide and as a treatment for parasites. In freshwater aquatic systems, Cu exists in complexes with organic matter, complexed with other chemicals and weakly associated with water molecules (U.S. Environmental Protection Agency (USEPA), 2007). All of these factors can affect the bioavailability of Cu in ambient water. USEPA uses the biotic ligand model (BLM) to assess Cu toxicity. The model assumes that free Cu and Cu monohydroxide bind to a biotic ligand on the organism's surface. Death occurs when a critical amount of the total biotic ligand sites are attached to Cu. Water chemistry is used to predict the amount of Cu that will accumulate on/in the gill of a freshwater fish and estimates toxicity from a relationship between gill Cu accumulation and mortality (Grosell *et al.*, 2007). Multiple studies demonstrate that gill rapidly accumulates Cu following the onset of waterborne exposure, and the accumulation of Cu results in the disturbance of multiple physiological processes. The USEPA BLM does not consider differences in sensitivity due to size of the fish. There is evidence that variation in Cu toxicity between species is accounted for by differences in physiology.

The uptake of copper ions across the gill of fish is dependent on many parameters, including water hardness (levels of calcium and magnesium ions). There is generally a small margin of safety for many aquatic species for Cu ions. Cupric ions ( $\text{Cu}^{2+}$ ) disrupt the ATP-dependent sodium/potassium pump located in the gill chloride cells. This allows increased efflux of sodium ions. Cupric ions also replace calcium ions at the tight junctions, resulting in an efflux of sodium ions. The net loss of sodium ions results in disruption of osmoregulation and cardiovascular collapse. Copper ions are neurotoxic in fish, disrupting the olfactory and mechanosensory systems (Baldwin *et al.*, 2003; Linbo *et al.*, 2006). Peripheral olfactory function is inhibited at levels as low as 4  $\mu\text{g/L}$ , and loss of neuromasts occurs at concentrations greater than 20  $\mu\text{g/L}$ . Exposure to copper ions also decreases immune function. Copper levels can be difficult to interpret because pH, carbonate ions, and dissolved organic carbon are interactive in forming unavailable forms of copper, and  $\text{Mg}^{2+}$  and  $\text{Ca}^{2+}$

compete for copper uptake by the fish (Sciera *et al.*, 2004). Changes in these parameters can cause a 60-fold difference in the lethal toxicity of Cu. Changes in water salinity at the extremes increase Cu toxicity in fish (Grosell *et al.*, 2007). Decreasing the pH increases the toxicity, and a 100 times increase in toxicity can occur with each unit decrease in pH. Warm-water fish are more tolerant of copper than are cold-water fish. In a study of fathead minnows, increasing sodium chloride and calcium chloride levels in the water decreased copper toxicity, whereas increasing potassium chloride increased sensitivity to Cu (Erickson *et al.*, 1996).

## Chlorine

Water is not considered safe for fish if a measurable level of chlorine ( $\text{Cl}_2$ ) is present. Morbidity can occur at 0.02ppm chlorine and mortality at 0.04ppm (Hadfield *et al.*, 2007). Municipal tap water can contain chlorine at 2ppm. Chlorine, chloramines, and other chlorine compounds are used as disinfection agents in municipal water and in aquaculture to disinfect ponds and tanks (Boyd and Tucker, 1998). Chlorine gas added to water forms a number of compounds (hypochlorous acid, hydrochloric acid, and hypochlorite), with the concentration of dissociated ion depending on the pH of the water. Chloramine is also formed by the reaction of chlorine with ammonia in water. Chlorine dioxide is used as a water disinfection agent and is reduced to chlorite. Chlorine dioxide is approximately 16 times more toxic to fish than is chlorite (Svecevicius *et al.*, 2005). For rainbow trout, safe levels for chlorine dioxide appear to be approximately 0.2ppm and approximately 3ppm for chlorite. The toxicity of chlorine residues is variable due to effects of water temperature. Residual chlorine in the water is generally oxidative and causes irritation and damage to the gills. The acute gill lesion is necrosis of gill epithelium occurring at higher chlorine concentrations, whereas the subacute and chronic lesions are gill epithelial hypertrophy and hyperplasia. Gill lesions not only cause hypoxia but also affect the acid-base homeostasis of fish. In this regard, gill damage in fish is akin to a mammal suffering concurrent pneumonia and nephritis.

## FEED

### Mycotoxins

#### *Fumonisin and moniliformin*

Fumonisin (FBs) are primarily produced by *Fusarium verticillioides*, *Fusarium proliferatum*, and 11 other *Fusarium*

spp. (Coppock and Jacobsen, 2009). Of the FBs,  $\text{FB}_1$  is considered to be the most toxic. Fumonisin is structurally similar to sphingosine, and they inhibit ceramide synthase, an enzyme in the sphingolipid synthesis pathway. Moniliformin (MON) is produced by *F. proliferatum* and other *Fusarium* spp. (Jestoi, 2008). MON inhibits pyruvate dehydrogenase and possibly other mitochondrial enzymes.  $\text{FB}_1$  and MON have been shown to reduce the productivity of fish. Nile tilapia (*O. niloticus*) fingerlings were fed  $\text{FB}_1$  or MON at 0, 10, 40, 70, and 150ppm for 8 weeks (Tuan *et al.*, 2003). The  $\text{FB}_1$  and MON were extracted from cultures of *Fusarium moniliforme* and *F. proliferatum*, respectively. Mortalities in all treatment groups were low and were not dose related. Feeding diets containing 150ppm  $\text{FB}_1$  or MON decreased hematocrit. Both mycotoxins disrupted metabolism. There was evidence that sphingolipid metabolism was disrupted in fish fed  $\text{FB}_1$ . Feeding MON increased serum pyruvate. For fish fed MON, decreased weight gains were observed at the 70 and 150ppm levels, and for fish fed  $\text{FB}_1$ , decreased weight gains were observed at the 40, 70, and 150ppm levels. Fish fed 10ppm  $\text{FB}_1$  had decreased weight gains for the first 2 weeks, but body weights at 4 weeks were not significantly different from those of controls. Histopathology linked to treatments was not observed in the fish. Studies on the combination of  $\text{FB}_1$  and MON showed interactions between the two toxins (Yildirim *et al.*, 2000). Channel catfish (*Ictalurus punctatus*) are more sensitive to  $\text{FB}_1$  and MON than are tilapia, and  $\text{FB}_1$  is more toxic than MON in channel catfish. Yearling carp were fed rations containing 10 and 100ppm of added fumonisin  $\text{B}_1$  for 42 days (Petrinec *et al.*, 2004). Observed histopathology included increased rodlet cell numbers in and around damaged tissues, with many damaged blood vessels containing stacks of rodlet cells outside the endothelium. Scattered lesions were observed in the exocrine and endocrine pancreas and interrenal tissues. The subchronic toxicity of  $\text{FB}_1$  was studied in 120–140g carp (*Cyprinus carpio* L.) (Pepeljnjak *et al.*, 2003). A balanced fish diet provided a dose of 0.5 and 5.0mg  $\text{FB}_1$ /kg body weight for 42 days. Fish on the 5mg  $\text{FB}_1$ /kg dose lost body mass and had a higher incidence of erythrodermatitis cyprini (*Aeromonas salmonicida* subsp. *nova*). Treatment with  $\text{FB}_1$  increased erythrocyte and platelet numbers. Also increased were serum levels of creatinine, total bilirubin, and the activities of aspartate aminotransferase and alanine aminotransferase. The  $\text{FB}_1$  diets were not lethal to the fish, but the parameters studied indicate the kidney and liver as target organs.

#### *Aflatoxins*

Fish feeds can be contaminated with aflatoxins (AFs). Aflatoxins were identified in the early 1960s as causing hepatic cancer in fish (Sinnhuber and Wales, 1978).

Rainbow trout are sensitive to AFs, and dietary levels as low as 0.4ppb fed for less than 1 year cause hepatic cancer. Salmon (family Salmonidae) are more resistant than rainbow trout to the carcinogenic effects of AFs. Aflatoxin B<sub>1</sub> (AFB<sub>1</sub>) is metabolized by the P450 enzyme system in the liver of fish to form the AFB<sub>1</sub>-8,9-epoxide. The AFB<sub>1</sub>-8,9-epoxide forms adducts with DNA, RNA, and proteins. The formation of adducts is considered to be the primary mechanism of action for the carcinogenicity of AFB<sub>1</sub>. *In vitro* cultures of rainbow trout peripheral blood leukocytes incubated with AFB<sub>1</sub> showed the trout leukocytes to be 1000 times more sensitive than mouse leukocytes to AFB<sub>1</sub> (Ottinger and Kaattari, 1998). Exposure of trout embryos to AFB<sub>1</sub> causes long-term immunodysfunction (Ottinger and Kaattari, 2000). Fry are considered to be more sensitive than mature fish to AFs. Feeding a diet containing 500ppm AFB<sub>1</sub> altered immune parameters and decreased the native resistance to disease in India major carp (*Labeo rohita*) (Sahoo and Mukherjee, 2003). AFB<sub>1</sub> has been studied in tilapia (Nguyen Anh *et al.*, 2002). One-month-old tilapia fingerlings were fed diets containing 0, 0.25, 2.5, 10, or 100ppm AFB<sub>1</sub> for 8 weeks. Fish fed 10 and 100ppm AFB<sub>1</sub> consumed less feed and expelled the feed after ingestion, suggesting feed refusal. At 6 weeks of feeding, the survival rate for the fish fed the 100ppm level of AFB<sub>1</sub> was 55%. Weight gains for the fish fed the diets containing 2.5ppm AFB<sub>1</sub> or greater were decreased. Hematocrit was reduced in the fish fed diets 0.25ppm AFB<sub>1</sub> or greater. Fish fed diets containing 10 and 100ppm AFB<sub>1</sub> had liver lesions. Pleiomorphic liver nuclei were present in 86% of the fish fed the diet containing 10ppm AFB<sub>1</sub> and 100% of the fish fed the diet containing 100ppm AFB<sub>1</sub>. Catfish have a high resistance to the carcinogenic effects of AFB<sub>1</sub>, and this is linked to a low rate of formation of the AFB<sub>1</sub>-8,9-epoxide (Gallagher and Eaton, 1995). Dietary vitamin C was shown to provide protection against AFB<sub>1</sub>.

There are concerns that dietary AFs can cause residues of AFs in edible fish tissues. The toxicokinetics of AFs were studied in rainbow trout in a 21-day study (Nomura *et al.*, 2011). A rainbow trout diet had pure AFs added to give various levels of AFs as AFB<sub>1</sub>, AFB<sub>2</sub>, AFG<sub>1</sub>, and AFG<sub>2</sub>. The uptake factor for muscle was calculated by dividing the level of AF in muscle by the AF level in feed (AF muscle/AF feed). The uptake factors were  $0.70 \pm 0.08 \times 10^3$ ,  $0.48 \pm 0.04 \times 10^3$ ,  $0.39 \pm 0.08 \times 10^3$ , and  $0.67 \pm 0.08 \times 10^3$ , respectively, for AFB<sub>1</sub>, AFB<sub>2</sub>, AFG<sub>1</sub>, and AFG<sub>2</sub>. The levels of AFB<sub>1</sub> in liver were 165–342 times higher than those in muscle. Aflatoxicol (AFL) was identified as a major metabolite of AFB<sub>1</sub>, and in muscle the AFL levels were two orders of magnitude higher than those of AFM<sub>1</sub>. AFL and AFM<sub>1</sub> were detected in muscle and liver and also in the rearing water. The elimination rate constant ( $\alpha$ ) of AFB<sub>1</sub> was 1.83 and 1.38 per day for muscle and liver, respectively. The  $\alpha$  value for AFL in muscle was 2.02 per day, and that for liver was 2.41 per day.

The half-life ( $t_{1/2}$ ) of AFB<sub>1</sub> in muscle was approximately 9.1h, and the  $t_{1/2}$  in liver was 12.0h. The  $t_{1/2}$  of AFL was approximately 8.2h and approximately 7.0h in muscle and liver, respectively. This study shows that for fish consuming a diet containing approximately 500ppb and switched to a diet that does not contain AFB<sub>1</sub>, approximately 37h is required for AFB<sub>1</sub> to be cleared (<20ng AFB<sub>1</sub>/kg of muscle) from muscle tissue. This study also shows that AFs are not biomagnified in fish.

### Ochratoxins

Ochratoxins A (OTA), OTB, and OTC are primarily produced by *Aspergillus alutaceus* var. *alutaceus* (syn. *Aspergillus ochraceus*), *Penicillium verrucosum* (Dierckx), and *Penicillium verrucosum viridicatum* (Westling) (Jacobsen *et al.*, 2007; Coppock and Jacobsen, 2009). Other *Aspergillus* spp. and *Penicillium* spp. have been reported to produce ochratoxins. *Penicillium* species are the most important in temperate climates and *A. alutaceus* var. *alutaceus* in tropical climates. All of these fungi grow under storage conditions when in equilibrium with 80–85% moisture (~16 to 18% for starchy cereal grains) and temperature values as low as 10°C. Early studies of parenteral exposure of rainbow trout to ochratoxins showed that OTA was approximately 10 times more toxic than OTB. OTA extracted from cultures of *A. ochraceus* was added to channel catfish diets at 0, 0.5, 1.0, 2.0, 4.0, or 8.0ppm (Manning *et al.*, 2003). The average initial weight was 6g/fish. Decreased body weight gain was observed at 2 weeks and at 8 weeks in the catfish fed the diet containing 1.0ppm OTA. At 8 weeks, a decrease in body weight gain was observed for the catfish fed the 2, 4, and 8ppm diets. Hematocrit was decreased in the fish fed the 8ppm diet, and white blood cell numbers were not changed. At 8 weeks, there was 80% survival in the fish fed the diet containing 8ppm OTA. Histopathologic lesions were observed in fish fed the OTA diet at the 1, 2, 4, and 8ppm levels. The lesions were described as enlarged melanomacrophage centers replacing the hepatopancreatic cells and the presence of melanomacrophage centers in the posterior kidney. These findings suggest that the hepatopancreatic cells and the kidney are targets for OTA in catfish. Diets containing 400 and 600ppb ochratoxin were fed to Nile tilapia (*O. niloticus*) with approximately 55-g body weight (Shalaby, 2004). Ochratoxin caused a significant decrease in red blood cell numbers, Hb, and Hct. The activity of alanine aminotransferase in liver and muscle was increased.

## Contaminants in aquaculture fish

### Chlorinated dioxins

Aquaculture animals are a dietary source of polychlorinated dibenzodioxins (PCDDs), polychlorinated

dibenzofurans (PCDFs), and polychlorinated biphenyl (PCBs) compounds. Each of these groups is a mixture of compounds. These groups of compounds are collectively referred to as persistent organochlorines (POCs). Health concerns exist because these compounds are bioconcentrated in body fat of animals. These compounds are also transferred to the human fetus during pregnancy and excreted in breast milk during lactation. Dietary animal protein, fat and clays are the predominant source of the POCs for cultured fish. Catfish have been identified as an important source of PCDDs for persons consuming them, and in these individuals, this can exceed the dietary exposure from dairy products (Jensen and Bolger, 2001). In a study on the transfer of PCDDs and PCDFs from diet to muscle fat, it was found that in the first 13.5 months of feeding, approximately 30% of the dietary PCDDs and PCDFs in a diet fed to rainbow trout were transferred to fat located in muscle tissue (Karl *et al.*, 2003). At 19 months, the transfer rate increased slightly to approximately 34% for male trout and decreased to approximately 27% for egg-laying female trout. A congener-specific pattern of PCDDs and PCDFs accumulation in the fish was not identified. The concentrations of PCDDs and PCDFs in diet were directly related to the concentrations of PCDDs and PCDFs in muscle fat. The levels of PCDDs and PCDFs in muscle fat increased during the 19-month feeding period.

### Methylmercury

Methylmercury (meHg) is a concern with regard to human foods from aquatic sources. The primary source of meHg in aquaculture is the use of fish byproducts in feedstuffs. Methylmercury is formed by biota in the benthic region of the aquatic system, and it is biomagnified in the food web. In fish, meHg has affinity for skeletal muscle and is bioaccumulated in skeletal muscle (Berntssen *et al.*, 2004). Approximately 23% of the dietary meHg and approximately 6% of dietary inorganic mercury (Hg) are absorbed by fish. Fish fed diets containing 5 and 10 ppm meHg for 4 months had 1.1 and 3.1 ppm of meHg in muscle (freeze-dried), respectively. The threshold toxic level for Atlantic salmon is estimated at 0.5 ppm meHg in diet. Studies in fathead minnows showed that the threshold level of dietary meHg on spawning parameters is less than 0.88 ppm (Hammerschmidt *et al.*, 2002).

## TOXICOLOGY INVESTIGATIONS

The triggers for a toxicological investigation generally are either increased mortality or decreased performance in reproduction, feed conversion, and growth. Food safety issues can also be another trigger. It is

important to document both when the toxicological incident occurred and any concurrent environmental events, changes in management, etc. Review of records can be helpful to determine when the incident started, and records/printouts from equipment monitoring water parameters are very important in this process. A complete history is important to direct the diagnostic procedures and analytical toxicology. The following are important questions to ask:

- Was the incident an acute event or did it occur over a period of time?
- What are the size, age, and location of the fish that are affected?
- Were clinical signs observed?
- Can the onset be linked to changes in feed sources, shipments of feed or feed ingredients, or a particular feed storage area?
- Are there links to changes in water handling, filtering, interruptions in electrical power, or a rainfall event?
- Are there links to ambient water temperature?
- Pesticide use and location of use?
- Use of drugs?
- Did deaths or disease also occur in terrestrial animals?
- Is the death of aquatic animals linked to a die-off of aquatic plants and phytoplankton?
- Previous land use in the area where the ponds have been constructed?
- Are pathology, analytical toxicology and feed ingredients data available?

The time of day that mortalities occur is important. These can be linked to changes in water temperature and a decrease in dissolved oxygen. Sporadic mortality is more likely to be related to parasites or changes within the tank and pond system. As a general rule, small fish are more resistant to low dissolved oxygen and are less resistant to chemical substances.

## CONCLUDING REMARKS AND FUTURE DIRECTIONS

Toxic substances and toxins generally enter fish aquaculture systems via the feed, from runoff or other liquid contamination of the water in which the fish are kept, or develop from the chemical dynamics of substances that are naturally in the water column. Fish may exacerbate the latter by their excretion products and sheer biomass in aquaculture systems. The toxicological security of fish stocks requires effective quality assurance and quality control programs in two main areas. Manufacturers and suppliers of feedstuffs to the aquaculture industry

can play a major role by ensuring that toxic substances and toxins do not enter the food chain. The operators of fish culture facilities control the aquatic environment, at least for pond- and tank-reared fish, and therefore have the main role in monitoring water for levels of toxic substances and ensuring that natural drainage of surface water does not introduce toxic substances into the aquaculture system.

Multiple uses of increasingly limited water resources present challenges of access to the aquaculture industry. Securing the quality of incoming water supplies in the face of multiple other uses for water and requirements to return the water to the environment in pristine condition will be ongoing concerns for the industry. High capital investment and operating costs also constitute constant challenges. Increased use of and research into recirculating systems will pose significant future research challenges.

The culture of aquatic organisms for food, environmental reconstitution, and a variety of other purposes becomes more common and more important year by year. This trend will continue into the foreseeable future. Toxicity due to factors inherent to the culture of large biomasses of fish in relatively small volumes of water or introduced through feed or water poses a threat not only to the fish but also to the humans or animals that consume those fish or fish products. Dietary adequacy and feed safety can be issues in aquaculture. Food safety related to fish products will become a greater societal issue in the future.

An emerging area of aquatic toxicology will be related to complex systems using fish, other aquatic organisms, and plant communities to clean sewage, waste, and other degraded water sources in environmental restoration systems. Such future toxicological challenges will not only include disturbances of well-known water parameters as described previously but also likely extend to complex sulfur/sulfate/sulfide toxicities and organic acid toxicities, among others.

# Toxicology and diversity of marine toxins

Aurelia Tubaro, Silvio Sosa and James Hungerford

## INTRODUCTION

Marine toxins are a structurally and toxicologically diverse group of compounds with potent biological activity. Like the mycotoxins, marine toxins are non-proteinaceous, are heat stable, and many are smaller than 1000 Da. With the exception of the tetrodotoxins with their bacterial origins, marine toxins are secondary metabolites of microalgae and often referred to as phycotoxins. The role of these secondary metabolites is not completely clear, but chemical defense is among their prominent hypothesized functions. The unicellular algae producing the toxins are themselves a diverse group, ranging from dinoflagellates to diatoms and even cyanobacteria. Dinoflagellates produce the majority of marine toxins. Remarkably, these microorganisms are unusual in having large genomes, some of which are 100 times larger than the human genome (Lin, 2006), which complicates use of modern genetic approaches in some marine toxin biosynthesis studies (Kalaitzis *et al.*, 2010). Only since 1987 have diatoms been known to produce marine toxins, and even then, production is restricted to the genus *Pseudonitzschia*. Marine cyanotoxins show considerable diversity (Golubic *et al.*, 2010), and some are neurotoxic (Araoz *et al.*, 2010). The vast majority of cyanotoxin-implicated poisonings involve terrestrial cyanobacteria, which are discussed elsewhere in this book.

Most, but not all, of the marine toxins exert their toxic effects by disrupting the nervous system. Other marine toxins impact protein phosphorylation or other critical processes. Their relative toxicities also vary considerably. Among the neurotoxins, there is again considerable diversity, with many of them binding to the

voltage-gated sodium channel (VGSC) and others binding to excitatory amino acid receptors and disrupting synaptic transmission. By far, those causing the greatest numbers of illnesses and some deaths share the common trait of binding to receptors of the VGSC to disrupt neurological function.

The impact of marine toxins on marine wildlife and humans is significant. Marine toxins are responsible for avian poisonings; massive fish kills; birth morbidity and mortality; and sanitary, ecological, and economic problems. Marine mammals are also impacted by marine toxins, including many fatalities, and an important and global ecological role for marine toxins in their health and survival has been suggested (Trainer and Baden, 1999). Most of the known marine toxins are a threat to human health and, especially among the marine neurotoxins, some can be fatal (Van Dolah, 2000). However, the marine toxins discussed here are not venoms: they are accumulated from the environment rather than being produced by a specialized toxin-producing gland. Poisonings of humans and other animals result from consumption of contaminated food at some level of marine food webs (Isbister and Kiernan, 2005). Although certain marine toxins can contaminate finfish, predominantly it is molluscan shellfish, due to their filter feeding on toxic algae, that are the target of the most extensive monitoring efforts. In the United States, this includes coastal harvest areas managed by the shellfish-producing states (Hungerford and Wekell, 1993) and offshore federal resources (Etheridge, 2010). In Europe, there are many shellfish-producing countries, with the Galicia region (Spain) comprising the greatest percentage among producers, and methodologies and regulation are the realm of the EU Reference Laboratory on Marine

Biotoxins and the European Community's DG-SANCO, respectively. Shellfish contaminated by algal toxins, when not properly monitored, can cause severe and life-threatening human poisonings. Shellfish poisonings account for 7.4% of marine intoxications in the United States (Isbister and Kiernan, 2005). All of these reported shellfish poisonings were due to recreational harvest, underscoring the effectiveness of monitoring and the safety of commercial shellfish product in the United States.

Regardless of the specific mechanism of toxicity, many of the marine toxins present the same limitations and challenges in both toxicological studies and in their management. Specifically, it is the very limited availability, particularly of large quantities of highly purified toxins needed for toxicological studies that has hampered and sometimes halted many research efforts addressing these and other algal toxins. Indeed, many of the toxins are not commercially available in any quantity. In many toxicological studies, a reduced number of animals are used, and sometimes, to maximize the toxicological effects of the test material, parenteral routes of administration are used. On the contrary, very few studies have examined the effects after oral intake, the usual exposure route. This chapter focuses on the toxicology of the most dangerous marine toxins for humans. The major clinical poisonings due to the consumption of fish and shellfish are also covered.

For the past few decades, detailed structural knowledge of the marine toxins, once obscured by the use of mouse bioassays in their detection, has been growing rapidly. Much of the recent progress seen in marine toxin research concerns the multiplicity of toxin profiles within each toxin class. Due to increasing use of chemical detection methods, variations in marine toxin profiles, regional variations among toxic algae, and variations between vector species such as fish and shellfish have been known since the 1980s. Increasing use of liquid chromatography–tandem mass spectrometry (LC-MS/MS) analysis and certain *in vitro* tools, as well as improving commercial availability of a greater variety of toxin congeners, has greatly expanded our knowledge of the toxins. Extensive metabolism and other biotransformations of the marine toxins as they pass through various trophic levels are becoming a familiar theme as a result of these new studies. Most important, a more detailed understanding of the fate of the toxins is in turn supporting a more informed approach to updating detection methods used in monitoring. Considerable progress is now being made in the development, validation, and application of new methods for use in the monitoring of seafood contamination by marine toxins. This is resulting in the gradual replacement of outdated and unspecific mouse bioassays with modern analytical methods. These advances, along with the discovery of

new metabolites (and appreciation for their importance in our understanding and management of the toxins), are described in this chapter.

## SAXITOXINS

Saxitoxins (STXs), a family of hydrophilic toxins based on the parent STX, were discovered in the past century and can contaminate seafood and drinking water. The name of this toxin group is derived from *Saxidomus giganteus*, the clam from which it was purified for the first time. The ingestion of STXs-contaminated seafood provokes a paralytic syndrome known as paralytic shellfish poisoning (PSP), one of the most common and dangerous forms of shellfish poisoning. Although PSP cannot be classified as a major public health problem due to its relatively low incidence rate, it is of considerable concern because a fatal dose for humans can be obtained eating a single highly contaminated shellfish. There is no available antidote, although supportive treatment, if done promptly, is generally sufficient for this potent but reversibly binding group of toxins. Furthermore, STX is the only marine natural product that is a declared chemical weapon (Llewellyn, 2006).

### Background

Victims of PSP can develop symptoms within 5–30 min after contaminated shellfish consumption. The first effect is typically paraesthesia, with burning or tingling of the tongue and lips, which spreads to the face, neck, fingers, and toes. In more severe cases, this is followed by a feeling of numbness in fingertips and toes, which progresses to the arms, legs, and neck within 4–6 h. Death is usually caused by respiratory paralysis, and without mechanical respiratory support, the fatality rate is 5–10%. There is a good prognosis for individuals surviving beyond 12 h, although muscular weakness can persist following recovery. Other minor anecdotal symptoms reported are a feeling of dizziness or “floating” (due to distortion of sensation and proprioception), generalized paraesthesia, arm and leg weakness, and ataxia. Headache, nausea, and vomiting can also occur in the initial phase of the poisoning. Reflexes may be normal or absent, and patients may remain conscious and alert throughout the poisoning. In patients with mild to moderate poisoning, the symptoms resolve in 2 or 3 days, but in more severe cases, weakness may persist for 1 week (Isbister and Kiernan, 2005; Llewellyn, 2006).

PSP diagnosis is based on characteristic neurological clinical signs and on a history of recent ingestion of

seafood (most often bivalve shellfish, hence the term PSP). The symptoms of PSP are difficult to differentiate from those of tetrodotoxin poisoning, due to the (pharmacological) similarities of the toxins.

The toxins responsible for PSP, STX, and its derivatives, including gonyautoxins (GTXs), are water-soluble, heat-stable, tetrahydropurine compounds that are among the most potent known neurotoxins. The chemical structure of STX is represented by two guanidinium moieties joined in a stable azaketall linkage (Figure 69.1). More than 30 natural STX analogs, which vary mainly by different combinations of hydroxyl and sulfate substitutions at four sites on the molecule as well as by forming epimeric pairs via ring opening and closure, have been isolated to date. STXs can be divided into four groups based on substitution at R<sub>4</sub>: the carbamate toxins, the sulfocarbamoyl toxins, the decarbamoyl toxins, and the deoxydecarbamoyl toxins. The guanidinium group at positions C-7, C-8, and C-9 and the hydroxyl group at C-12 are essential for binding of STXs to Na<sup>+</sup> channels; the substitution at R<sub>4</sub> leads to substantial changes in toxicity, with the carbamate toxins being the most potent group (Ciminiello and Fattorusso, 2004; Isbister and Kiernan, 2005).

The toxins are produced by marine dinoflagellates, including *Alexandrium* ssp., *Pyrodinium bahamense* var. *compressum*, and *Gymnodinium catenatum*. Shellfish accumulate the toxins by filter feeding the toxic microalgae. PSP toxins have also been identified in freshwater blue-green algae (cyanobacteria) species, but no human poisoning has been reported. Also, red algae of the genus *Jania* were reported to produce STX. Controversial is the production of STXs by a symbiotic bacteria isolated from *Alexandrium tamarense* (Isbister and Kiernan, 2005; Llewellyn, 2006).

Shellfish contamination by STXs is a global concern, being endemic in northwest America. PSP cases have also occurred in Chile, Taiwan, Japan, South Africa, Australia, India, England, Guatemala, Costa Rica, Singapore, Canada, Spain, and Mexico (Gessner, 2000; Llewellyn, 2006). STXs are concentrated by bivalve shellfish such as clams, oysters, mussels, and scallops but also by crabs, puffer fish, gastropods, and cephalopods. Shellfish contamination can persist for a long time after exposure to the toxic microalgae, although in most cases, bivalves clear the toxin quickly enough to allow later reopening of harvest areas. Although PSP is widely distributed, crustacean-induced PSP seems to be concentrated in the tropics, where predator crabs of the Xanthidae family are often contaminated by paralytic toxins and have caused human deaths. In recent years in Florida, puffer fish thought to be *Sphoeroides nephelus* provoked the poisoning of more than 12 people due to the presence of large amounts of PSP toxins (Llewellyn, 2006). The occurrence of STX as the major toxin in

Toxin	R1	R2	R3	R4

another puffer fish (*Arothron firmamentum*) has also been reported (Nakashima *et al.*, 2004).

The STXs have also been implicated in the deaths of humpback whales feeding on STX-laden mackerel, with the further suggestion that the whales' diving adaptation and other physiological factors increase their susceptibility to STXs (Geraci *et al.*, 1989). STX can also be taken in directly through the gills of Atlantic salmon (Bakke and Horsberg, 2010), and the elimination half-life following intraperitoneal (i.p.) injection is 102 min. Monk seal mortalities have also been blamed on exposure to the STXs (Reyero *et al.*, 1999).

### Pharmacokinetics/toxicokinetics

Although the mechanism of action of STXs is well established at the molecular level, little is known about their absorption, distribution, biotransformation, and

elimination. The charged nature of STXs makes these molecules poor candidates for oral availability, but their uptake from the gut occurs within minutes from ingestion, and no toxin is eliminated in the feces of test animals (Llewellyn, 2006). Studies in animals and evidence from PSP poisonings in humans revealed that STXs are eliminated mainly through the urine (Stafford and Hines, 1995; Gessner *et al.*, 1997; Andrinolo *et al.*, 1999, 2002). The half-life of urinary elimination of a sublethal dose of STX in rats (2 µg/kg, i.v.) is approximately 90 min (Stafford and Hines, 1995). Urinary elimination of STX was also demonstrated in cats: after i.v. injection of 2.7 or 10 µg/kg STX, excretion involved glomerular filtration, which dropped to low levels at the highest dose due to STX hypotensive effect. The study also showed the presence of the toxin in liver, spleen, and brain (Andrinolo *et al.*, 1999). By oral route in cats, GTX 2/3 epimers (70 µg/kg) were completely absorbed at the intestinal level and, similarly to STX, the excretion involved glomerular filtration (Andrinolo *et al.*, 2002).

Metabolic transformation of paralytic shellfish toxins by mammals has been little studied. Serum and urine of poisoned humans revealed the occurrence of GTX2 sulfation, which is in contrast with the findings in rats, in which no metabolism of STX occurs during passage in urine. In another case report, STX was found mainly in the gut contents, whereas the urine contained only 50% STX, with neoSTX and dcSTX becoming quite prominent (Llewellyn, 2006). The marked difference between the toxin compositions in the ingested mussels and in human sera, as well as the similar toxin profile between sera and urine samples, suggests that PSP toxins are metabolized at gastrointestinal and/or hepatic levels (Gessner *et al.*, 1997). It has to be considered that the transformations of the PSP toxins in mammals can be the consequence of both biochemical metabolism and the conditions to which the toxins are exposed, such as the gastric juice, which can convert small amounts of the less toxic sulfated PSP toxins to more potent compounds (Llewellyn, 2006). An early study on clearance of PSP toxins from human serum showed completion in less than 24 h (Gessner *et al.*, 1997), and in 2007 detailed clearance data were obtained (Etheridge *et al.*, 2007) following a human outbreak of PSP: Rapid elimination from blood serum was observed, and urinary clearance of the toxins gave half-lives dependent on the toxin class, with gonyautoxins clearing three times faster than saxitoxin or neosaxitoxin.

## Mechanism of action

STX is a potent neurotoxin that selectively blocks the sodium channel by binding to site 1 (Cestèle and Catterall, 2000), preventing the entry of Na<sup>+</sup> ions into

cells, thus preventing nerve conduction and resulting in motor and sensory nerve abnormalities. All the STX analogs bind to the same (site 1) receptor, although with different affinities (Isbister and Kiernan, 2005). This binding site is shared with another group of sodium channel-blocking toxins, the tetrodotoxins. The VGSC binding sites for these and other marine toxins, and other natural toxins, were mapped during studies of the ion channels (Cestèle and Catterall, 2000).

## Toxicity

### Human toxicity

STXs provoke potentially lethal PSP in humans. The most common symptom of PSP, occurring in almost all affected, is perioral paraesthesias, described as either numbness or tingling. Among those displaying more severe illness, in some cases gastrointestinal symptoms (nausea, vomiting, abdominal pain, and diarrhea) were reported. More severe intoxication leads to a variety of neurological symptoms, including weakness, dysarthria, diplopia, ataxia, and vertigo or dizziness, and, in some cases, respiratory arrest or death. It is unclear whether PSP provokes significant direct effects on the myocardium (Lagos and Andrinolo, 2000). Both diastolic and systolic hypertension were reported in almost all the 11 PSP intoxicated patients studied by Gessner *et al.* (1997). Another report referred hypertension in 3 PSP patients from England. Experimental studies in cats and dogs emphasized a hypotensive effect after i.v. exposure to high doses of STX and a hypertensive effect at low doses (Lagos and Andrinolo, 2000). Death results from respiratory arrest and collapse, the terminal symptoms in patients without medical care. No long-term clinical effects of PSP have been reported (Gessner, 2000).

Several PSP incidents have been recorded throughout the world. The exposure to STX was estimated based on an examination of approximately 20 PSP incidents that occurred in Canada between 1970 and 1990 involving approximately 60 people (ages 3–72 years). The symptoms were classified as mild, moderately severe, or extremely severe. Mild cases were generally associated with an STX exposure of 2–30 µg/kg, whereas in the more severe cases STX exposure was greater than 10–300 mg/kg. Based on these data, a lowest-observable-adverse-effect level (LOAEL) of 2 µg/kg was established (FAO/IOC/WHO, 2005).

### Experimental toxicity

#### Single administration

The mouse LD<sub>50</sub> (median lethal dose) values of STX by i.v., i.p., and oral routes are 3.4, 10, and 263 µg/kg,

respectively. Significant species differences in oral toxicity have not been observed. The potency of different STXs varies widely. After i.p. injection in mice, the carbamates and the decarbamoyl derivatives are the most toxic PSP toxins, whereas the sulfocarbamoyl derivatives are the least toxic (Andrinolo *et al.*, 1999; Llewellyn, 2006).

## Treatment

Treatment for PSP is only supportive. Admission to an intensive care unit is necessary in moderate to severe cases to prevent respiratory failure: artificial respiration must be prompt and is the most vital treatment in many cases. Patients have to be carefully observed in the early stages of poisoning to immediately recognize and treat the progressing paralysis and respiratory failure.

## Concluding remarks

PSP due to the intake of toxins from the STXs group has provoked many fatalities. Because a specific antidote is not available for PSP, prevention is important and monitoring programs are carried out in many countries. A regulatory level of 0.8mg STX equivalents/kg shellfish meat has been set up in North America, in the European Community, as well as in many other countries worldwide. The AOAC International validated mouse bioassay (MBA) has been widely used in monitoring programs and has provided health protection (FAO/IOC/WHO, 2005). Three mice are intraperitoneally injected with the contaminated shellfish extracts, and their survival times are compared with those of mice injected with different concentrations of STX. The detection limit is only 0.4mg STX equivalents/g shellfish meat (Luckas, 1992). Various other methods, including cytotoxicity assays, receptor binding assays, immunoassay, surface plasmon resonance, and several chromatographic methods, have been developed to detect the paralytic toxins, as reviewed by Degrasse *et al.* (2010). AOAC-validated methods include the Lawrence pre-column liquid chromatography fluorescence method AOAC 2005.06 (Lawrence *et al.*, 2005) and the post-column oxidation method of CFIA (Rourke *et al.*, 2008; van de Riet *et al.*, 2011), which is officially approved as AOAC 2011.02. Both of these LC fluorescence methods can provide nearly full coverage of STXs (with the exception of GTX6 and dcNEO) and complete coverage of the most toxic forms. In Europe, method 2005.06 was approved in 2006, with some minor restrictions, as an alternative method to the MBA in monitoring programs. Also, as of 2010, in the United Kingdom, monitoring of the STXs is accomplished solely using a modified and

semi-automated version of this method (Turner *et al.*, 2009). Ireland and New Zealand made the same transition in 2011. Official AOAC approval of the post-column oxidation LC method AOAC 2011.02 for the saxitoxins will likely allow a phasing out of the mouse bioassay in Canada. Degrasse *et al.* (2010) compared performance and practical aspects of these LC fluorescence methods for the STXs. The receptor binding assay for paralytic shellfish toxins was interlaboratory studied (Van Dolah *et al.*, 2012) and approved as official method 2011.27 by AOAC. Official method status will increase the likelihood that one of these methods will be considered as a potential “type II” (reference) method in international application by Codex Alimentarius.

## TETRODOTOXIN

### Background

Puffer fish are an esteemed delicacy in Japan, despite the presence of a lethal toxin, tetrodotoxin (TTX), in the gonad, liver, viscera, and skin. TTX poisoning is the most common lethal marine poisoning. Its clinical effects develop rapidly: early symptoms are sensory, including perioral and distal numbness and paraesthesia. In mild poisoning cases, only sensory symptoms associated with minor gastrointestinal effects (mainly nausea and vomiting) occur. In moderately severe poisonings, patients develop distal muscle weakness and facial weakness and, later, ataxia and incoordination with normal reflexes. Dizziness can also be accompanied by a sensation of floating. Severe poisoning provokes generalized flaccid paralysis, respiratory failure, and aphonia. In severe and life-threatening poisoning, cardiovascular effects (bradycardia, hypotension, and dysrhythmias) occur together with respiratory failure and coma. Patients with severe poisoning rapidly progress to flaccid paralysis. Most moderate and severe cases generally resolve after 5 days or longer in severe poisoning. In minor cases, complete recovery occurs within a few hours (Isbister and Kiernan, 2005).

The symptoms are very similar to those of PSP due to the similar mechanism of action of the involved toxins. The anamnesis (if possible) and the analysis of uneaten fish or patient's urine or serum confirms diagnosis for tetrodotoxin. TTX and its analogs are water-soluble and heat-stable heterocyclic compounds with a guanidinium group that is positively charged in the biological pH range (Figure 69.2) (Yotsu-Yamashita *et al.*, 2003); they are not produced by microalgae but, rather, by other microorganisms. A bacterium initially classified as *Pseudomonas* sp. and later amended as *Shewanella alga* was confirmed to produce TTX (Yasumoto, 2000). A list

**FIGURE 69.2** Chemical structure of tetrodotoxin (from Yasumoto, 2000).

of bacteria known to produce TTX is reported by Yu *et al.* (2004). Yu *et al.* (2004) and Wu *et al.* (2005) referred other species of TTX-producing bacteria: *Microbacterium arabinogalactanolyticum*, *Serratia marcescens*, and the actinomycete *Nocardioopsis dassonvillei*.

TTX mainly concentrates in fish of the Tetraodontidae family, which includes puffer fish. TTX has also been found in xanthid crabs, horseshoe crabs, some frogs and newts, and the blue-ringed octopus. Puffer fish poisoning mainly occurs in Asia, where *fugu* is a delicacy. In the first half of the 20th century, in Japan approximately 100 deaths per year from ingestion of *fugu* were reported. The mortality rate substantially decreased with improved legislation of *fugu* preparation and marketing, although TTX poisoning remains the major cause of fatal food poisoning in Japan (Isbister and Kiernan, 2005).

### Pharmacokinetics/toxicokinetics

Although the pharmacokinetics in humans is not fully understood, serum concentrations of TTX fall rapidly and may be undetectable after 12–24 h. In contrast, TTX can be detected in urine for up to 5 days after ingestion (Isbister and Kiernan, 2005).

After single subcutaneous injection in rats, TTX was detected in kidneys, heart, liver, lungs, intestine, brain, and blood, reaching a peak in 20 min. The concentrations were highest in kidneys and heart, and they were lowest in brain and blood. A rapid appearance of high TTX concentration in the kidneys and a slow disappearance from these organs were observed, suggesting that an appreciable amount of unchanged toxin is excreted in the urine (Kao, 1966).

### Mechanism of action

TTX affects the nervous system by preventing the propagation of the nerve impulse. It blocks Na<sup>+</sup> conductance by extracellular binding at receptor-site 1 of Na<sup>+</sup> channels to occlude the outer pore and thereby prevent

access of monovalent cations, blocking the membrane depolarization (Isbister and Kiernan, 2005).

## Toxicity

### Human toxicity

Onset of TTX poisoning generally occurs within minutes, seldom more than 6 h after consumption of contaminated fish. TTX intoxication has been categorized into four stages of progression. Stage 1 includes oral paraesthesias with or without gastrointestinal symptoms. Stage 2 includes paraesthesias in other areas and motor paralysis. Stage 3 includes muscular incoordination, aphonia, dysphagia, respiratory distress, cyanosis, and hypotension. Stage 4 includes respiratory paralysis and severe hypotension. The mortality rate in TTX poisoning depends, among other things, on access to intensive care facilities. Patients who have not died within 24 h generally recover completely. As with PSP, symptoms of TTX poisoning generally are completely resolved within 1 or 2 days (Gessner, 2000).

### Experimental toxicity

#### Single administration

Although the mechanism of action of TTX is well known, only outdated and limited data on its toxicity in animals are available. The effects of TTX have been tested on a variety of animal species. After i.p. injection in mice, the minimal lethal dose of TTX was 8 µg/kg, whereas the LD<sub>50</sub> was estimated to be 10 µg/kg and doses ranging from 12 to 14 µg/kg killed all the mice. After oral and subcutaneous administration in mice, the LD<sub>50</sub> was 332 and 16 µg/kg, respectively (Kao, 1966). Similar results were observed in a study in which LD<sub>50</sub> values after i.p., subcutaneous, and oral administration in mice were determined to be 10.7, 12.5, and 532 µg/kg, respectively. In rabbits, the minimal lethal doses and the lethal doses for all the animals were respectively 5.3 and 3.1 µg/kg after intramuscular injection and 5.8 and 3.8 µg/kg after i.v. injection (Xu *et al.*, 2003). In almost all animal species, the observed symptoms were similar and comparable. The toxic effects involve mainly the peripheral neuromuscular system, with varying extent of paralysis. Furthermore, TTX is a highly potent emetic agent so that vomiting was frequently observed in both cats and dogs. Moreover, a pronounced and long-lasting hypotension and hypothermia were observed (Kao, 1966).

### Treatment

There is no antidote available for clinical use. To appropriately treat respiratory failure or cardiac effects, a careful

observation of the poisoned patient is recommended. Admission to an intensive care unit is necessary in moderate to severe cases to prevent complications. In case of severe poisoning, atropine can be used to treat bradycardia. Respiratory support may be necessary for 24–72 h. Because the patient may be fully conscious during the poisoning, sedation is important when the patient is paralyzed.

## Concluding remarks

Due to the severity of TTX intoxication, prevention is very important: public education is essential to reduce puffer fish poisoning (How *et al.*, 2003). In Japan, low mortality rates were achieved after the introduction of legislation related to the preparation and marketing of *fugu* (Isbister and Kiernan, 2005). The official method to detect TTX in puffer fish in Japan is the MBA (Yasumoto, 1991), as translated to English by Dr. Yotsu-Yamashita (Hungerford, 2006). In the United States, no regulatory limits for TTX have been established, but personal importation of puffer fish is prohibited (Gessner, 2000). Various other methods have been developed for detecting tetrodotoxin, including LC-MS/MS, as briefly reviewed by Taylor *et al.* (2008) in their description of a surface-plasmon resonance sensor for TTX.

## CIGUATOXINS AND MAITOTOXINS

In tropical regions, many species of fish may become toxic, provoking neurological, gastrointestinal, and, sometimes, cardiovascular symptoms when ingested. Eating these contaminated fish, humans can develop ciguatera, a marine fish poisoning that causes diverse and often long-lasting health problems. Although this poisoning is rarely fatal (0.1%), it has been estimated that more than 25,000 people are affected every year.

## Background

Ciguatera is characterized by moderate to severe gastrointestinal symptoms (vomiting, diarrhea, and abdominal cramps), neurological signs (myalgia, paraesthesia, cold allodynia, and ataxia), pruritus, and, less common, cardiovascular effects. Both gastrointestinal and neurological symptoms are typical of ciguatera, but the proportion of each type depends on the region. Gastrointestinal symptoms characterize the first stage of this poisoning and are predominant in Caribbean cases of ciguatera. Generally, they appear within 2–12 h of contaminated fish ingestion and are represented mainly by

nausea, vomiting, and diarrhea, but also by abdominal pain. Neurological symptoms predominate in the Pacific area and develop over 24 h, although onset can be very different, even in patients who eat the same fish. Cold allodynia, a dysesthesia that induces a burning sensation on contact with cold objects, is one of the most typical symptoms of ciguatera and is commonly incorrectly referred as “temperature reversal” (Isbister and Kiernan, 2005).

Persistent effects of ciguatera have been reported, including a case-control study. Reported clinical effects of chronic ciguatera (CC), which impacts approximately 5% of ciguatera victims, include fatigue, arthralgia, myalgia, headache, and pruritus. Immune response abnormalities seen in CC parallel the chronic systemic inflammatory response syndrome seen in several chronic diseases (Shoemaker *et al.*, 2010). Also, depression and anxiety have been associated with CC (Isbister and Kiernan, 2005). Cardiovascular symptoms, not very frequent, include bradycardia and hypotension.

Initially, this poisoning can present similar symptoms to those of diarrheic shellfish poisoning or microbial food poisoning, so anamnesis data are important. Mild ciguatera cases are often misdiagnosed as a common illness such as the flu. Whereas symptoms of cold allodynia are indicative of ciguatera, differential diagnosis of neuropathy can be needed (Glaziou and Legrand, 1994; Isbister and Kiernan, 2005).

Ciguatoxins (CTXs) enter the food chain through the epiphytic benthic dinoflagellate *Gambierdiscus toxicus*. This species is common in coral reef waters and lives at temperature ranging from 20 to 34°C, in conditions of low salinity and depths (3–15 m). Its growth is increased in places where there is reef degradation by human or natural factors. Different strains of *G. toxicus* produce chemically distinct lipo- and water-soluble toxins, named CTXs and maitotoxins (MTXs), respectively (Lehane and Lewis, 2000; Lewis, 2001). Because the actual role of MTX in ciguatera is unclear, the two groups of toxins are treated separately.

The accumulation of these toxins through the food chain involves the ingestion of *G. toxicus* by herbivorous fish that are eaten by carnivorous species. CTXs are concentrated both into viscera (e.g., liver, intestines, and gonads) and into fish muscle, whereas MTXs seem to be confined only to the viscera. Pacific and Caribbean reef-fish species associated with ciguatera include *Lutjanids* (red bass and snappers), *Serranids* (coral trout from the Great Barrier Reef, sea bass, and groupers), *Epinephelids* (cod, including flowery cod and spotted cod), *Lethrinids* (emperors and scavengers), *Muraenids* (moray eels), *Scombrids* (mackerel, including Spanish mackerel, and tunas), *Carangids* (jacks and scads), and *Sphyraenids* (barracuda) (Lehane and Lewis, 2000; Yasumoto, 2001; Isbister and Kiernan, 2005).

Ciguatera is endemic in subtropical and tropical regions of the western Indian and Pacific Ocean regions and in the Caribbean Sea (Lehane and Lewis, 2000). In 2004 and 2008–2009, ciguatera outbreaks occurred for the first time near the west coast of Africa, in the Canary Islands (Boada *et al.*, 2010), tentatively due to climate changes. Due to the increase in trade of fish, ciguatera is not confined to the tropics. Epidemiological characterization of ciguatera has been limited by the lack of laboratory tests to confirm the presence of the toxins (Lewis *et al.*, 2000). A role for marine cyanobacteria in ciguatera has also been suggested (Golubic *et al.*, 2010).

## CIGUATOXINS

Toxins responsible for ciguatera are the CTXs (Figure 69.3), which are lipid-soluble and heat-stable polyethers with a backbone composed of 10–14 rings transfused by ether linkages into a ladder-like structure reminiscent of the brevetoxins (PbTx). Structural differences have been found in CTXs isolated in different regions so that Pacific (P-CTXs) and Caribbean (C-CTXs) CTXs are usually referred to separately (Lehane and Lewis, 2000; Yasumoto, 2001). The Pacific CTXs are the most potent and the most studied CTXs, and thus they are referred to here omitting the Pacific Ocean (P-) designation. Pacific CTXs form CTX1B, which possesses the highest toxicity of all CTXs, and the total toxicity of a sample is often expressed in CTX1B equivalents. Even among the Pacific group of CTXs, there is considerable regional diversity among Pacific CTX congener profiles, as described by Yogi *et al.* (2011). Studies have clarified just how complex is the evolution of ciguatoxicity. For many years, it was believed that oxidation of the less toxic forms produced by the algae (CTX4A and CTX3C; Figure 69.4) by cytochrome enzymes in the liver of fish (Lehane and Lewis, 2000; Yasumoto, 2001; Cembella, 2003) was necessary to produce the more toxic, oxidized CTX forms implicated in Pacific region outbreaks of ciguatera (primarily CTX1B and also 51-hydroxyCTX3C). However, Yogi *et al.* reported that some of the oxidized forms of the CTXs also occur directly in *G. toxicus*, including 52-epi-54-deoxyCTX1B, 54-deoxyCTX1B, and 51-hydroxyCTX3C (Figure 69.4). Thus, the role of fish metabolism in the transformation and ultimate toxicity of CTXs in the food web must be reexamined.

### Pharmacokinetics/toxicokinetics

Only limited data are available on absorption, distribution, metabolism, and excretion of CTXs. Most of the

toxicokinetic information is not obtained from actual pharmacokinetic studies but often derives either from direct clinical observations or from schemes hypothesized on the basis of the chemical properties of CTXs. The oral absorption of these toxins should be complete or almost complete due to their lipophilicity; it has been hypothesized that CTXs can also penetrate the skin and mucous membranes due to the observed human effects after local exposure (Lehane and Lewis, 2000). CTXs are able to cross the placenta (Pearn *et al.*, 1982) and they are also excreted in breast milk, although hyperaesthesia of the nipples of a lactating mother may interfere with breast-feeding (Bagnis and Legrand, 1987). Blood collected from mice exposed to a sublethal dose of C-CTX-1 was found to contain toxin concentrations of 0.25 and 0.12 ng/mL 30 min and 12 h after exposure, respectively (Bottein Dechraoui *et al.*, 2005).

### Mechanism of action

CTXs increase cell Na<sup>+</sup> permeability by binding to site 5 neuronal voltage-sensitive sodium channels (Cestèle and Catterall, 2000), which open at normal resting membrane potential. Therefore, CTXs affect various Na<sup>+</sup>-dependent mechanisms to enhance membrane excitability. They also induce mobilization of intracellular Ca<sup>2+</sup> and provoke cell swelling. The effects of CTXs are most prominent in nerves (Lewis *et al.*, 2000). The action of ciguatoxins and their precursors is highly dependent on toxin structure, with gambiertoxin (P-CTX4B) having a greater impact on K<sup>+</sup> channels than on Na<sup>+</sup> channels (Schlumberger *et al.*, 2010).

### Toxicity

#### Human toxicity

Ciguatera outbreaks sometimes produce fatalities, even though only a few fatal cases of ciguatera are reported. Postmortem analysis shows acute visceral congestion with eosinophilic necrotic lesions in the liver at light microscope and ultrastructural changes in the sural nerve with swelling Schwann cells, axonal compression, and vesicular degeneration of myelin (Lehane and Lewis, 2000; Terao, 2000). CTX-1B poses a health risk at concentrations higher than 0.1 pg/g (Pearn, 2001), which is in relatively close agreement with an outbreak reported by Oshiro *et al.* (2010) at just 0.175 pg/g. In its typical form, ciguatera is characterized initially by the onset of intense vomiting, diarrhea, and abdominal pain within hours after fish ingestion, but the neurological symptoms tend to be the most distinctive and permanent ones. They include sensory disturbances, such as

FIGURE 69.3 Chemical structure of ciguatoxins implicated in ciguatera outbreaks (from Dickey and Plakas, 2010, and Yogi *et al.*, 2011).

**FIGURE 69.4** Chemical structures of ciguatoxin congeners of note found in *Gambierdiscus toxicus* (from Dickey and Plakas, 2010, and Yogi *et al.*, 2011).

generalized pruritus, circumoral numbness, long-lasting weakness, and fatigue, and the unusual and perhaps pathognomic sensory discomfort triggered by cold stimuli ("cold allodynia"). Patients with bradycardia and/or hypotension may require urgent care because the infrequent cardiovascular symptoms may indicate a poor prognosis. It has been hypothesized that the cardiovascular effects can result from a positive inotropic effect and myocardium response to intracellular  $\text{Ca}^{2+}$  increase (Lehane and Lewis, 2000; Lewis *et al.*, 2000).

### Experimental toxicity

#### Single administration

After single administration in mice, toxicity is similar after either oral or i.p. administration, suggesting that oral absorption is almost complete in this species. P-CTXs and C-CTXs show a different potency by i.p. injection. The i.p.  $\text{LD}_{50}$  values in mice are 0.25, 2.3, and  $0.9\mu\text{g/kg}$  for P-CTX-1, -2, and -3, respectively, whereas  $\text{LD}_{50}$  values of 3.6 and  $1.0\mu\text{g/kg}$  were recorded for C-CTX-1 and -2. The acute i.p. injection or oral administration of P-CTX-1 or P-CTX-4C ( $0.7\mu\text{g/kg}$ ) in mice provoke similar toxicity, initially characterized by severe diarrhea. Target organs were heart, medulla of the adrenal glands, autonomic nerves, and penis. Light microscopy analysis shows marked swelling and focal necrosis of cardiac muscle cells. Degeneration of cells in the medulla of the adrenal glands was also observed. A marked lung edema, with congestion at alveolar spaces and bronchioles, was reported in mice with severe dyspnea. Continuous erection of the penis was observed in approximately 15% of the mice suffering from ciguatoxicosis (Lehane and Lewis, 2000; Terao, 2000). Hypothermia is also observed in mice, and toxicogenomics studies show that this is followed by activation of phase I and II detoxification pathways (Morey *et al.*, 2008). Using a murine macrophage model (Matsui *et al.*, 2010), CTXs have been shown to modulate mRNA expression of pro- and anti-inflammatory cytokines and of inducible nitric oxide synthase, and in bovine chromaffin cells they promote catecholamine secretion (Nguyen-Huu *et al.*, 2010).

#### Repeated administration

After repeated i.p. and oral administrations ( $100\text{ng/kg}$  of P-CTX-1 or P-CTX-4C) for 15 days, marked swelling of cardiac cells and endothelial lining cells of blood capillaries in the heart was observed. Although single doses of the same toxins did not provoke any discernible change at macroscopic, light microscopic, and even ultrastructural levels in the hearts of mice, the repeated administration of CTXs resulted in severe morphological but reversible cardiac changes. At the ultrastructural

level, the changes induced by repeated CTX administration were similar to those of mice receiving a CTX single dose ( $700\text{ng/kg}$  or more) (Terao, 2000). Bottein Dechraoui *et al.* (2008) related blood CTX levels to repeated administration of ciguatoxin to enhanced and sustained thermoregulatory, motor activity, and pain threshold and responses in mice.

### Treatment

For ciguatera poisoning, there is only supportive and symptomatic treatment, such as the control of fluid and electrolyte balance, because no effective antidote is available. The infrequent cardiovascular complications, such as symptomatic bradycardia and severe hypotension, may require treatment. The most common treatment during the acute phase is i.v. infusion of mannitol, but controversial data are reported about its efficacy: a double-blind, randomized, controlled trial found no difference between mannitol and saline treatment. Local anesthetics and antidepressants may also be useful (Lehane and Lewis, 2000; Lewis, 2001; Isbister and Kiernan, 2005).

### Concluding remarks

Because ciguatera remains a significant problem, prevention is important in endemic regions. The most widely used method for monitoring purposes is the MBA, based on clinical signs (marked hypothermia) and death observed for up to 48 h after i.p. injection of a 20-mg ether extract from fish muscle. Due to its poor sensitivity, this assay cannot detect the presence of CTXs in low-level contaminated ciguateric fish (Lehane and Lewis, 2000). Development of modern methods for detecting CTXs has been exceptionally challenging because the purified toxins are seldom available, and even then in minute quantities and generally not commercially. A rapid extraction procedure has been described for the LC-MS/MS detection of CTXs (Lewis *et al.*, 2009), and impressive gains have been made by Yogi *et al.* (2011) in the detection of 16 different CTXs forms using 12 toxin standards synthesized or isolated from nature. In the United States, ciguatera outbreaks are investigated (Dickey and Plakas, 2010) using a laboratory-based cytotoxicity screening, employing N2A neuroblastoma cells to screen for CTXs via (site 5) modulation of the VGSC (Manger *et al.*, 1993). Following N2A screening using a modified format, confirmation of CTXs contamination in positive samples is by LC-MS (Dickey and Plakas, 2010). Rapid assays have also been developed using neuroblastoma cells treated with voltage-sensitive dyes (Louzao *et al.*, 2004), and flow cytometry offers selection of the most responsive cells in

such assays, allowing for rapid estimation of CTX (site 5) toxicity in fish extracts (Manger *et al.*, 2007). Using flow cytometry, it is possible to directly observe depolarization of the N2A neuroblastoma cells by CTX (Manger *et al.*, 2007), contradicting assertions (LePage *et al.*, 2005) that neuroblastoma (N2A cells)-based cytotoxicity assays are insensitive to CTX without veratridine also present. Addition of veratridine enhances the signal obtained using CTX alone by three orders of magnitude, enabling high-sensitivity detection of the CTXs.

Although cytotoxicity and binding assays have been helpful in ciguatera research and various assays, including radioimmunoassay, enzyme-linked immunosorbent assay (ELISA), and binding and cytotoxicity assays, have been developed and reviewed (Dickey and Plakas, 2010), there is still a need for easy diagnostic and screening methods for CTXs. Attempts at developing a commercially available rapid test kit for CTXs have been plagued by false positives and negatives (Wong *et al.*, 2005) and have failed to be officially AOAC approved (Hungerford, 2009). Total synthesis of CTX3C and fragments of the predominant toxin CTX1B shows promise for supporting future development of a sandwich ELISA based on two synthetic fragments (Tsumuraya *et al.*, 2010). However, the cross-reactivity of the (CTX3C-derived) antibodies for CTX1B is not sufficient to allow the assay's application in screening toxic fish. In April 2011, the U.S. Food and Drug Administration established the first regulatory (advisory) levels for ciguatoxins at 0.01ng CTX1b equivalents/g fish for the Pacific and 0.1ng C-CTX1 equivalents/g fish for the Caribbean (Dickey and Plakas, 2010; FDA, 2011). These advisory levels were determined from assessment of human ciguatera outbreaks using data from variations of the N2A cytotoxicity assay (Manger *et al.*, 1993) combined with LC-MS/MS (Dickey and Plakas, 2010) and discussions between experts in the United States, Japan, and Australia.

## MAITOTOXINS

MTX, a water-soluble compound isolated together with CTXs, was considered as a biotoxin involved in ciguatera (Yasumoto, 2001). However, because its content is insignificant in fish flesh and it has low oral toxicity, MTX seems to play a limited role in ciguatera (Estacion, 2000; Yasumoto, 2000). MTX, also called MTX-1 (Figure 69.5), is a polycyclic polyether and, with the exception of biopolymers, the largest natural compound isolated and structurally elucidated to date ( $C_{164}H_{256}O_{68}S_2Na_2$ ; molecular weight (MW) = 3422) (Yasumoto, 2001). It is produced by the epiphytic dinoflagellate *Gambierdiscus toxicus* and accumulates in the liver of fishes such as surgeonfish and parrotfish. MTX

was first detected in viscera of *Ctenochaetus striatus* (maito), from which MTX derived its name. MTX analogs (MTX-2, MW = 3298; and MTX-3, MW = 1060) have been purified from *G. toxicus* strains (Holmes and Lewis, 1994; Bouaïcha *et al.*, 1997; Terao, 2000).

## Pharmacokinetics/toxicokinetics

No data on the absorption, distribution, biotransformation, and elimination of MTXs are available.

## Mechanism of action

MTX is a powerful activator of  $Ca^{2+}$  entry via nonselective cation channels in a wide variety of cells. Thus, it causes an increase in cytosolic  $Ca^{2+}$  levels that stimulates a broad spectrum of calcium-dependent processes, including cell death (Escobar *et al.*, 1998; Estacion, 2000; Morales-Tlalpan and Vaca, 2002).

## Toxicity

### Human toxicity

MTX toxicity in humans is unclear because its role in ciguatera is not completely understood (Estacion, 2000).

### Experimental toxicity

#### Single administration

After i.p. injection in mice, the  $LD_{50}$  of MTX was 500ng/kg (Yasumoto, 2000). An i.p. injection of MTX in mice (200–400ng/kg) and rats (400ng/kg) induced severe alterations at the gastric mucosa, cardiac muscle, and lymphoid tissues, as well as an increase in plasma cortisol, which was probably involved in the involution of lymphoid tissues (Terao, 2000). A hypothermic effect after i.p. injection in rats (338ng/kg) has also been reported (Gordon and Ramsdell, 2005).

#### Repeated administration

Repeated daily i.p. injection of MTX in mice (45ng/kg for 13 days) resulted in marked atrophy of lymphoid tissues, reduced circulating lymphocytes and serum immunoglobulin M levels, as well as increased calcium content of adrenal glands and plasma cortisol (Terao, 2000).

## Concluding remarks

Although MTX is accumulated mainly in viscera of herbivorous fish and seems to play a marginal role in

FIGURE 69.5 Chemical structure of maitotoxin (from Yasumoto, 2001).

ciguatera, its possible contribution should not be disregarded, considering the practice in some areas of eating small fish without eliminating their viscera (Yasumoto, 2000). Therefore, detection of MTXs in fish and phytoplankton is of particular importance, so biological and chemical methods based on HPLC and zone electrophoresis with ultraviolet and/or MS detection have been developed (Fessard *et al.*, 1994; Lewis *et al.*, 1994; Van Dolah *et al.*, 1994; Bouaïcha *et al.*, 1997). Although not demonstrated for seafood extracts or proposed analytically, it appears feasible that an assay could be designed based on the depolarization of synaptosomal plasma membrane by MTX and a voltage-sensitive dye as per the study of Tagialatela *et al.* (1990).

## DOMOIC ACID AND ANALOGS

### Background

Amnesic shellfish poisoning (ASP) is a toxic syndrome provoked by domoic acid (DA)-contaminated shellfish consumption. ASP differs from most other neurotoxic marine poisonings because the main effect is on the central nervous system (Isbister and Kiernan, 2005). It was reported for the first time in Canada in 1987 when, after consumption of contaminated mussels, people developed gastrointestinal symptoms within 24 h (vomiting, abdominal cramps, and diarrhea) and/or

neurological symptoms within 48 h (headache, loss of short-term memory, disorientation, lethargy, seizures, and, sometimes, convulsions and coma). Mortality was also recorded. Because the most relevant clinical effect was memory loss, the condition was termed ASP. The loss of memory in patients intoxicated with DA-contaminated mussels appeared to be similar to that of patients with Alzheimer's disease. However, whereas symptoms of Alzheimer's disease are generally present in older people and intensify with advancing age, loss of memory in mussel-intoxicated patients is not affected by patient age. Furthermore, the finding that higher cortical functions, such as intellect, were not affected by DA poisoning distinguished ASP from Alzheimer's disease (Nijjar and Nijjar, 2000; Jeffrey *et al.*, 2004).

The toxin responsible for ASP is DA (Figure 69.6), an amino acid of the kainoid class of compounds and 10 DA isomers (isodomoic acids A–H and DA 5'-diastereoisomer) that are less toxic than the parent compound. DA and its isomers are water-soluble and heat-stable tricarboxylic amino acids. Initially, DA was only known from the red algae *Chondria armata*. After 1987, *Pseudonitzschia* marine diatoms, such as *P. multi-series*, *P. pseudodelicatissima*, and *P. australis*, were shown to produce DA. *Pseudonitzschia navis-varengica* has been found to produce isodomoic acids A and B as main toxins (Kotaki *et al.*, 2005).

DA has been shown to accumulate in blue mussels (*Mytilus edulis*, *M. galloprovincialis*, and *Perna canaliculus*) as well as in other shellfish, such as cockles (*Cerastoderma*

FIGURE 69.6 Chemical structure of (a) domoic acid, (b) kainic acid, and (c) glutamic acid (from Nijjar and Nijjar, 2000).

*edule*), razor clams (*Siliqua patula*), scallops (*Pecten maximus*), and crabs (*Cancer magister*), and also in furrow shell (*Scrobicularia plana*) and anchovies (Jeffery *et al.*, 2004). DA-contaminated shellfish and potentially toxic *Pseudonitzschia* ssp. have been detected worldwide. Although DA has caused bird (via toxic anchovies) and other animal mortalities, the only toxic episode with confirmed human illnesses is that which occurred in Canada.

### Pharmacokinetics/toxicokinetics

Very limited data are available on the absorption, distribution, metabolism, and excretion of DA, showing no appreciable differences in the effects observed after i.p. and oral administration. It has been suggested that DA is poorly absorbed after the usual exposure route (Jeffery *et al.*, 2004). Furthermore, in the two studies comparing i.p. and oral administration in rodents, involving a small group size ( $N = 51$  or 2/dose) (Iverson *et al.*, 1989), DA was almost completely excreted in the feces, supporting the hypothesis that DA is not well absorbed. Truelove *et al.* (1996) reported that only 2% of the orally administered dose of DA (5 mg/kg/day) in rats ( $N = 510$ ) was excreted in the urine. Similar results (mean DA urinary excretion of the daily dose ranged from 4 to 7%) were obtained in cynomolgus monkeys ( $N = 53$ ) treated with a subtoxic dose of DA for 32 days (Truelove *et al.*, 1997). Once absorbed, DA appears to be poorly metabolized. In fact, approximately 75% of a dose of  $^3\text{H}$ -labeled DA i.v. injected in rats ( $N = 58$ ) was excreted unchanged in the urine within 160 min, suggesting that it is not significantly metabolized before rapid elimination. In the same study, metabolism to compounds of greater hydrophilicity was hypothesized to be due to remaining radiolabel eluted earlier than DA during LC separation (Suzuki and Hierlihy, 1993). In another study on the distribution and excretion of i.v. administered DA in rats (500 and 1000  $\mu\text{g/kg}$ ) and monkeys, half-lives of approximately 20 and 110 min, apparent volume of distribution of approximately 300 and 180 ml/kg, and apparent clearances of approximately 10 and 1 mL/min/kg were reported. Although a limited number of animals were included in the study, these data suggest that i.v. injected DA is well

distributed into the body fluids in both species and is rapidly eliminated (Truelove and Iverson, 1994).

After DA i.v. administration in rats, DA poorly permeates across the blood–brain barrier and appears not to cross via a specific transport carrier (Preston and Hynie, 1991). However, despite this limited transfer across the blood–brain barrier, the brain is the primary organ of DA-induced toxicity.

### Mechanism of action

The toxicity of DA in the nervous system is known to occur on excitatory amino acid receptors and on synaptic transmission. Two amino acids, L-glutamate and L-aspartate, are considered to be neurotransmitters and act upon several receptor types. Three receptor subtypes have been described for excitatory amino acids, with the kainic acid (KA) and the N-methyl-D-aspartate receptors being best characterized.

DA produces its action through pre- and postsynaptic receptors in a manner similar to KA opening the channel to  $\text{Ca}^{2+}$  and inducing cellular lethality. Due to the structural similarity of DA to glutamic acid and, in particular, to KA (Figure 69.6), DA has a strong affinity for subclasses of kainate receptors. Kainate receptors are widely distributed in the mammalian brain and are particularly concentrated in the CA1–CA3 regions of the hippocampus in rodents, in the CA2 and CA3 regions in nonhuman primates, and in the CA3 region in humans. The high affinity of DA to kainate receptors and the apparent co-localization of these receptors at sites where DA induced damage in the brains of rodents and primates suggest that DA–kainate receptor interactions play a major role in the toxic response. This binding of DA to glutamate receptor subtypes appears to stimulate neuronal firing, eliciting an excitatory response both *in vitro* and *in vivo*. Although the exact mechanism of neuronal stimulation leading to tissue brain damage is not completely understood, an influx of  $\text{Ca}^{2+}$  into cells was observed in brain tissue slices exposed to DA, and increased cytosolic  $\text{Ca}^{2+}$  levels in hippocampal pyramidal neurons exposed to DA were reported. It seems that DA binding to glutamate receptors in specific brain regions leads to excitation of neurons, giving rise to an

influx of  $\text{Ca}^{2+}$  resulting in a failure to maintain intracellular ion homeostasis and in cell death (Jeffery *et al.*, 2004).

## Toxicity

### Human toxicity

The ASP outbreak occurred in 1987 in Canada after the mussel (*M. edulis*) ingestion was characterized by gastrointestinal and unusual neurological symptoms. Although 150 reports of this illness were recorded, only 107 individuals met the clinical definition of the poisoning (Jeffery *et al.*, 2004). The most common gastrointestinal symptoms were vomiting (76%), abdominal cramps (50%), and diarrhea (42%); the most common neurological symptoms were headache (43%) and loss of short-term memory (25%) (Nijjar and Nijjar, 2000).

The poisoning was particularly severe in 19 people who were hospitalized: 12 individuals with particularly severe symptoms (e.g., seizures, coma, profuse respiratory secretions, or unstable blood pressure) required treatment in the intensive care unit. Although in most patients, decreased arousal and somnolence were seen, in some cases leading to coma, in less severely affected patients, agitation was observed. Cardiovascular symptoms (tachycardia, hypotension, and arrhythmias) may have been a consequence of dysfunction of the central autonomic centers because there was no evidence of primary cardiovascular impairment. In most patients, symptoms resolved in a few weeks, but residual memory impairment can persist (Doble, 2000).

Three hospitalized patients died 11–24 days after consumption of mussels, and a fourth patient died of myocardial infarction within 3 months. Postmortem histological examination showed neuronal necrosis and astrocytosis, most prominent in the hippocampus and amygdala nucleus (Nijjar and Nijjar, 2000).

In nine cases of poisoning, estimates of DA exposure were derived from analysis of leftover mussels collected from households or restaurants. The amount of DA ingested ranged from 60 to 290 mg in poisoned patients. Thus, it seems that 60 mg DA/person (<1 mg/kg) is sufficient to provoke gastrointestinal symptoms, whereas ingestion of 270 mg DA/kg (<4.5 mg/kg) provokes neurological effects (Jeffery *et al.*, 2004).

### Experimental toxicity

#### Single administration

After i.p. administration in mice, LD<sub>50</sub> values of 2.4 and 3.6 mg DA/kg were reported in two different studies using DA-contaminated mussel extracts. Clinical symptoms such as scratching, tremors, and seizures at both

lethal and sublethal doses of the extracts were observed. LD<sub>50</sub> values have been recorded for newborn mice after i.p. administration at different postnatal days: the results suggest that they may be much more sensitive to DA than are adult mice (Jeffery *et al.*, 2004).

Neuropathological studies were carried out in both mice and rats. Dose-related lesions in the brains (edema in the hypothalamus and hypothalamic arcuate nucleus and neuronal degeneration in different areas of the hippocampus) of mice and rats were found after i.p. and after *per os* administration of mussel extracts containing DA (Iverson *et al.*, 1989).

Similar effects have been reported in studies of nonhuman primates after i.p. and i.v. injection. Severe vomiting and scratching were reported after single i.v. DA administration (0.24, 0.5, 1.0, 1.25, 1.5, 2, and 4 mg/kg) in cynomolgus monkey, with a dose-related latency in the appearance of the symptoms. DA doses greater than 1.0 mg/kg provoked death by respiratory failure in four of seven animals. Postmortem examination revealed lesions in the hippocampus (Scallet, 1995), and in a similar study utilizing specialized histochemistry, the thalamus also appeared to be affected (Schmued *et al.*, 1995).

#### Repeated administration

After repeated (64 days) *per os* exposure to DA (0.01 or 5 mg/kg/day) of male and female rats, neither clinical abnormalities nor differences in hematology, clinical chemistry, or histopathology were observed in treated animals (Jeffery *et al.*, 2004). Neither clinical symptoms nor significant changes in body weight, hematology, clinical chemistry, or brain histology were observed in cynomolgus monkey orally treated with low doses of DA (0.5 mg/kg/day for 15 days and 0.75 mg/kg/day for a further 15 days) (Truelove *et al.*, 1997).

#### Teratogenicity

The effects of DA (0–2 mg/kg) injected daily i.p. to pregnant rats from gestational days 7 to 16 were studied both on mothers and offspring at gestational day 22. Mother death was recorded only at the higher DA doses (6/12 and 6/9 at 1.75 and 2.0 mg/kg, respectively). At doses greater than 0.5 mg/kg/day, a reduction in live fetus number at term was recorded, but the number of deaths was not increased dose dependently. A nonsignificant increase in the number of fetuses with visceral/skeletal anomalies was reported (Khera *et al.*, 1994).

#### Genotoxicity

Because the structure of DA contains a butadiene moiety, there is the possibility for the formation of DNA-reactive epoxides *in vivo*. Although only limited data are available about its possible genotoxicity, DA (87 or 174  $\mu\text{M}$ )

did not increase mutation frequency in V79 Chinese hamster lung cells *in vitro* measured by thioguanine or ouabain resistance, sister chromatid exchange, or micronucleus assays, nor does it give rise to DNA-reactive metabolites (Jeffery *et al.*, 2004). *In vivo* data on DA carcinogenicity are not available.

## Treatment

The diagnosis is based on the history of ingestion of bivalve mollusks followed by characteristic symptoms. Environmental surveillance programs of phytoplankton in risk regions may be suggestive of a possibility of poisoning. Due to the risk of convulsions, emesis should not be induced. Severe cases should be admitted to the intensive care unit and monitored for convulsions, central nervous system depression, cardiovascular collapse, or gastric hemorrhages. Treatment is symptomatic, and no antidote is available (Gulland *et al.*, 2002).

## Concluding remarks

After the human outbreak of ASP in 1987, a regulatory limit for shellfish flesh was introduced in Canada and consequently in other countries. The limit, 20 mg/kg, is based on a retrospective estimate of the DA amount in mussels that resulted in human illness in the 1987 Canadian ASP outbreak and incorporates a 10-fold safety factor. Due to the worldwide distribution of the diatoms producing DA, the action limit employed by Canada has been adopted elsewhere and is the limit enforced in the European Union, the United States, New Zealand, and Australia (Jeffery *et al.*, 2004). An HPLC-UV method has gained favor in various countries (FAO/IOC/WHO, 2005).

# BREVETOXINS

## Background

Algal brevetoxins (PbTx) are neurotoxic polyethers produced by the dinoflagellates of *Karenia* genus (mainly *K. brevis*, formerly known as *Gymnodinium breve* or *Ptychodiscus breve*), which forms "red tide" blooms along the Florida coast and the Gulf of Mexico. These harmful blooms cause mass mortality of fish and other marine organisms. They also cause episodes of respiratory distress in humans after inhalation of the sea spray and eye and skin irritation after swimming in the sea. Dolphin and manatee mortalities have been traced to PbTx in the marine food web (Flewelling *et al.*, 2005).

Because shellfish are resistant to PbTx and accumulate these compounds, their ingestion may provoke an illness called neurotoxic shellfish poisoning (NSP) (Landsberg, 2002). NSP is characterized by acute gastrointestinal and neurological symptoms, including nausea, vomiting, diarrhea, chills, sweats, headache, muscle weakness and joint pain, paraesthesia, arrhythmias, difficult breathing, mydriasis, double vision, and troubles in talking and swallowing. Recovery occurs in 2 or 3 days, and no fatal cases from NSP have been reported (Baden and Adams, 2000; Hallegraeff, 2003; Isbister and Kiernan, 2005).

The PbTx are lipid-soluble and heat-stable polycyclic ether compounds grouped into two types (A and B) according to their backbone structures consisting of 10 (type A) or 11 (type B) transfused rings, and additional forms exist in which the lactone (A ring) is open (Figure 69.7). At least 15 PbTx can be found in cultures and natural blooms of *K. brevis* (Figure 69.7) (Plakas and Dickey, 2010). Metabolism of these toxins within shellfish, first reported by Ishida *et al.* (2004), is now known to be extensive (Plakas and Dickey, 2010), producing a variety of brevetoxin metabolites, many of them more polar than the PbTx (Figure 69.8).

The brevetoxin metabolites found in molluscan shellfish have widely ranging acute mouse i.p. toxicities, as summarized by Plakas and Dickey (2010). Some of these conjugates are more toxic than the algal forms; for example, metabolites BTX-B1 and BTX-B4 are respectively four and two times more toxic than their precursor, PbTx-2. Oral toxicity data are not available for any of the brevetoxin shellfish metabolites because isolation of these toxins and their synthesis have been challenging (Plakas and Dickey, 2010). Following an NSP outbreak, additional brevetoxin metabolites have also been identified in human urine (Figure 69.9). Other *Karenia* species were involved in NSP, whereas some raphidophytes (*Chattonella marina*, *C. antiqua*, *Fibrocapsa japonica*, and *Heterostigma akashiwo*) were reported to produce brevetoxin-like compounds, but no documented cases of NSP were caused by these species (Landsberg, 2002; Hallegraeff, 2003; Ciminiello and Fattorusso, 2004). *Karenia* blooms have occurred mainly in the Gulf of Mexico, where NSP has historically been limited, but occasional blooms associated with NSP have also been reported along the mid- and south Atlantic coast of the United States and in New Zealand. Shellfish involved in NSP are mainly oysters, clams, cockles, and mussels (Landsberg, 2002).

## Pharmacokinetics/toxicokinetics

After oral administration of [<sup>3</sup>H]-labeled PbTx-3 to rats, the toxin was shown to distribute to all organs and concentrated mainly in the liver. It was eliminated in

equivalent quantities through urine and feces: approximately 80% of the dose was excreted within 7 days (during the first 48h, PbTx-3 was cleared mainly through the feces, and afterward it was cleared mostly through urine) (Cattet and Geraci, 1993).

After i.p. injection of PbTx-3 in mice, blood concentration of the toxin was maximal between 0.5 and 4h. After 24 h, it was reduced by one-third, and it was still detectable after 7 days. A significant part of PbTx-3 in mouse plasma binds to high-density lipoproteins (Fahey *et al.*, 2001; Woofter *et al.*, 2003, 2005). In rats, after i.p. injection of PbTx-2 and PbTx-3, the toxins were detected in blood within 1h, and for PbTx-2, a rapid metabolism to polar cysteine conjugates, eliminated in urine over 24h, was observed (Radwan *et al.*, 2005).

An i.v. administration of  $^3\text{H}$ -labeled PbTx-3 to rats showed that the toxin cleared rapidly from the blood (<10% remained after 1min) and distributed mainly to the liver, skeletal muscle, and gastrointestinal tract (18, 70, and 8% of the dose after 30min, respectively). Within 24h, PbTx-3 concentration in skeletal muscle decreased to 20% of the dose, whereas that in liver

remained constant and increased in the gastrointestinal tract and feces, probably because of biliary excretion. By day 6, approximately 14% of the toxin had been excreted through urine and 75% in feces, also in the form of more polar metabolites (Poli *et al.*, 1990).

Intratracheal instillation of [ $^3\text{H}$ ]-labeled PbTx-3 to rats revealed that more than 80% of the dose was cleared within 0.5h from the lung and distributed throughout the body, mainly to the carcass (49%), intestine (32%), and liver (8%). Blood, brain, and fat contained the lowest levels of the toxin. Approximately 20% of the initial level in tissues was retained for 7 days. The majority of PbTx-3 was excreted within 48 h in feces (60%) and urine (30%) (Benson *et al.*, 1999). Also in mice, after intratracheal instillation, PbTx-3 distributed rapidly to tissues, mainly in liver and gastrointestinal tract, whereas approximately 90% of excretion occurred within 4 days in urine (11%) and feces (64%) (Tibbetts *et al.*, 2006). After repeated inhalation of PbTx-3 by rats for 5 or 22 days, small amounts of the toxins were detected in splenic and peribronchiolar lymphoid tissue as well as in liver, in which no accumulation of brevetoxin occurred (Benson *et al.*, 2004, 2005).

**FIGURE 69.8** Chemical structure of molluscan shellfish metabolites of the brevetoxins (PbTx-2 and PbTx-3 also occur and are shown in Figure 69.7; from Dickey and Plakas, 2010).

**FIGURE 69.9** Chemical structure of brevetoxins and metabolites found in human urine following an NSP outbreak (from Dickey and Plakas, 2010).

Cutaneous application of  $^3\text{H}$ -labeled PbTx-3 on pig skin revealed a rapid penetration of the toxin to the dermis, with maximal dermal accumulation at 4h (Kemppainen *et al.*, 1991).

## Mechanism of action

PbTxS and BTXs bind to site 5 on the  $\alpha$  subunit of voltage-sensitive sodium channels in the cell membranes (Cestèle and Catterall, 2000). Normally, these channels open in response to membrane depolarization and subsequently inactivate, returning to closed configuration during the membrane repolarization. Toxin binding opens the voltage-sensitive sodium channels due to a negative shift in activation potential resulting in a sustained influx of  $\text{Na}^+$  and membrane depolarization. There is also alteration of the normal changes of the voltage-sensitive sodium channels configuration during the depolarization/repolarization processes. These actions affect the membrane properties of excitable cells and are the basis of the neurotoxic effects of the toxins. A structural feature of these compounds (Figure 69.7) required for this activity is the lactone in the A ring (“head” of

the molecule) as well as the conserved structure on the “tail” rings. Receptor binding studies with synaptosome preparations from manatee brain showed tritiated PbTx3 binding with an affinity somewhat lower than that of rat and similar to that of fish excitable tissues (Trainer and Baden, 1999; Ciminiello and Fattorusso, 2004).

Respiratory problems associated with the inhalation of aerosolized PbTxS are believed to be due in part to opening of sodium channels. Other actions involved in the bronchoconstriction and/or the immunological effects at the respiratory tract seem to be related to stimulation of neurotransmitter release and mast cell degranulation, as well as to an inhibition of the phagocytic cell lysosomal proteinases known as cathepsins (Abraham *et al.*, 2005; Baden *et al.*, 2005).

## Toxicity

### Human toxicity

Ingestion of PbTxS and their metabolites in contaminated shellfish can cause NSP, a syndrome that includes some symptoms similar to ciguatera but less severe. The symptoms occur within 30min to 3h, last a few

days, and include nausea, vomiting, diarrhea, chills, sweats, headache, muscle weakness and joint pain, paraesthesia, arrhythmias, difficulty breathing, mydriasis, double vision, and trouble in talking and swallowing. Sometimes, coma occurs, but no mortality or chronic symptoms have been reported (Baden and Adams, 2000; Isbister and Kiernan, 2005).

Due to the fragility of *Karenia* cells, PbTxS can be released in seawater and aerosolized by wind and surf, with the possibility of inhalation exposure to these compounds, causing respiratory distress and irritation of the eyes and of respiratory tract mucosa. Normally, these symptoms are rapidly reversible by leaving the beach area. The main brevetoxin responsible for respiratory discomfort seems to be PbTx-3. During swimming, direct contact with toxic blooms and consequent skin, nasal, and eye irritation can occur (Landsberg, 2002).

### Experimental toxicity

#### Single administration

After i.p. injection in mice, the LD<sub>50</sub>s of PbTx-1, -2, and -3 were calculated to be 100, 200, and 170 µg/kg, respectively. The symptoms include immediate irritability, followed by hindquarter paralysis, dyspnea, salivation, lachrymation, urination, defecation, and death from respiratory paralysis (Landsberg, 2002; FAO/IOC/WHO, 2005).

The oral LD<sub>50</sub> in mice ranges from 520 µg/kg for PbTx-3 to 6600 µg/kg for PbTx-2 (FAO/IOC/WHO, 2005). PbTx-3 caused tremors followed by marked muscular contractions or fasciculations, tail elevation, labored breathing, and death (van Apeldorn *et al.*, 2001).

#### Repeated administration

Studies on repeated exposure to PbTxS were carried out in rats after inhalation of PbTx-3. Exposure to 500 µg PbTx-3/m<sup>3</sup> by nose-only inhalation for 0.5 or 2 h/day for 5 days (corresponding to 8.3 and 33 µg/kg/day, respectively) provoked a reduction of body weight at the highest dose, but no tissue lesions or signs of cytotoxicity and inflammation in bronchoalveolar lavage fluid were observed. In contrast, the humoral-mediated immunity was suppressed. A more prolonged inhalation exposure of rats (22 days) to PbTx-3 (corresponding to 0.9 and 5.8 µg/kg/day, respectively) showed similar results: reduced body weight in both PbTx-3 dosed groups of rats, suppression of humoral-mediated immunity, as well as minimal alveolar macrophage hyperplasia and increased blood reticulocytes (Benson *et al.*, 2004, 2005).

### Toxicity for fish and other marine animals

PbTxS are potent ichthyotoxins, being responsible for the deaths of billions of fish throughout the years. These toxins are thought to be absorbed through the gills, but

ingestion and mortality can also occur in the presence of approximately 250 *K. brevis* cells/mL. Signs of intoxication in fish include violent twisting and corkscrew swimming, defecation and regurgitation, pectoral fin paralysis, caudal fin curvature, loss of equilibrium, quiescence, vasodilatation, convulsions, and death due to respiratory failure. Chronically intoxicated fish show little pathology aside from slight precipitate hemolysis. Chronic hemolysis was detected via anemia, cyanosis, viscous blood, splenomegaly, hepatic hemosiderosis, and dehydration. Frequently, birds are also found moribund or dead, particularly double-crested cormorants, red-breasted mergansers, and lesser scaup, as are dolphins and manatees (Landsberg, 2002).

### Treatment

The treatment is symptomatic and supportive. Recovery occurs in 2 or 3 days (van Apeldorn *et al.*, 2001).

### Concluding remarks

In the United States and other countries, the regulatory level of 80 µg of PbTx-3 equivalents/100 g shellfish was established. Monitoring for NSP toxins is performed by *in vivo* MBA based on the observation of the survival time of mice after i.p. injection of an ether extract of shellfish. Brevetoxins are extensively metabolized in shellfish, and ELISA and LC-MS/MS alternatives for the monitoring of shellfish for the brevetoxins are being validated (Plakas and Dickey, 2010).

## PALYTOXIN AND ITS ANALOGS

### Background

Palytoxin (PLTX) is one of the most toxic nonprotein compounds known to date, originally isolated from the coral *Palythoa toxica* in Hawaii. It is a water-soluble compound characterized by a long, partially unsaturated aliphatic polyhydroxylated backbone with spaced cyclic ethers, 64 chiral centers, and two amide groups (Figure 69.10). PLTX and a series of its analogs, such as homoPLTX, bishomoPLTX, neoPLTX, deoxyPLTX, and 42-hydroxyPLTX, were subsequently identified in *Palythoa* species. Moreover, PLTX and its analogs, including ostreocin-d, mascarenotoxin-a, -b and -c, and ovatoxin-a, -b, -c, -d, and -e, were identified in benthic dinoflagellates of the genus *Ostreopsis*, which have been proposed as producing organisms even though a bacterial origin has been suggested (Katikou, 2008;

FIGURE 69.10 Chemical structure of palytoxin and two of its analogs (from Ciminiello *et al.*, 2011).

Ciminiello *et al.*, 2010). These species bloom in tropical and subtropical coastal waters, but their distribution has increased markedly in the past few years in temperate waters, such as the Mediterranean Sea (Rhodes, 2011).

A series of poisonings in humans have been associated with PLTXs by different exposure routes, although data confirming a direct relation between the illness and involvement of PLTXs are often lacking. The occurrence of toxic *Ostreopsis* species may result in the accumulation of PLTXs in edible marine organisms. Human illness and death arising from consumption of crabs and fish contaminated or suspected to be contaminated with PLTXs have been reported in tropical and subtropical areas. The most frequent symptoms include gastrointestinal ones, myalgia, muscle cramps, cardiac dysfunctions, respiratory problems, and cyanosis, with rhabdomyolysis the most commonly reported complication. Recent cases of human poisoning were associated with inhalation and/or cutaneous/systemic exposures after direct contact with aerosolized seawater during *Ostreopsis* blooms in Europe or through maintaining aquaria containing zoanthids. In these cases, the most common symptoms

were respiratory distress, rhinorrhea, cough, and fever. Dermatitis was also reported. Toxin identification and/or quantification are often incomplete or missing, and cases of poisoning are frequently ascribed to PLTXs on the basis of symptoms, anamnesis, and environmental/epidemiological data (i.e., zoanthid handling and ingestion of a particular fish or crab species) (Tubaro *et al.*, 2011a).

### Pharmacokinetics/toxicokinetics

No pharmacokinetic/toxicokinetic studies on PLTXs are available. An attempt to use Caco-2 cell lines to predict the PLTX absorption was hindered by its cytotoxicity (Pelin *et al.*, 2011).

### Mechanism of action

The main molecular target of PLTX seems to be Na<sup>+</sup>/K<sup>+</sup>-ATPase, a plasma membrane pump involved in the maintenance of transmembrane ionic gradients of animal

cells, which is essential for cell functions. Interaction of PLTX with  $\text{Na}^+/\text{K}^+$ -ATPase induces a change in the protein conformation that results in its conversion into a nonselective channel for monovalent cations. Therefore, the gates on the two sides of the membrane are simultaneously opened with consequent  $\text{Na}^+$  influx into the cells and  $\text{K}^+$  efflux, causing depolarization and triggering a series of adverse biological effects (Wu, 2009; Rossini and Bigiani, 2011).

## Toxicity

### Human toxicity

Human illnesses ascribed to PLTXs have occurred after seafood consumption but also after inhalation and cutaneous/systemic exposures to aerosolized seawater during *Ostreopsis* blooms or from handling zoanthids containing aquaria. Poisonings by oral exposure, with some fatalities, have occurred in tropical and subtropical areas. The most common signs and symptoms are gastrointestinal ones, myalgia, muscle cramps, cardiac dysfunctions, respiratory problems, and cyanosis, with frequent elevated serum levels of creatine phosphokinase and myoglobinuria raised by rhabdomyolysis. On the other hand, the most common signs after supposed inhalational and cutaneous/systemic exposures are respiratory distress, rhinorrhea, cough, fever, and a minor incidence of dermatitis. The actual toxicological potential of PLTXs has yet to be fully evaluated, as reported by Tubaro *et al.* (2011a). Despite the limited toxicological data on PLTXs, an oral acute reference dose (ARfD) of  $0.2\text{ }\mu\text{g/kg}$  (sum of PLTX and ostreocin-d) has been established using experimental toxicity data (EFSA, 2009a).

### Experimental toxicity

#### Single administration

The acute toxicity of PLTX to mammals is strongly dependent on the exposure route. PLTX is most toxic after parenteral administration. The rabbit, dog, rhesus monkey, and rat seem to be the most susceptible species to PLTX by i.v. injection, and the mouse seems to be the least susceptible, although wide variations in estimated  $\text{LD}_{50}$  values ( $0.025\text{--}0.53\text{ }\mu\text{g/kg}$ ) in mice are reported. This is also because different PLTX preparations (with varying purity) have been used, especially in the first studies. PLTX is less toxic i.p. than by i.v. injection, with  $\text{LD}_{50}$  values in mice ranging from  $0.31$  to  $1.5\text{ }\mu\text{g/kg}$ ; the i.p. toxicity in mice of the PLTX analog ostreocin-d (Figure 69.10) was lower (lethality  $>4\text{ }\mu\text{g/kg}$ ).  $\text{LD}_{50}$  values of PLTX by i.p. injection are similar to those after intramuscular and subcutaneous injections.

PLTXs are also highly toxic by intratracheal instillation: the lethal dose of PLTX and ostreocin-d was greater than 2 and  $11\text{--}13\text{ }\mu\text{g/kg}$ , respectively (Wiles *et al.*, 1974; Ito and Yasumoto, 2009). PLTX is much less toxic by the oral route, and in mice,  $\text{LD}_{50}$  values of 510 and  $767\text{ }\mu\text{g/kg}$  have been calculated (Munday, 2008a; Sosa *et al.*, 2009). Comparable lethality ( $\text{LD}_{50} = 651\text{ }\mu\text{g/kg}$ ) was estimated in mice for 42-hydroxyPLTX (Figure 69.10) (Tubaro *et al.*, 2011b), whereas no lethality was observed for ostreocin-d at  $300\text{ }\mu\text{g/kg}$  (Ito and Yasumoto, 2009). PLTX and ostreocin-d ( $200\text{ }\mu\text{g/kg}$ ) seem also to be toxic after sublingual administration to mice (Ito and Yasumoto, 2009).

Following PLTX i.p. injection in mice, adhesions were observed in the peritoneum, with ascites and small intestine dilation. At the histological level, the toxin induced single-cell necrosis in the hearts and necrosis of thymus and spleen lymphocytes. Bleeding, edema, and necrosis were recorded in the small intestine. Electron microscopy showed rounding of mitochondria and separation of organelles in myocytes, loss of microvilli in renal tubules, and vacuolation of pancreatic acinar cells (Terao *et al.*, 1992; Ito *et al.*, 1996). Ostreocin-d injection in mice caused erosion in the stomach and intestines (Ito and Yasumoto, 2009).

Intratracheal PLTX instillation in mice caused alveolar hemorrhage, pulmonary edema, gastrointestinal erosion, and glomerular atrophy. Similar lung injuries were observed in ostreocin-d-treated mice but showed slower progression and recovery than those from PLTX (Ito and Yasumoto, 2009).

After oral administration of PLTX, increased plasma levels of creatine phosphokinase, lactate dehydrogenase, and aspartate transaminase were recorded in mice. At the histological level, forestomach inflammation was observed in mice surviving up to 24 h after administration; other aspecific tissue alterations were noted in the liver and pancreas, whereas cardiac and skeletal muscle cells revealed only ultrastructural alterations visible by electron microscopy (Sosa *et al.*, 2009). Similar findings were noted in 42-hydroxyPLTX-treated mice, in which a plasma increase of potassium ions was also recorded (Tubaro *et al.*, 2011b). Application of PLTX to mouse ear skin induced irritation, and the dose causing erythema in 50% of mice was  $0.02\text{ }\mu\text{g/ear}$  (Fujiki *et al.*, 1986).

#### Repeated administration

After repeated i.p. injections of PLTX in mice ( $0.25\text{ }\mu\text{g/kg}$ , five times per week; total injections: 5, 10, 15, and 29), diarrhea and peritonitis were recorded after 29 doses (60% of mice). Necrosis of thymic and splenic lymphocytes was also observed. Moreover, decreased thymus weights and increased spleen weights were noted after 10–15 doses. These changes were reversible within 1 month after the 29th dose (Ito *et al.*, 1997).

#### Mutagenic and genotoxic activity

PLTX was negative in the Ames mutagenicity test using strains of *Salmonella typhimurium* with or without microsomal activation. Furthermore, it did not act as an initiator in the *in vitro* BALB/c 3T3 cell transformation assay or in mouse skin *in vivo* (Fujiki *et al.*, 1986; Munday, 2011).

#### Tumor-promoting activity

PLTX is a tumor promoter, as evidenced by two-stage carcinogenesis studies in mouse skin and in the *in vitro* BALB/c 3T3 cell transformation assay (Fujiki *et al.*, 1986; Munday, 2011).

#### Treatment

The treatment of poisonings implicating PLTX is mainly supportive and depends on the exposure route. After oral intake, treatments such as gastric lavage, forced diuresis therapy, artificial respiration, and fluids administration were applied but in some cases could not prevent fatalities. After inhalational and/or skin exposure, in some cases corticosteroids, nonsteroidal anti-inflammatory drugs, histamine antagonists, nebulized  $\beta$ -agonists, and/or oxygen therapy were administered to alleviate the symptoms, with recovery within a few hours or days (Tubaro *et al.*, 2011a).

#### Concluding remarks

PLTXs may contaminate edible marine organisms, with possible severe toxic effects in humans after seafood consumption. Adverse effects can also occur by inhalation and cutaneous/systemic exposures after contact with aerosolized seawater during *Ostreopsis* blooms and/or handling zoanthids containing aquaria. Episodes of poisoning have often been indirectly ascribed to PLTXs on the basis of symptoms, anamnesis, and environmental/epidemiological data. Thus, careful case reports are necessary to identify PLTXs as the causative agents of the poisoning and to unambiguously define the toxicological risk related to PLTX exposure. Despite the increasing occurrence of *Ostreopsis* species producing PLTXs in temperate coastal areas, there are no regulations on PLTXs in shellfish. Considering the lack of reliable quantitative data on PLTX toxicity in humans and the LOAEL of 200  $\mu\text{g}$  PLTX/kg for acute oral toxicity in mice as the reference point, an ARfD of 0.2  $\mu\text{g}/\text{kg}$ , applied to the sum of PLTX and ostreocin-d, has been established by the European Food Safety Authority to propose 30  $\mu\text{g}/\text{kg}$  as tolerance limit in shellfish meat (EFSA, 2009a).

To detect PLTXs in shellfish, cell-based assays such as cytotoxicity assays on neuroblastoma cells and hemolysis assay have also been developed but not standardized.

High-performance liquid mass spectrometry methods and LC-MS/MS methods are promising tools for PLTX detection. However, their optimization and validation, as well as the development of certified reference materials and standards, are necessary (EFSA, 2009a; Ciminiello *et al.*, 2011).

## OKADAIC ACID AND ITS DERIVATIVES

### Background

Okadaic acid (OA) and its derivatives provoke the human illness called diarrhetic shellfish poisoning (DSP). DSP symptoms are mainly gastrointestinal distress, diarrhea, nausea, vomiting, and abdominal cramps, occurring between 30 min and several hours after contaminated shellfish consumption. It is not a fatal illness, and complete recovery occurs within 3 days, generally without any treatment. Nevertheless, DSP is an important cause of morbidity worldwide, causing serious problems for the shellfish industry and regulators. DSP toxins are lipid-soluble and heat-stable polyethers, including OA and its derivatives, dinophysins (DTXs), the most frequent being DTX-1, DTX-2, and DTX-3 (Figure 69.11). OA, the main DSP toxin originally isolated from *Halichondria okadae* sponge, is produced by dinoflagellates of the genus *Dinophysis*, similarly to DTX-1 and DTX-2. These compounds are also produced by cultured dinoflagellates of the *Prorocentrum* genus, but these species were sporadically detected in phytoplankton during DSP outbreaks. DTX-3, a mixture of OA, DTX-1, and/or DTX-2 esterified with a fatty acid generally at the 7-hydroxy group, is believed to be a metabolic product of shellfish rather than algal metabolites (Tubaro *et al.*, 2008a). The first documented dinoflagellate species involved in DSP was *D. fortii* in Japan and later in other areas. Other species, such as *D. acuminata*, *D. acuta*, *D. caudata*, *D. mitra*, *D. norvegica*, *D. rotundata*, *D. tripos*, *D. sacculus*, and *D. trunculus*, have also been reported as sources of DSP toxins. Toxin production may vary considerably among these species as well as among regional and seasonal morphotypes in one species (Hallegraeff, 2003). Several bivalves, such as mussels, scallops, oysters, and clams, by filtering the seawater and the toxic phytoplankton, can accumulate the toxins and cause human poisoning after their ingestion.

DSP cases have been reported in many different areas of the world, but most cases have been reported in Japan, Europe, and, to a lesser extent, North and South America, Thailand, Australia, and New Zealand (Hallegraeff, 2003; Fux *et al.*, 2011). One major DSP outbreak, involving more than 300 people, occurred in Italy in September 2010. In 2011, the first documented

FIGURE 69.11 Chemical structure of okadaic acid (OA) and dinophys toxin (DTX)-1, -2, and -3 (from Quilliam, 2003).

outbreaks of DSP in North America occurred in waters of the Pacific Northwest: more than 60 cases were reported from shellfish harvested at Salt Spring Island, British Columbia, Canada, and farther south, 3 cases were reported from shellfish of Sequim Bay, Washington (NOAA, 2011). LC-MS/MS analysis revealed the presence of DTX-1 and its fatty acid esters. DSP cases, or at least the presence of algae-producing OAs, appear to be increasing, but this perception may also be influenced by improved knowledge of the disease and surveillance programs.

### Pharmacokinetics/toxicokinetics

Some toxicokinetic studies on OA have been performed in mice. Twenty-four hours after single oral [<sup>3</sup>H]OA administration to mice (50 or 90 µg/kg), the toxin was detected in all organs and fluids, including skin, and was most concentrated in urine, intestinal contents, and intestine. The slow OA elimination suggested an enterohepatic circulation (Matias *et al.*, 1999). A study by Ito *et al.* (2002a) revealed that after wider oral doses of OA in mice (75–250 µg/kg), the toxin was quickly absorbed from the small intestine, mainly from jejunum, reaching the liver within 5 min. The distribution of the toxin, evaluated by an immunostaining method, involved the whole body, being detected in lungs, liver, heart, kidneys, and intestine, in which it was still detectable after 2 weeks. Excretion from kidneys and intestine began 5 min after administration, and elimination through feces continued for 4 weeks. Another immunohistochemical study after acute oral OA administration in mice (115 and 230 µg/kg) showed the presence of low amounts of the toxin in the liver 24 and 48 h

later, respectively; the toxin was detected in the duodenum and ileum (localized in the mucosal secretions of the goblet cells) but not in the colon secretions (Le Hégarat *et al.*, 2006). Thus, after acute oral administration in mice, OA seems to be distributed in the following rank order: intestinal content > urine > feces > intestine tissue > lung > liver > stomach > kidney > blood (Toyofuku, 2006).

After i.p. injection of [<sup>3</sup>H]OA to mice (14 µCi/0.2 mL), most of the radioactivity (33%) was detected in the gastrointestinal contents 3 h later, whereas 5% was measured after 19 h. In the liver, 27 and 16% of the radioactivity was detected after 3 and 19 h, respectively, suggesting a hepatobiliary circulation (Fujiki and Suganuma, 1993; Nishiwaki *et al.*, 1994).

After intramuscular injection of [<sup>3</sup>H]OA to mice (25 µg/kg), the toxin was detected in bile and intestinal contents 1 h later, and its elimination pattern showed biliary excretion and enterohepatic circulation. OA transplacental passage in mice was also observed (Matias and Creppy, 1996a,b).

A poisoning episode in humans due to ingestion of DTX-3-contaminated mussels gave evidence for a biotransformation into DTX-1, which was the only DSP toxin detected in the feces (García *et al.*, 2005).

An *in vitro* study using Caco-2 cells as a model of human intestinal barrier showed that low-level exposure of the cell monolayer to OA (20–200 nM) allows only limited passage of the toxin from the “luminal” to the “blood side,” but a significant efflux was observed, suggesting an active transport mechanism for OA elimination (Ehlers *et al.*, 2011). Another *in vitro* study showed OA biotransformation to oxygenated metabolites by two liver P450 cytochromes – a process that does not seem to detoxify OA (Guo *et al.*, 2010).

## Mechanism of action

OA and DTX-1 inhibit protein phosphatases, mainly protein phosphatases 1 and 2A, which are two enzymes that dephosphorylate serine/threonine residues of eukaryotic cell proteins (Bialojan and Takai, 1988). As a consequence, a rapid increase in phosphorylated proteins occurs in cells. The diarrhea and the degenerative changes in absorptive epithelium of small intestine induced by these toxins have been attributed to an increased level of the phosphorylated proteins controlling ions secretion in intestinal cells and of cytoskeletal and/or junctional elements regulating the permeability to solutes: these events result in a passive loss of fluids (Domínguez *et al.*, 2010). Inhibition of protein phosphatases is also involved in other effects, including the tumor-promoting properties of these toxins (Fujiki and Suganuma, 1993). A free carboxyl group in the DSP molecule is essential mechanistically because methyl and diol esters do not show inhibition (Mountfort *et al.*, 2001).

## Toxicity

### Human toxicity

DSP symptoms are mainly diarrhea, nausea, vomiting, and abdominal pain. Although the intoxication can be highly debilitating for some days, no human mortalities from DSP have been reported. Recovery is usually complete in 3 days, despite the pharmacological treatment. A LOAEL of 0.8 µg OA equivalents/kg has been estimated, deriving an ARfD of 0.3 µg OA/kg (EFSA, 2008a).

### Experimental toxicity

#### Single administration

After single i.p. injection in mice, the LD<sub>50</sub> of OA ranged from 192 to 225 µg/kg (Tubaro *et al.*, 2008a). An LD<sub>50</sub> of 352 µg/kg was determined for DTX-2, and a relative potency of 0.6 was estimated compared to that of OA, which was ascribed to the axial 35-methyl group of DTX-2 that would give rise to lower affinity for PP2A (Aune *et al.*, 2007; Huhn *et al.*, 2009). Intraperitoneal injection of OA or DTX-1 (≥200 and 375 µg/kg) in rodents (mice and rats) induced damages in the intestinal mucosa, particularly the duodenum and upper part of the jejunum, within 15 min. The injuries can be divided into three consecutive stages: increased capillary permeability and extravasation of serum into the lamina propria of villi, degeneration of absorptive epithelium of villi, and desquamation of the degenerated epithelium from the lamina propria. At sublethal doses, these alterations are reversible, and the recovery process, observed already after 2 h, is complete within 24 h (Terao *et al.*, 1986, 1993; Ito and Terao, 1994). Morphological changes

induced by DTX-3 are less pronounced and consist only of dilation of the cisternae of the Golgi apparatus and the presence of vesicles in the cytoplasm of the absorptive epithelium (Terao *et al.*, 1993). Intraperitoneal injection of OA, DTX-1, or DTX-3 in rodents also induces liver damage, with vacuolization and/or necrosis of hepatocytes (Terao *et al.*, 1993; Ito and Terao, 1994; Aune *et al.*, 1998; Tubaro *et al.*, 2003).

OA-induced liver damage also occurs after i.v. injection in rats, with congestion of blood in the liver and dissolution of hepatic bile canalicular actin sheaths (Berven *et al.*, 2001).

OA, DTX-1, and DTX-3 are less toxic orally than intraperitoneally. By the oral route, the LD<sub>50</sub> of OA in mice ranges between 1 and 2 mg/kg (Tubaro *et al.*, 2003). In addition to diarrhea, the signs of toxicity are similar to those observed after i.p. injection. DTX-1 and DTX-3 also cause the degeneration of surface cells of the gastric mucosa (Terao *et al.*, 1993; Ito and Terao, 1994; Ito *et al.*, 2000; Berven *et al.*, 2001).

#### Repeated administration

Daily repeated oral OA administration in mice (1 mg/kg/day for 7 days) induced diarrhea, body weight loss, reduced food consumption, and death of two of five mice after 5 days. Toxic effects are noted in forestomach and liver, whereas ultrastructural changes are seen in cardiomyocytes (mitochondria and fibers) (Tubaro *et al.*, 2004).

#### Mutagenic and genotoxic activity

Although OA is not mutagenic in *S. typhimurium* in the absence or presence of metabolic activation, it is mutagenic in various eukaryotic cells *in vitro* (Aune and Yndestad, 1993; Fessard *et al.*, 1996). No genotoxicity data are available for DTX-2 and DTX-3. Genotoxic effects of OA, such as micronuclei formation, mitotic arrest, and polyploidy, were observed in human Caco-2 cells (Le Hégarat *et al.*, 2006). OA is not reported on any of the lists of the International Agency of Research on Cancer.

#### Tumor-promoting activity

OA and DTX-1 are tumor promoters, as evidenced by two-stage carcinogenesis studies on mouse skin (Fujiki and Suganuma, 1993) and rat glandular stomach (Suganuma *et al.*, 1992).

## Treatment

The treatment of the diarrheic poisoning is symptomatic and supportive with regard to short-term diarrhea and loss of fluids and electrolytes. In general, hospitalization is not necessary. Other diarrheic illnesses associated with

shellfish consumption, such as bacterial and viral contamination, should be ruled out on the basis of anamnesis of the patients (Aune and Yndestad, 1993).

### Concluding remarks

OA and DTXs are involved in DSP and possess tumor-promotion activity through their inhibition of protein phosphatases. DSP risk is managed by monitoring seafood for toxicity: frequency of sampling should ensure that contamination does not rise to dangerous levels in temporal or spatial gaps between sampling times or locations. Monitoring programs should also assess the toxin-producing phytoplankton organisms in the water column. When this is accomplished in real time, a potentially toxic bloom can be detected earlier than chemical analysis can be applied to detect shellfish contamination. An example is provided by the first instance in which OA was confirmed in U.S. shellfish: although OA was later detected in Texas shellfish by LC-MS/MS (Deeds *et al.*, 2010), the harvest had already been closed due to prior detection of the (*Dinophysis*) bloom by a remote instrument, the FlowCytobot (Campbell *et al.*, 2010).

Various methods have been developed for analysis of DSP toxins, including *in vivo* bioassays and *in vitro* biochemical or biological assays, as well as chemical methods of analysis. The MBA is the accepted method for DSP toxins determination in shellfish because it can detect all DSP toxins, although other lipophilic compounds can interfere. It evaluates the survival time of mice injected i.p. with a suspension of a shellfish extract usually over a 24-h observation period (Fernández *et al.*, 2003). Immunoassays include enzyme-linked assays (ELISA kits are commercially available) or radioactivity-based immunoassays and also lateral flow immunochromatography test kits, which are threshold based, use visual endpoints, and are now commercialized. Protein phosphatase 2A inhibition assays are particularly sensitive *in vitro* functional assays, being based on the mechanism of OA action (Cembella *et al.*, 2003), and have been commercialized in test kit formats. Chemical methods of analysis include HPLC, capillary electrophoresis, and LC-MS techniques (Quilliam, 2003). For the functional, ELISA, and instrumental methods, the results should include the toxins release by hydrolysis of their esters. The maximum tolerated level of these toxins was set at 160 µg OA equivalents/kg of shellfish meat (European Commission, 2002).

Regarding the control of DSP toxins, their regulation in most countries is based on the negative results of shellfish samples by the MBA. The European Union is phasing out the MBA (European Commission, 2011), which will be replaced by an LC-MS/MS method that has been interlaboratory validated at the EU Reference

Laboratory for Marine Biotoxins (Villar-González *et al.*, 2011). Alternatives or complementary methods can be used when properly validated; however, there are inherent advantages in using LC-MS/MS to monitor lipophilic toxins because several classes of toxins addressed in regulations can be detected at once.

## AZASPIRACIDS

### Background

Azaspiracid poisoning (AZP) is a relatively recent development, first reported in 1995 in the Netherlands when eight people became ill following ingestion of blue mussels from Ireland. The victims developed symptoms very similar to those of DSP, despite the low content of OA and its derivatives. Subsequently, the azaspiracid toxin group was discovered. The structural elucidation of the first AZP toxin, azaspiracid1 (AZA1), showed its polyether backbone with a unique spiral ring assembly, a cyclic amine, and a carboxylic acid (Figure 69.12). More than 30 analogs have been identified, but AZA1, AZA2, and AZA3 are the most important ones based on occurrence and toxicity (Twiner *et al.*, 2008; EFSA, 2008b).

AZAs, first detected in blue mussels (*M. edulis*), have been found in other bivalves, including other *Mytilus* species, oysters (*Crassostrea gigas* and *Ostrea edulis*), scallops (*Pecten maximus* and *Argopecten purpuratus*), clams (*Tapes philippinarum*, *Ensis siliqua*, and *Donax* spp.), and cockles (*C. edule*), as well as in crustaceans (*Cancer pagurus*) (Twiner *et al.*, 2008; López-Rivera *et al.*, 2010). Reports of AZA poisonings and/or contaminated shellfish have been documented from several European countries, including Ireland, the United Kingdom, Norway, the Netherlands, France, Spain, and Italy. The source of AZAs has been identified as the dinoflagellate *Azodinium spinosum*. Although AZAs have been identified mainly in western Europe, they have recently been detected in northwestern Africa, eastern Canada, and South America. AZP may be widespread but generally under-reported because its gastrointestinal symptoms are similar to those of DSP or of bacterial enterotoxin poisoning (Furey *et al.*, 2010).

### Pharmacokinetics/toxicokinetics

Aasen *et al.* (2010, 2011) observed absorption of AZA1 after acute oral administration to mice (100–300 µg/kg). A dose-dependent increase in the toxin concentration in tissues was observed, and after 24 h, the highest levels of AZA1 were found in the gastrointestinal tissues (stomach > duodenum > jejunum > ileum > colon); in other

**FIGURE 69.12** Chemical structure of azaspiracid-1 (from James *et al.*, 2004).

organs, the order of ranking was lungs > heart > liver, and only trace amounts were detected in the brain. After 7 days, the levels of AZA1 had markedly decreased in all organs except the kidneys. The amount of toxin was the highest in the liver, followed by kidneys, lungs, spleen, and heart. After 24h, the total amount of toxin in the internal organs was approximately 2% of the administered doses.

### Mechanism of action

The mechanism of action of AZAs is unclear. However, several effects on *in vitro* cell cultures have been reported for AZA1, including cytoskeletal alterations and decreased F-actin pools, with irreversible effects after toxin withdrawal; alteration of tight junction proteins and E-cadherin degradation; activation/apoptosis; membrane cholesterol reduction; cytosolic  $\text{Ca}^{2+}$  and cAMP level modulation; and alteration of expression of different cellular proteins and energy metabolism as well as neuronal cells signaling (Ryan *et al.*, 2008; Vilariño, 2008; Furey *et al.*, 2010). The AZA-induced F-actin and cytoskeletal alterations and tight junction protein changes could be responsible for some of the *in vivo* toxic effects, such as the gastrointestinal toxicity and diarrheic activity. A possible factor contributing to increased fluid secretion in AZA-induced diarrhea seems to be the increased paracellular permeability of intestinal epithelium, as suggested by *in vitro* findings in human intestinal Caco-2 cells. In fact, alterations in the levels and localization of tight junction proteins, involved in the regulation of intestinal barrier function, were observed and correlated with the increased paracellular permeability (Ryan *et al.*, 2008; James *et al.*, 2010).

## Toxicity

### Human toxicity

The human symptoms include nausea, vomiting, severe diarrhea, and stomach cramps (James *et al.*, 2010). A LOAEL of 1.9  $\mu\text{g}$  AZA1 equivalents/kg was estimated, and an ARfD of 0.2  $\mu\text{g}$  AZA1/kg was established (EFSA, 2008b).

### Experimental toxicity

#### Single administration

By i.p. injection, the lethal dose of AZA1 in mice has been determined to be 200  $\mu\text{g}/\text{kg}$ ; AZA2 and AZA3 are more toxic (110 and 140  $\mu\text{g}/\text{kg}$ , respectively), contrary to AZA4 (470  $\mu\text{g}/\text{kg}$ ) and AZA5 (<1 mg/kg). Although diarrhea is the main symptom in humans, AZAs did not cause diarrhea by i.p. injection: before death, mice showed progressive paralysis of the limbs, dyspnea, and convulsions (James *et al.*, 2004; Twiner *et al.*, 2008).

After oral administration of AZA1 ( $\geq 300 \mu\text{g}/\text{kg}$ ) to mice, necrosis in the lamina propria of the small intestine and in thymus, spleen, and Peyer's patches was observed (necrotic T and B lymphocytes). Fatty changes in the liver were also observed. The authors hypothesized that the oral toxicity is 2.5 times higher than that after i.p. injection, but no data on  $\text{LD}_{50}$ s are available (Ito *et al.*, 2000). Following sublethal dosing of AZA1 (100–300  $\mu\text{g}/\text{kg}$ ) to mice, pathological changes were only detected in duodenum after 24h (mild cellular detachment in the tips of the villi, expansion of the crypts and necrotic/apoptotic changes in lamina propria, and neutrophil infiltration), which were recovered after 7 days (Aasen *et al.*, 2010). No data on oral toxicity are available for AZA analogs.

#### Repeated administration

After repeated oral intake of sublethal doses of AZA1 (250–450  $\mu\text{g}/\text{kg}$ ), death in some mice occurred, and serious gastrointestinal, pulmonary, and hepatic effects that persisted for a prolonged period in survived mice were observed. Repeated oral administration of AZA1 once or twice a week (20–50  $\mu\text{g}/\text{kg}$  for 10–20 weeks) caused interstitial pneumonia, shortening of intestinal villi, as well as death of some mice. Lung tumors developed in 4/20 mice treated with 20 or 50  $\mu\text{g}$  AZA1/kg, but further studies are needed to confirm the carcinogenicity of this toxin (Ito *et al.*, 2002b). No genotoxicity data are available, and no definitive conclusions regarding relevance to humans can be drawn (EFSA, 2008b; Twiner *et al.*, 2008).

## Treatment

As for DSP, a specific antidote is not available for AZP. The treatment is only symptomatic and supportive.

## Concluding remarks

The maximum overall level of azaspiracid was set by the European Union at 160 µg of AZA1 equivalents/kg of edible meat (European Commission, 2002). Mouse or rat bioassay can detect AZAs with a limit of detection of approximately 160 µg/kg, but other lipophilic toxins can potentially interfere. As with the okadaic acids, European use of the MBA in detecting the azaspiracids is being gradually phased out, to be replaced by the same LC-MS/MS methodology approved for OA toxins and other lipophilic marine toxins of concern in Europe (Villar-González *et al.*, 2011). Alternative or complementary methods may possibly be used after their international validation (European Commission, 2011).

## OTHER LIPOPHILIC TOXINS

### YESSOTOXINS

#### Background

Yessotoxin (YTX) (Figure 69.13) is a ladder-shaped polycyclic ether that was first isolated from the scallop *Patinopecten yessoensis*. YTX and its analogs were initially included in the DSP group, being detected with OA

and other lipophilic toxins during the shellfish extraction for DSP bioassay. Subsequently, YTXs have been classified and regulated separately because they do not induce diarrhea. More than 30 YTX analogs have been isolated from shellfish or microalgae, and the existence of approximately 100 analogs has been reported to date. No human toxicity has been ascribed to YTXs, but many YTXs are highly toxic to mice intraperitoneally (Tubaro *et al.*, 2010).

YTXs are produced by dinoflagellates such as *Protoceratium reticulatum* (= *Gonyaulax grindley*), *Lingulodinium polyedrum* (= *Gonyaulax polyedra*), and *Gonyaulax spinifera*. Because these algal species are common in coastal waters of many regions, YTXs may occur worldwide, and during their filter-feeding activity, edible shellfish can concentrate these compounds (Paz *et al.*, 2008).

#### Pharmacokinetics/toxicokinetics

Twenty-four hours after acute oral YTX administration in mice (1 and 5 mg/kg), the highest toxin levels were found in ileum, followed by colon, jejunum and duodenum, kidneys, spleen, heart, and blood (Aasen *et al.*, 2011). Twenty-four hours after the last gavage to mice (1 mg YTX/kg/day for 7 days), Tubaro *et al.* (2008b) detected a mean YTX blood concentration of approximately 6 ng/ml (5 nM) by an ELISA method. No data on the metabolism of YTXs are available.

FIGURE 69.13 Chemical structure of yessotoxin (from Quilliam, 2003).

## Mechanism of action

Although low concentrations of YTX affect many systems *in vitro*, some of these effects are not confirmed *in vivo* after *per os* exposure and the precise mechanism of action of YTXs is not yet known. It is known that YTX is a cytotoxic against several cell lines, affecting a variety of cellular activities. YTX has been shown to induce apoptosis-activating caspases, to open the mitochondrial permeability transition pore, to impair protein disposal and phagocytic activity, to affect cytoskeletal components, and to modulate intracellular  $\text{Ca}^{2+}$  and cAMP levels. YTX has also been shown to inhibit cardiomyocyte beating frequency (Tubaro *et al.*, 2010).

## Toxicity

### Human toxicity

There are no reports of human poisoning by YTXs. A dose of 5mg/kg has been adopted as the most robust no-observed-adverse-effect level for acute cardiotoxicity of YTX on the basis of light microscopy findings in mice; an ARfD of 25µg YTX equivalents/kg has been established (EFSA, 2008c).

### Experimental toxicity

Only YTX, de-sulfo-YTX, homo-YTX, and 45-OH-homoYTX have been submitted to actual toxicological studies.

#### Single administration

After i.p. injection in mice, LD<sub>50</sub> values ranging from 100 and 750µg/kg were reported for YTX and homoYTX, whereas 45-OH-homoYTX was not lethal at 750µg/kg (Tubaro *et al.*, 2010). Light microscopy revealed only slight intracellular edema in the heart of animals treated with 750 and 1000µg/kg (Aune *et al.*, 2002). Electron microscopy revealed swelling of some cardiomyocytes and rounded mitochondria (Terao *et al.*, 1990; Aune *et al.*, 2002; Tubaro *et al.*, 2003). Damages to cerebellar Purkinje cells after i.p. injection of YTX (420µg/kg) were also observed, but these were not confirmed by oral exposure (Hungerford, 2006).

After oral administration, YTXs are much less toxic. No lethality or signs of toxicity were observed in mice after acute administration of YTX (0.5–10mg/kg). Only ultrastructural changes were noted in myocardium, similar to those described after i.p. injection (Terao *et al.*, 1990; Aune *et al.*, 2002; Tubaro *et al.*, 2003). Although YTX induces apoptosis *in vitro* in various cell lines, no apoptotic changes were noted in the myocardium of mice by *in situ* TUNEL staining (Tubaro *et al.*, 2003). A study found that the oral effects of YTX (1 and 5mg/kg) are

not enhanced by a sublethal (200µg/kg) dose of AZA1 (Aasen *et al.*, 2011).

#### Repeated administration

Following repeated oral administration for 7 days, no deaths, changes in behavior or growth, or macroscopic abnormalities were observed for YTX (1 and 2mg/kg/day), homoYTX, and 45-OH-homoYTX (1mg/kg/day). Only ultrastructural changes in cardiomyocytes (rounded mitochondria and alterations of cell boundary) were observed (Tubaro *et al.*, 2004). These ultrastructural changes were also noted 30 days after the last YTX administration (1mg/kg/day) but seemed to be recovered within 90 days (Tubaro *et al.*, 2008b). In another study, mice were exposed to YTX seven times during 21 days (1–5mg/kg) and sacrificed 3 days after the last treatment: by electron microscopy, vacuoles were seen in the myocardium at the highest toxin dose (Espenes *et al.*, 2006).

## Concluding remarks

Due to the lack of evidence of adverse effects in humans and the significant reduction in potency after oral administration compared to i.p. injection in mice, a regulatory level of 1mg YTX equivalents/kg shellfish has been established in some countries. For regulatory purposes, LC-MS/MS has been adopted in the European Union as the reference method for YTX detection in shellfish, but alternative or complementary methods can be used (European Commission, 2011).

## PECTENOTOXINS

### Background

Pectenotoxins (PTXs) are hepatotoxic compounds that were initially classified as DSP toxins because DSP toxins are often detected in shellfish and phytoplankton together with these compounds. Nevertheless, despite the fact that a PTX derivative was associated with severe diarrheic illnesses in Australia, the actual diarrhogenic potential of PTXs and the actual health threat to consumers of contaminated mussels are unclear (EFSA, 2009b; Dominguez *et al.*, 2010).

PTXs are polyether macrolides containing a spiroketal group, three substituted oxolanes, a bicyclic ketal, and a six-membered cyclic hemiketal. PTXs have been detected in shellfish and/or phytoplankton from many areas of the world, including Japan, Australia, New Zealand, and Europe. More than 20 PTX analogs (Figure 69.14) have been identified in phytoplankton or shellfish, and several of them derive from a parent PTX that is metabolized

FIGURE 69.14 Chemical structure of pectenotoxin-2 (PTX-2) and its seco acids (from Draisci *et al.*, 2000).

within the shellfish. The most commonly found PTX in algae is PTX-2, produced by dinoflagellates of the genus *Dinophysis*. PTXs are accumulated in the digestive glands of filter-feeding bivalves, such as scallops (*Patinopecten yessoensis*), green-shell mussels (*Perna canaliculus*), blue mussels (*M. galloprovincialis* and *M. edulis*), cockles (*C. edule*), and pipis (*Donax delatoides*), after filtration of *Dinophysis* cells (Munday, 2008b; Suzuki, 2008; Dominguez *et al.*, 2010). These organisms can transfer the toxins to humans after their consumption.

### Pharmacokinetics/toxicokinetics

The distribution of PTX-2 and PTX-2 seco acid was studied in mice by oral and i.p. routes. After oral intake, both toxins were detected mainly in the gastrointestinal tract content and/or feces, only a small portion of toxins were found in the gastrointestinal tissue, and an extremely low amount of PTX-2 seco acid was found in the liver. After i.p. injection, the distribution of the toxins was similar, with a slightly higher presence in the liver and detectable levels in blood and kidney. Moreover, a considerable amount of PTX-2 was converted to PTX-2 seco acid or 7-*epi*-PTX-2 seco acid. Thus, PTXs do not seem to be readily absorbed after oral intake (Munday, 2008b).

### Mechanism of action

The mechanism of hepatotoxic action of PTXs has to be clarified. PTXs are cytotoxic against several cancer cell

lines, and PTX-1 and PTX-2 have been shown to induce apoptotic effects. *In vitro* studies revealed a disruption of actin cytoskeleton by PTX-1, PTX-2, and PTX-6. Furthermore, PTX-6 modified cAMP levels in human lymphocytes (Leira *et al.*, 2002; Espiña and Rubiolo, 2008; Dominguez *et al.*, 2010).

## Toxicity

### Human toxicity

PTXs have been associated with severe diarrheic illness in Australia. However, although the shellfish involved in the poisoning contained PTX-2 seco acid, the gastrointestinal effects were later attributed to OA esters. Consequently, no evidence of gastrointestinal or other adverse effects in humans from PTXs is available. For intestinal toxicity of PTX-2 observed in mice, a LOAEL of 250 µg/kg was considered and an ARfD of 0.8 µg/kg was established (EFSA, 2009b).

### Experimental toxicity

#### Single administration

After i.p. injection in mice, LD<sub>50</sub> values of PTXs were determined to be 250 µg/kg (PTX-1 and PTX-11), 219–260 µg/kg (PTX-2), 350 µg/kg (PTX-3), 770 µg/kg (PTX-4), and 500 µg/kg (PTX-6), whereas the LD<sub>50</sub> of PTX-7, PTX-8, PTX-9, PTX-2 seco acid, and 7-*epi*-PTX-2 seco acid was greater than 5 mg/kg. Thus, it seems that the oxidation of substituent in C-18, occurring in the

digestive glands of shellfish, reduces the toxicity of PTXs (Draisci *et al.*, 2000; Dominguez *et al.*, 2010).

A hepatotoxic effect was observed in suckling mice for PTX-1 as well as for PTX-1, PTX-2, PTX-6 in adult mice and rats. None of the toxins caused diarrhea, and no damage at the intestinal level was observed in suckling mice after i.p. injection of up to 1 mg PTX-1/kg. On the other hand, PTX-1 and -2 induced an increased permeability of capillaries in the digestive tract and ascites and increased fluid accumulation in the thorax and pericardium of adult mice and rats at a dose of 375 µg/kg (Terao *et al.*, 1986, 1993). Hepatotoxic effects were also observed for PTX-6, which caused severe bleeding in the liver, whereas PTX-2 caused congestion under the liver capsule from circulatory disorder (Ito *et al.*, 2008).

Although some data on PTX toxicity after oral administration are controversial, Terao *et al.* (1993) observed that PTX-1 and PTX-2 (750 µg/kg) did not induce changes at the intestinal level of mice and rats. No lethality and no diarrhetic effects were evidenced for PTX-2, PTX-2 seco acid, and PTX-6 in mice at a dose of 5 mg/kg (Miles *et al.*, 2004; Ito *et al.*, 2008). After PTX-6 oral administration to rats (2 mg/kg), the middle-lower small intestine was eroded at villi by edema. Moreover, no synergistic toxicity of PTX-6 with OA or PTX-2 after oral administration to mice was observed (Ito *et al.*, 2008).

## Concluding remarks

The European Union has not set a maximum overall level for PTXs alone in shellfish because the established level of 160 µg/kg of edible parts is referred to as the sum of PTXs and diarrhetic toxins of the OA group (European Commission, 2002). MBA can detect PTXs but not the seco acids. The presence of other lipophilic toxins, such as AZAs and DSP toxins, can be detected by the mouse bioassay. Because PTXs are synthesized by the same microalgae-producing OA and its derivatives, it is important to distinguish the two toxin groups. LC-MS/MS has been adopted in the European Union as the reference method for detection of at least PTX-1 and PTX-2 in shellfish, but alternative or complementary methods, such as immunochemical assays, can be used if properly validated (European Commission, 2011).

## CYCLIC IMINE TOXINS

### Background

In recent years, a group of macrocyclic compounds with imine- and spiro-linked moieties have been discovered through their rapid lethality in mice by the mouse

Spirolide	R1	R2	R3
A	H	CH <sub>3</sub>	CH <sub>3</sub>
B	H	CH <sub>3</sub>	CH <sub>3</sub>
C	CH <sub>3</sub>	CH <sub>3</sub>	CH <sub>3</sub>
D	CH <sub>3</sub>	CH <sub>3</sub>	CH <sub>3</sub>

FIGURE 69.15 Chemical structure of spirolides A–D (from Ciminiello and Fattorusso, 2004).

bioassay used for detection of lipophilic shellfish toxins. These toxins include spirolides, gymnodimines, pinnatoxins, pteriatoxins, and prorocentrolides, and their threat to human health is unclear (Cembella and Krock, 2008; Munday, 2008c).

Several spirolides, possessing a spiro-linked tri-cyclic ether structure and an imine or amine function, have been identified in shellfish and phytoplankton: spirolides A–G and their derivatives, among which spirolides E and F are nontoxic metabolites formed in shellfish (Hu *et al.*, 1996; Falk *et al.*, 2001; Aasen *et al.*, 2005) (Figure 69.15). Spirolides, produced by the dinoflagellate *Alexandrium ostenfeldii*, are accumulated in filter-feeding bivalves, such as mussels, oysters, and clams. They have been detected in the United States, Canada, Chile, Norway, Denmark, Scotland, Spain, France, and Italy (Cembella *et al.*, 2001; Munday, 2008c; Álvarez *et al.*, 2010).

Gymnodimines (Figure 69.16), containing a spiro center and an imine function, structurally related to spirolides, are produced by dinoflagellates of the *Gymnodinium* (*Karenia*) genus and accumulated in bivalves, such as oyster species (*C. gigas* and *Tiostrea chilensis*), Greenshell mussels (*Perna canaliculus*), blue mussels (*M. edulis*), and scallops (*Pecten novaezelandiae*), and also in tissues outside the digestive gland. These toxins have been detected in New Zealand and other countries, such as Tunisia and Canada (Munday, 2008c).

Pinnatoxins (Figure 69.17) are compounds consisting of a 20-membered ring with 5,6-bicyclo, 6,7-azaspiro, and 6,5,6-triketal moieties in their structure. They are

**FIGURE 69.16** Chemical structure of gymnodimine (from Quilliam, 2003).

**FIGURE 69.17** Chemical structure of pinnatoxin A (from Quilliam, 2003).

accumulated in shellfish of the genus *Pinna*, a common seafood in Japan and China. In these countries, consumption of *Pinna* caused human poisonings initially attributed to pinnatoxins (Kuramoto *et al.*, 2004) but that were later shown to be due to *Vibrio* species contamination (FAO/IOC/WHO, 2005). Pinnatoxins are structurally similar to the pteriatoxins, differing in that the cyclohexenyl side chain of the latter compounds ends in a cysteine. It has been suggested that pteriatoxins are biotransformed from pinnatoxins in shellfish (EFSA, 2010).

Other cyclic imines of algal origin are the cyclic polyether prorocentrolide (Figure 69.18) and its analog prorocentrolide B produced by dinoflagellates of the genus *Prorocentrum* (Munday, 2008c).

### Pharmacokinetics/toxicokinetics

No data on absorption, metabolism, distribution, and elimination of these cyclic imines are available.

### Toxicity

#### Human toxicity

No human poisoning syndrome due to cyclic imines has been documented. Due to the lack of adequate

**FIGURE 69.18** Chemical structure of prorocentrolide (from Torigoe *et al.*, 1988).

quantitative data on oral toxicity for cyclic imines, no ARfD has been established by the European Food Safety Authority Panel on Contaminants in the Food Chain (EFSA, 2010).

### Experimental toxicity

#### Single administration

After i.p. injection in mice, spirolides caused death within minutes, preceded by neurotoxic symptoms such as piloerection, abdominal spasms, hyperextension of the back, and arching of the tail (Gill *et al.*, 2003; Ciminiello and Fattorusso, 2004). By i.p. injection, spirolides B and D are of similar toxic potential, whereas spirolides E and F, in which the cyclic imine moiety is destroyed, are much less toxic. In mice, the LD<sub>50</sub> of a mixture of spirolides was calculated to be approximately 40 µg/kg after i.p. injection, with the lethality being approximately 25 times higher than that by the oral route (LD<sub>50</sub> = 1 mg/kg). The oral LD<sub>50</sub> values for pure desmethyl spirolide C, desmethyl spirolide C, and 20-methyl spirolide G were in the range of 157–176 µg/kg (Cembella *et al.*, 2002; Munday, 2008c).

For i.p. injection in mice, an LD<sub>50</sub> of 96 µg/kg was determined for gymnodimine, which induced paralysis and respiratory distress (Munday *et al.*, 2004). After administration in mice by gavage, an LD<sub>50</sub> of 755 µg/kg was calculated, but no toxicity was seen if the toxin was administered with finely ground food suspension at a level corresponding to a dose of approximately 7500 µg/kg (Munday *et al.*, 2004).

By i.p. injection in mice, the LD<sub>50</sub> of pinnatoxins E (45 µg/kg), F (16 µg/kg), and G (50 µg/kg), recently isolated from Japanese shellfish, was determined. Before death, mice were hypoactive and showed abdominal breathing, extension of the hind legs, low respiratory

rate, and exophthalmia (Selwood *et al.*, 2010). Data on acute i.p. toxicity of pteriatoxins in mice consist of an LD<sub>50</sub> of pteriatxin A (100 µg/kg), which was more toxic than a mixture (1:1) of pteriatoxins B and C (LD<sub>50</sub> = 8 µg/kg) (Munday, 2008c).

The “lethality” of prorocentrolide by i.p. injection in mice was reported to be 400 µg/kg, with death occurring within minutes (Torigoe *et al.*, 1988).

## Mechanism of action

The mechanism of action of the cyclic imines is not completely known. Biological studies on spirolides suggest hippocampus and brain stem as their main toxicity targets, with the toxins acting as muscarinic acetylcholine receptor antagonists and weak L-type transmembrane calcium channel activators (Gill *et al.*, 2003; Sleno *et al.*, 2004; Wandscheer *et al.*, 2010). The active pharmacophore of these compounds seems to be the cyclic imine moiety because spirolides E and F, lacking this structure, are inactive (Luckas *et al.*, 2005). Gymnodimine seems to block muscular and neuronal nicotinic acetylcholine receptors (Munday *et al.*, 2004; Kharrat *et al.*, 2008), and also pinnatoxins probably target these receptors at the neuromuscular junction (EFSA, 2010; Araoz *et al.*, 2011).

## Concluding remarks

Although cyclic imines are lethal in mice when injected i.p. and contaminate shellfish in several areas of the world, no cases of adverse effects in humans have been reported, and thus no maximum tolerated level for these toxins has been established (EFSA, 2010). The MBA has traditionally been used to detect cyclic imines in shellfish, and due to their high i.p. toxicity, these compounds complicate use of the MBA for lipophilic toxins. Other methods to quantify these toxins, such as LC-MS, have been set up to detect individual cyclic imines, but none of the current methods have been formally validated by interlaboratory studies (EFSA, 2010).

# Botulinum neurotoxins

Julie A. Coffield and Dorothy D. Whelchel

## INTRODUCTION

Botulism, or “sausage poisoning,” was reportedly first recognized in Germany in approximately the late 1700s. However, it was not until the 1820s that Justinus Kerner systematically studied and described the fatal paralytic disease (aka, “Kerner’s disease”) associated with the ingestion of spoiled sausage. Kerner recognized that a poisonous substance isolated from the spoiled sausage was responsible for the clinical signs associated with botulism; however, he was unable to identify the origin of the deadly poison. With the subsequent introduction of anaerobic microbiological techniques in the late 1800s, the source of the poison was finally determined. In 1897, van Ermengem was able to identify the offending etiological agent as a bacterium, now known as *Clostridium botulinum*, in spoiled ham. The deadly poison produced by the bacteria is now known as botulinum neurotoxin (BoNT), the most potent biological toxin ever encountered, with lethal doses as low as 0.03 ng/kg body weight depending on both toxin type and animal species (Gill, 1982). This chapter describes the toxicology of BoNT in relation to various animal species.

## BACKGROUND

BoNT is produced under anaerobic conditions primarily by *C. botulinum*, a rod-shaped, spore-forming (subterminal) bacterium; however, other clostridial

species, such as *C. barati* and *C. butyricum*, are also capable of producing the neurotoxin (Hatheway, 1989). Although often referred to collectively as a single toxin, there are actually seven immunologically distinct serotypes of BoNT, and they are designated alphabetically, A–G (Simpson, 1981). Serotypes A, B, C1, and D have been associated with outbreaks of botulism in domestic animals, livestock, poultry, and wildlife, whereas serotypes A, B, E, and, rarely, F are known to cause disease in humans. When isolated from the bacterium, native BoNTs are found in complex with hemagglutinins and other nonhemagglutinin, nontoxic proteins. These accessory proteins are thought to protect the toxin from harsh environmental conditions such as those found in the gut following ingestion of toxin-contaminated food products. The molecular masses of these toxin complexes range between 300 and 500 kDa, depending on the toxin serotype. Although serologically distinct, the seven toxin serotypes share both structural and functional similarities. When not complexed with other proteins, the active neurotoxin has a molecular mass of 150 kDa and exists as a polypeptide di-chain molecule. The di-chain consists of a heavy chain linked by a single disulfide bond to a light chain. The 100-kDa heavy chain is responsible for membrane targeting and cellular uptake, whereas the 50-kDa light chain mediates its intracellular action. The neurotoxin molecule can be further divided both structurally and functionally into three domains. The heavy chain contains both a binding domain and a translocation domain, whereas the smaller light chain contains a catalytically active domain.

## MECHANISM OF ACTION

BoNTs are potent zinc-dependent metalloproteases that exquisitely target acetylcholine (ACh)-containing nerve terminals (Schiavo *et al.*, 2000). Because BoNTs are too large to cross the intact blood–brain barrier, their selective action on cholinergic terminals is generally limited to peripheral cholinergic systems. The primary target site is the neuromuscular junction (NMJ), where they act within the motor nerve terminal to prevent the release of ACh, the primary neurotransmitter at this major synapse. Intoxication by BoNT has been described as a multistage process (Simpson, 1981, 1989; Montecucco, 1986). In the first stage of intoxication, the toxins must bind selectively, via their heavy chains, to protein receptors (and gangliosides) located on the plasma membrane of the motor nerve terminal. The binding of the toxins to the nerve terminal membrane initiates the second stage of the intoxication process, which is characterized by receptor-mediated uptake of the toxins into endosomes (e.g., endocytosis). The third stage of intoxication occurs within the endosome, where the disulfide linkage between the toxin heavy and light chains is reduced, and a subsequent drop in endosomal pH promotes a conformational change in the toxin molecule, allowing the light chain to escape across the endosomal membrane into the cytosol, possibly mediated by the translocation domain of the toxin (e.g., translocation). Following this translocation to the cytosol, the toxin light chain is free to act upon its intracellular target during the final stage of intoxication. During this last stage of the process, the neurotoxins enzymatically cleave one of three specific proteins found within the presynaptic terminal. These three proteins – SNAP-25, synaptobrevin, and syntaxin – known collectively as SNARE (soluble *n*-ethylmaleimide sensitive factor attachment protein receptor) proteins, are necessary for neurotransmitter release. Synaptobrevin, an integral membrane protein, is found on the synaptic vesicle, whereas SNAP-25, a membrane associated protein, and syntaxin, another integral membrane protein, are both localized to the presynaptic terminal membrane. In normal circumstances, these SNARE proteins interact to form a four-helical “fusion” or “SNARE” complex that brings the ACh-containing synaptic vesicles into close apposition with the terminal membrane. Fusion of the vesicular and terminal membranes and the subsequent release of ACh are triggered by fast  $\text{Ca}^{2+}$  signaling. Proteolysis of any one of the SNARE proteins by BoNT either destabilizes or prevents the formation of functional SNARE complexes, inhibiting vesicular fusion and neurotransmitter release. The catalytic active sites of the different BoNT serotypes vary slightly, giving each serotype both substrate and cleavage site specificity. Toxin serotypes A, C, and E cleave SNAP-25; serotypes B, D, F, and G cleave synaptobrevin; and serotype C cleaves syntaxin.

## CLINICAL BOTULISM

Clinically, botulism is recognized as a lower motor neuron disease resulting in progressive flaccid paralysis. Although deficits in somatic neuromuscular transmission are the most prominent effects, motor deficits in cranial nerve function, as well as the autonomic nervous system, have also been reported. With the exception of impaired vision (most likely related to disruption in autonomic function), neither altered sensation nor mentation has been specifically reported in botulism. In animals, paresis begins in the hind limbs and progresses cranially, often resulting in quadriplegia and recumbency. As in humans, death may result from respiratory muscle paralysis. The onset of clinical signs may be within hours or days of exposure, and it is dependent on exposure conditions (dose and duration), as well as individual sensitivity. Susceptibility to the different serotypes varies across species. Botulism in large animals (herbivores) is commonly, but not exclusively, due to serotype B, whereas botulism in small animals (carnivores) and avian species is most commonly due to serotype C1. With the exception of serotype C1, the different toxin serotypes produce similar clinical disease. Serotype C1 toxin-producing strains of *C. botulinum* bacteria may produce multiple exotoxins, including the C1 neurotoxin, and the C2 and C3 cytotoxins. The concurrent presence of these cytotoxins with C1 neurotoxin may account for the different clinical scenarios that have been reported in botulism associated with serotype C1 intoxication, including dysautonomias in horses and cats.

Botulism is most often acquired from the ingestion of preformed toxin in either spoiled vegetation or carrion-contaminated foodstuffs, although this may vary among species. In addition, two other forms of botulism are well recognized in veterinary medicine: wound contamination with *C. botulinum* and gastrointestinal (GI) colonization by *C. botulinum* (toxico-infection). The mainstay of therapy for all animal species with botulism is supportive care, although the specifications of this therapy may differ slightly between species. Antitoxin (equine origin) may be administered in certain instances; however, because the antitoxin is only protective against toxin in the general circulation, it must be given early in the disease course to be effective. Once the patient displays symptoms, antitoxin administration may be ineffective. Furthermore, antitoxin administration can cause adverse effects. Antibiotic administration may be indicated to reduce the risk of secondary infections; however, aminoglycosides, tetracycline, and procaine penicillin should be avoided because these drugs potentiate neuromuscular weakness (L’Hommedieu *et al.*, 1979). *Clostridium botulinum* is not sensitive to metronidazole, an antimicrobial used to treat anaerobic infections. Furthermore, metronidazole has been associated

with an increased risk of botulism in laboratory animals and workers exposed to the bacterium, possibly due to alterations in GI flora that permit clostridial growth (Wang and Sugiyama, 1984; Whitlock, 2002).

## LABORATORY DIAGNOSIS

The diagnostic gold standard for botulism is the mouse bioassay (MBA). Although the MBA is still the most widely utilized test for botulism, alternative diagnostic avenues are being developed in an effort to minimize the use of animals in toxicity testing. For example, enzyme-linked immunoabsorption (ELISA) techniques have been used to identify BoNT in both avian and bovine specimens. For an in-depth discussion on this topic, the reader is referred to the review by Lindström and Korkeala (2006).

## SPECIES-SPECIFIC DISEASE

### Equine botulism

Horses are thought to be among the most susceptible of species to intoxication by BoNT. The serotype most commonly reported to cause equine botulism in North America (>80% of equine cases) is serotype B; however, serotypes A and C1 have also been associated with clinical disease in the horse (Whitlock *et al.*, 1989; Johnson *et al.*, 2010). Serotype B-producing strains of *C. botulinum* are found ubiquitously in the soils of the northeastern and central United States, particularly in regions extending from Kentucky to the mid-Atlantic states. Conversely, serotype A-producing strains are more prominent in the western states (California, Utah, Idaho, and Oregon) and have also been reported in Ohio. Although intoxication with BoNT/C1 occurs with less frequency, cases have been reported in California, Florida, the New England states, and Canada.

Horses acquire botulism in one of three ways: (1) from the ingestion of preformed toxin in contaminated foodstuffs, (2) from the contamination of wounds with *C. botulinum*, and (3) from the colonization of the intestinal tract with *C. botulinum* bacteria (toxico-infection). The ingestion of preformed toxin, in either spoiled vegetation or carrion-contaminated foodstuffs, is the most common scenario for equine botulism. Contaminated feed sources such as alfalfa cubes, alfalfa hay, baled hay, wheat, oats, potatoes, bale silage, rye silage, grass clippings, oat chaff, and brewer's grains have all been purported sources of botulism in large animals (Whitlock and Buckley, 1997).

Serotype B is more commonly associated with contamination of spoiled foodstuffs or moldy hay. Interestingly, the feeding of silage or hay stored in large plastic bags has been implicated as an increased risk factor for botulism. The damp, alkaline conditions of spoiled vegetation provide an optimal environment for clostridial growth, sporulation, and toxin production. For these reasons, it is recommended that silage with a pH greater than 4.5 should not be fed to horses (Whitlock and Buckley, 1997; Galey, 2001).

Cases of equine botulism associated with the ingestion of carrion-laden foodstuffs are more often the result of intoxication with BoNT serotype C1 (Galey, 2001). A herd outbreak of BoNT/C1 intoxication in California was determined to be the result of the ingestion of preformed toxin in alfalfa cubes contaminated with rodent carcasses (Kinde *et al.*, 1991). Interestingly, another report of an outbreak of BoNT/C1 intoxication in horses revealed that birds may act as vectors, transporting toxin or bacterial spores from a rotting carcass to nearby horse farms (Schoenbaum *et al.*, 2000).

Wound botulism occurs from the contamination of a wound with the *Clostridium* bacteria. The anaerobic environment of the wound provides optimal conditions for *C. botulinum* growth and toxin production. The neurotoxin (most commonly serotype B) is produced within the wound and enters the peripheral circulation, where it is distributed to the toxin's site of action, the NMJ. Distal limb wounds, castration sites, umbilical hernias, and injection site abscesses have all been associated with wound botulism.

"Shaker foal syndrome" is a form of toxico-infectious botulism that occurs in foals usually between 2 and 5 weeks of age (Rooney and Prickett, 1967; Vaala, 1991; Whitlock, 2002). The infection occurs most commonly in fast-growing foals on high planes of nutrition. GI ulcerations and liver abscesses have been documented post-mortem in foals that succumbed to botulism (Swerczek, 1980). Thus, exposure to stress, high nutrient diets, or corticosteroid use may all play a role in the foal's susceptibility to toxico-infection. Such underlying conditions may lead to gastric ulcers, which then serve as a nidus for *C. botulinum* colonization. Furthermore, as in human neonatal toxico-infection, the immature GI tract of foals may be more permissible to overgrowth by *C. botulinum*. Shaker foal syndrome is commonly associated with the production of toxin serotype B; however, a case of serotype C1 intoxication was documented in a foal in Florida (MacKay and Berkhoff, 1982). Serotype C1-producing clostridial strains have been identified in Florida soils, and in this particular case, it was concluded that the foal developed a toxico-infection after ingesting bacterial spores from the soil. In addition, this foal was also diagnosed with sand colitis; an irritated GI mucosa likely increased this foal's susceptibility to toxico-infection.

Toxico-infection with BoNT serotype C1 has also been implicated as a potential causative agent of equine dysautonomia, also known as equine grass sickness (EGS). EGS is frequently diagnosed in Great Britain, and its occurrence correlates with the grazing season. EGS presents as an acute or subacute illness resulting in death (or euthanasia) within days of onset; however, classic neuromuscular symptoms of botulism are not observed in EGS. Rather, the primary symptoms associated with this syndrome include dysphagia, ileus, and weight loss. If the horse survives the subacute phase, a chronic form may persist. In addition, histological examination revealed neuronal degeneration in autonomic ganglia, the myenteric plexus, and the submucosal plexus (McGorum *et al.*, 2003). Such histological findings are not reported with classic botulism. Increased BoNT/C1 has been detected in ileal and fecal contents of horses diagnosed with EGS; however, in this same study, BoNT/C1 was also isolated from a small number of control animals (Hunter *et al.*, 1999). Conversely, Garrett *et al.* (2002) demonstrated an increased number of bacterial colonies with a prominent number of clostridial species in the GI tract of horses with EGS compared with healthy control horses. However, the possibility that the increased colonization of the gut by clostridia was secondary to the ileus produced in EGS cannot be ruled out. McGorum *et al.* (2003) documented the occurrence of clinical and pathological signs associated with both EGS and toxico-infectious botulism in the same foal. One theory proposes that in addition to the blockade of ACh release at cholinergic nerve terminals, the C1 neurotoxin also causes nerve cell degeneration. However, note that serotype C1-producing clostridial strains may also produce the ADP-ribosylating cytotoxic toxins, C2 and C3. Interestingly, the C2 toxin has been associated with an increase in vascular permeability leading to the development of edema, congestion, and hemorrhage in *in vivo* models. It is plausible that these exotoxins may play a role in producing the clinical symptoms of EGS that deviate from those of classic botulism (Cottrell *et al.*, 1999; Hunter *et al.*, 1999; Garrett *et al.*, 2002). To date, however, the exact cause of EGS and the potential role of a *C. botulinum* toxico-infection in its manifestation remain elusive.

### **Clinical signs, diagnosis, and treatment**

The onset of clinical signs associated with equine botulism is variable and can occur anywhere between 12h and 10 days post-exposure. The clinical presentation of poisoned horses may be gradual, acute, or peracute depending on exposure dose and duration, as well as on individual sensitivity to the toxin. Adult horses that ingest low doses of toxin may show only mild dysphagia and recover with minimal treatment, whereas ingestion of large doses is associated with peracute illness and

a grave prognosis. In peracute illness, muscle paralysis progresses rapidly and the animal is recumbent within 8–12h; ultimately, paralysis of the respiratory muscles results in death.

With the exception of serotype C1 and EGS, clinical symptoms of equine botulism vary little between the different botulinum toxin serotypes (Whitlock, 1996; Whitlock and Buckley, 1997; Johnson *et al.*, 2010). Myasthenia and dysphagia are often the first symptoms observed. Astute horse owners may first notice mild signs such as depression, exercise intolerance, and difficulty with grain consumption. Ataxia, gait stiffness, and muscle tremors (particularly in the triceps muscles) may be noted early in the course of disease. In addition, mydriasis, ptosis, and decreased pupillary light responses, as well as decreased palpebral reflexes, are characteristic of early botulism. As the disease progresses, pupillary light responses diminish further. Periods of exercise may worsen paresis due to the reduction of ACh release at the NMJ. As dysphagia and pharyngeal weakness progress, the swallowing of food becomes more difficult and secondary aspiration pneumonia may ensue. Horses may also have difficulty drinking because they tend to stand with their muzzles submerged in water troughs without swallowing. In horses infected experimentally with serotype C, there was a more pronounced mydriasis and an inability to lift the head; facial edema and inspiratory stridor resulted from low head carriage.

Initially, vital signs such as heart rate, respiration rate, body temperature, and capillary refill time are within normal limits. However, decreased borborygmi, ileus, colic, and constipation develop as botulism progresses. Diarrhea is often associated with serotype C, possibly in association with C2 toxin. Urine retention with resultant bladder distention often occurs, thereby increasing the risk of urinary tract infection. As the disease progresses, horses spend more time in sternal recumbency and ultimately become laterally recumbent. Heart and respiratory rates may increase as recumbent horses struggle to stand. In late stages, dyspnea and other signs of respiratory distress may be observed. With serotype C intoxication, an exaggerated expiration and “prolonged abdominal lift” may be noted. In the final stages of botulism, horses are laterally recumbent, demonstrate significant respiratory difficulty, and develop anoxia. As the anoxia progresses, horses may exhibit agonal paddling. At this point, the patient either dies due to respiratory failure or is euthanized.

In the foal, botulism most commonly occurs between 2 and 5 weeks of age. The first clinical signs usually observed are increased periods of recumbency and muscle tremors. Soon after the foal rises, muscle tremors are evident, and after brief periods of standing, the foal collapses from weakness. Recumbent foals appear

to be bright and alert. Foals may dribble milk from their muzzles soon after nursing due to dysphagia and pharyngeal muscle paresis. Thus, aspiration pneumonia is a common sequela in the foal. Constipation and ileus are also frequently observed. Other symptoms are similar to those observed in the adult horse.

A tentative diagnosis of botulism can be made following a comprehensive neurological assessment. Typically, abnormalities in palpebral reflexes, pupillary light responses, tail tone, tongue tone, prehension of food, dysphagia, and gate are detected with botulism. Both the tongue stress test and the grain test are sensitive measures for botulism. Difficulty in prehension, slow consumption, and a characteristic grain/saliva mixture hanging from the lips are indicative of botulism. These examination findings may also be useful in the assessment of disease progression and treatment efficacy.

Abnormalities in routine diagnostic indicators (complete blood cell (CBC) count, blood chemistry, cerebral spinal fluid (CSF) analysis, and urinalysis) are not typically detected in early botulism, but they do usually accompany other neurological diseases. Therefore, normal laboratory values in light of neurological deficits support the diagnosis of botulism. Differential diagnoses for botulism include infectious diseases such as equine protozoal myeloencephalitis, equine herpes virus-1, eastern and western equine encephalitis, rabies, guttural pouch mycosis, and listeriosis; other toxicoses such as leukoencephalomalacia (moldy corn poisoning), ionophore poisoning (monensin, salinomycin, and narsin), yellow star thistle poisoning, yew poisoning, white snake root poisoning, and organochlorine poisoning; metabolic disorders such as equine motor neuron disease, azoturia, eclampsia, hypocalcemia, hyperkalemic periodic paralysis, and white muscle disease; and pharyngeal ulceration.

A tentative diagnosis of equine botulism may be confirmed by (1) MBA detection of formed toxin in horse sera, GI contents, viscera, or wounds; (2) detection of *C. botulinum* spores or toxin in suspect foodstuffs in association with clinical signs; and (3) ELISA detection of serum anti-toxin antibodies in unvaccinated horses with clinical signs. However, a definitive diagnosis of botulism is often difficult to achieve in the horse. There are no gross or pathognomonic histological lesions associated with botulism, and serum toxin levels in the horse are often too low to be detected by the MBA. Because the horse is more sensitive than the mouse to BoNT, the MBA is most valuable in early, peracute equine botulism, when higher concentrations of toxin may be present in the bloodstream. In addition to serum, GI contents and liver samples can also be submitted for the MBA, although greater diagnostic success may be achieved through detection of BoNT in the foodstuff rather than within the patient (Galey, 2001). Fecal or tissue culture enrichment

can be used to enhance bacterial spore numbers and toxin levels for greater detection. However, because spores may be present in the feces of healthy horses, direct detection of BoNT within the animal is a more reliable finding. Following a positive result from the MBA, the serotype can be identified using the mouse neutralization test.

Once botulism is suspected, the patient should be confined to the stall to prevent exertion. Polyvalent antiserum (antitoxin) should be given as soon as possible; the recommended dose for an adult horse is 70,000 IU (500 mL), and that for the foal is 30,000 IU (200 mL). One dose usually provides passive immunity for approximately 60 days (Sprayberry and Carlson, 1997; Whitlock and Buckley, 1997). The use of parasympathomimetics should be avoided because these agents deplete ACh stores and exacerbate paresis/paralysis. Antibiotic therapy is indicated in cases of wound botulism or secondary infections; however, as previously stated, aminoglycosides, tetracycline, procaine penicillin, and metronidazole are contraindicated. Aminoglycosides block neurotransmission at the NMJ and will exacerbate muscle weakness and paralysis (Barsanti, 1990). Although gram-positive anaerobes are sensitive to penicillin and metronidazole, administration of these drugs is controversial. These antimicrobials may cause more bacterial lysis, thus increasing the release of toxin (in the case of a toxico-infection), or they may promote *C. botulinum* colonization by altering the normal intestinal flora. Drugs such as the aminopyridines and guanidines should also be avoided because they will further deplete ACh stores (Critchley, 1991).

Second only to antitoxin administration, supportive care is the mainstay of therapy for botulism. H<sub>2</sub> blockers and proton pump inhibitors may be indicated, especially for foals. Topical ophthalmic ointments should be used to prevent corneal abrasions and ulceration. Adult horses may need to be sedated with xylazine or diazepam to reduce anxiety and exertion. Patients should be muzzled between feedings to prevent aspiration pneumonia. Nutritional support should be provided to dysphagic patients. Alfalfa slurries with adequate amounts of water may be administered through a nasogastric tube to adult horses. Foals should receive milk replacer through a nasogastric tube or parenteral nutrition if ileus is present. Patients should be maintained in sternal recumbency to prevent aspiration pneumonia and checked periodically for gastric reflux because ileus may lead to the accumulation of ingesta/fluid in the stomach. If gastric reflux is not present, some authors recommend that mineral oil be administered via a nasogastric tube to alleviate ileus and constipation; however, this should be done under close supervision due to the increased risk of aspiration in these patients. Recumbent patients should be turned frequently or suspended periodically by full-body slings to prevent decubital ulcer formation, myopathies, and other

complications of prolonged recumbency. Recumbent stallions and geldings should be catheterized twice daily to empty the bladder and prevent pressure necrosis or cystitis (Whitlock and Buckley, 1997).

A tracheostomy should be performed in cases of botulism in which horses show signs of upper airway obstruction as a result of paralysis of the nares or larynx. In more complicated cases, patients may require intravenous (i.v.) fluids to correct respiratory acidosis resulting from decreased ventilation. For foals in particular, arterial blood gases should be monitored frequently to determine the need for artificial ventilation. Intranasal oxygen insufflation and mechanical ventilation can be instituted in foals with poor arterial blood gas values and/or metabolic acidosis (Wilkins and Palmer, 2003). Unfortunately, mechanical ventilation is not practical in the adult horse (Mitten *et al.*, 1994).

The overall prognosis is favorable for horses that are exposed to low doses of the toxin, exhibit a slow disease progression (3–7 days), or display mild symptoms. Likewise, a grave prognosis is given to patients exposed to high doses of toxin, that manifest a rapid onset of clinical disease, or that become recumbent within 8–12 h. Patients responsive to antitoxin therapy should be able to eat within 7–10 days post-treatment and regain full strength within a month. Recumbent foals are often able to stand within 7–10 days post-antitoxin administration. Although the prognosis for recumbent adult horses is poor, if the patient does not become distressed or show severe respiratory compromise, recovery may be achieved with extensive supportive care. The most common complications associated with botulism are decubital ulcers and aspiration pneumonia; these problems can be resolved with supportive care and antimicrobial therapy.

### Prevention

Following recommended vaccination protocols, along with sound husbandry methods, reduces the occurrence of equine botulism. Forages should be examined for carrion, and pastures should be cleared of decaying vegetation and rotting animal carcasses. Appropriate wound management is also an important preventative measure. To date, only serotype B toxoid vaccine is marketed for horses in the United States. The American Association for Equine Practitioners recommends vaccination only for horses in endemic areas. Adult horses in endemic areas should be vaccinated annually. Mares should be boosted 4–6 weeks prior to parturition to achieve adequate antitoxin immunoglobulin (Ig) levels in colostrum. Foals born to vaccinated mares should receive a series of three vaccinations, each 1 month apart, starting at 2 or 3 months of age. Foals born to unvaccinated mares should be vaccinated at 2, 4, and 8 weeks of age (Whitlock and Buckley, 1997; Galey, 2001).

### Avian botulism

Avian botulism, otherwise known as “limberneck” or “western bird disease,” has been a significant problem worldwide in both domestic and wild fowl. The occurrence of avian botulism has been globally widespread, having been documented in as many as 17 countries and on every continent except Antarctica (Jensen and Price, 1987). The majority of the natural outbreaks of avian botulism have occurred in fowl (Lamana, 1987). Carnivorous, omnivorous, carrion scavengers, and insectivorous birds, as well as aquatic bottom-feeding birds, are all susceptible to botulism. In 1984, 117 avian species were determined to have been affected by the disease. Specifically, botulism has been reported in chickens, ducks, turkeys, pheasants, and ostriches. Although broiler outbreaks are not uncommon, botulism is a more significant problem for waterfowl, resulting in millions of deaths worldwide. Avian species are sensitive to serotypes A, B, C1, and E, although serotype C1 is most commonly associated with outbreaks. Outbreaks of serotype C1 intoxication have been reported worldwide, whereas outbreaks of serotype A botulism have only been reported in western regions of North and South America; serotype B in the eastern United States, England, Europe, and China; and serotype E in the Great Lakes and North Sea. Interestingly, serotype A was found to be more toxic than serotype C1 when administered i.v. to chickens; however, when given orally, serotype C1 demonstrated greater toxicity.

The etiology of botulism among wild avian species and waterfowl differs from that observed in other animals. The process is a complex cycle involving environmental contamination, toxico-infection, bird die-offs, bacterial proliferation in bird carcasses, and invertebrate vectors. *Clostridium botulinum* often colonizes the intestinal tract and cecum of clinically normal birds, increasing the potential for toxico-infection in avian species (Dohms, 2003). Because these birds are already seeded with the bacteria, upon death, avian carcasses provide an excellent substrate for *C. botulinum* growth. The proliferating bacteria spread from the GI tract to other tissues, the carcass becomes flyblown, and toxin accumulates in the fly larvae. Invertebrates concentrate the bacterium or toxin after feeding on contaminated carcasses; however, due to their neurophysiological differences, BoNT does not affect insects and aquatic invertebrates. Subsequently, birds ingest these animals and accumulate lethal amounts of BoNT. One gram of fly larvae may contain  $1.8 \times 10^5$  mouse LD<sub>50</sub>s, and ingestion of as little as eight fly larvae was sufficient to kill a pheasant. Bird and invertebrate die-offs perpetuate botulism outbreaks by increasing the levels of *C. botulinum* in soils, lakes, rivers, and estuaries. Environmental factors such as shallow alkaline waters, warm seasons/summer

months, and flooding of mudflats or dried-out lakes may promote invertebrate die-offs, further enhancing environmental levels of *C. botulinum*. As *C. botulinum* levels increase in the environment, the intestinal tracts of wild birds and waterfowl become seeded with the bacteria, and any cause of bird deaths can trigger an outbreak of botulism.

Contaminated feed, water, litter, carcasses, and insects may be associated with botulism in broilers. Often, the source of BoNT cannot be identified, and toxico-infection has been hypothesized to be the perpetuating factor. *Clostridium botulinum* has been isolated from the intestinal tract and cecum of healthy birds; furthermore, the chicken body temperature (41°C) and cecal pH (7.4) are optimum for *C. botulinum* growth (Miyazaki and Sakaguchi, 1978; Trampel *et al.*, 2005). Most broiler outbreaks have occurred in chickens between 2 and 3 weeks of age; however, an outbreak in postcaponized chickens was documented in birds as old as 14 weeks. Coprophagy has also been implicated as a causative factor in poultry outbreaks because both BoNT/C1 and *C. botulinum* are secreted in cecal droppings. Broiler outbreaks are also more likely to occur in hot weather.

Morbidity and mortality of avian botulism increase with the dose of BoNT ingested. The onset of clinical symptoms may be from a few hours to 2 days post-exposure. The mortality rate in broilers has been reported to be as high as 27%, whereas thousands to millions of birds may have been lost as a result of outbreaks in waterfowl. In fact, it had been suggested that botulism may have been the limiting factor of waterfowl population growth in predisposed areas of the United States (Jensen and Price, 1987).

### *Clinical signs, diagnosis, and treatment*

As in other species, avian botulism is characterized by lower motor neuron deficits resulting in flaccid muscle paralysis. Paresis begins in the legs and progresses cranially to involve the wings, neck, and eyelids. Mildly affected birds may appear ataxic, reluctant to move, have a ruffled coat, and have easily epilated feathers. The wings may droop and the neck may become flaccid, hence the name “limberneck.” Diarrhea is often noted in broilers. As the disease progresses, birds become recumbent. Neck muscles become paralyzed, and birds eventually lie down with necks extended out, resting on the ground. Birds may appear comatose due to eyelid paralysis. Dyspnea may develop as paralysis progresses. Birds usually die from respiratory failure and dehydration. Broilers may succumb to hyperthermia as sick birds are smothered by others and the respiratory mucosal cooling mechanism is compromised.

The diagnosis of avian botulism is based on clinical signs, a lack of specific pathological changes, and

the isolation of toxin from serum/tissues of clinically ill birds. Although no pathognomonic changes have been described, postmortem hepatic and renal congestion along with signs of dehydration may be found. The most definitive diagnosis of botulism is the isolation of BoNT from the sick bird. Ten milliliters of blood is the suggested minimum amount for the MBA; however, if necessary, equal aliquots of blood from individual sick birds may be pooled to accommodate volume requirements of the assay (Dohms, 1987). Following a positive result from the MBA, the serotype can be identified using the mouse neutralization test. Most outbreaks of avian botulism are due to BoNT/C1; therefore, antiserum for serotype C1 is usually tested first. One IU of antiserum/mouse typically neutralizes BoNT/C1 levels found in chickens suffering from botulism. BoNT/C1 and other serotypes can also be detected in bird serum using ELISA technology. For small sample volumes, the MBA appears to be more sensitive; however, for larger serum samples, the ELISA sensitivity may be comparable to the MBA. Isolation of BoNT or *C. botulinum* from the bird intestines, cecum, or other tissues may aid in a diagnosis; however, these tests are less valuable because the bacterium can be isolated from the intestinal tract of healthy birds. Furthermore, isolation of BoNT or the bacterium from carcass tissues is not definitive because *C. botulinum* may proliferate and spread from the intestinal tract to surrounding tissues of the carcass. The MBA can be performed on intestinal, cecal, and crop flushes, or samples can be assayed for toxin or bacterium after culture enrichment. Polymerase chain reaction methods have been used to identify genes encoding BoNT/C light chain in cecal contents. In order to identify the source of contamination, feed, water, litter, carcasses, and insects should be assayed for toxin or cultured to isolate the bacterium. Both ELISA and the passive hemagglutination test can be performed to identify serum antibodies to BoNT. However, the levels of toxin that produce illness are usually insufficient to stimulate an immune response in chickens and ducks. Interestingly, antibody titers to several BoNT serotypes have been identified in healthy carrion-eating birds such as vultures and crows (Ohishi *et al.*, 1979).

Differential diagnoses for avian botulism in poultry include transient brain paralysis, coccidiostat toxicity, pesticide or other chemical toxicity, New Castle disease, Marek's disease, avian encephalomyelitis, avian reovirus, and musculoskeletal problems. Fowl cholera and chemical toxicity, particularly lead poisoning, are the common differentials for botulism in waterfowl. However, eyelid paresis and the lack of postmortem lesions are supportive of botulism as the diagnosis.

When possible, clinically ill birds should be isolated and provided fresh water; once these measures are taken, birds often recover fully within a few days.

Waterfowl should be herded to uncontaminated shores, and carcasses should be removed daily in poultry operations. Antitoxin therapy may be administered for valuable birds or zoo animals, but it is impractical for most production operations or wildlife. Furthermore, antitoxin protection is transient, and birds may again become susceptible to BoNT. In broiler outbreaks, antimicrobial therapy may be instituted through watering systems or feed. Administration of bacterin (100 g/ton of feed) or streptomycin (500–1000 g/ton of feed or 1 g/L of water for 3 days) was shown to decrease mortality rates in chickens (Schettler, 1979; Sato, 1987). Penicillin may also be administered, but a mixed efficacy has been reported with this treatment. Periodic use of chlortetracycline was reported to reduce botulism outbreaks on one poultry farm. Additives such as sodium selenite (6 g/1000 L of water for 5 days) and vitamins A, D<sub>3</sub>, and E may also reduce mortality (Schettler, 1979). Conversely, elevated iron levels in water or feed may promote the intestinal proliferation of *C. botulinum*; therefore, citric acid, an iron chelator, may be added to water as a preventative (Pecelunas *et al.*, 1999). Furthermore, citric acid may lower the pH of the GI tract, inhibiting the growth of *C. botulinum* and promoting the growth of normal flora.

### Prevention

Immunization with the toxoid vaccine has been explored in broilers, pheasants, and ducks with mixed results (Shimizu and Kondo, 1978). Protection in broilers between 3 and 8 weeks of age was variable after vaccination at 1 and 14 days of age. Chickens are most susceptible to botulism between 2 and 8 weeks of age, and vaccinations to protect this group may be less efficacious due to interference from maternal antibody and immaturity of the immune system. Routine vaccination further increases production costs, and the toxoid may not provide adequate protection against the high doses of toxin obtained from maggot ingestion. Toxoid immunizations are also impractical for waterfowl. Therefore, preventative measures to minimize outbreaks of avian botulism should be aimed at flock and environmental management in both production birds and waterfowl.

In broiler outbreaks, the goals are to limit further exposure and eliminate *C. botulinum* or BoNT from the environment. Unaffected birds should be moved to uncontaminated houses. Carcasses should either be incinerated or buried in a deep hole. Rodents should be eliminated from broiler houses because rodent carcasses may harbor *C. botulinum*. Chicken houses associated with outbreaks should be emptied and cleaned. All litter should be removed. Houses should be washed with high-pressure steam and cleaned with a detergent agent. A surface-active solution should be sprayed on the

interior walls. The walls should then be disinfected with an organic iodine solution or an organic iodine and calcium hypochlorite solution. Twenty-four hours later, the interior walls should be sprayed with 10% formalin. Soil in contaminated areas may also be treated with calcium hypochlorite. Houses should also be sprayed with pesticides to limit flies. Iron levels in feed and water sources should be monitored.

Prevention of waterfowl outbreaks is best achieved by reducing the potential for environmental contamination associated with the proliferation of *C. botulinum* in the carcasses of dead vertebrate and invertebrate animals. Carcasses should be collected, and flocks should be herded away from shores associated with outbreaks. Pond management should maintain deep waters, steep banks, and smooth bottoms to prevent deaths of invertebrates and vertebrates. Routine flooding, which may lead to the death of terrestrial invertebrates, should be avoided in areas utilized by waterfowl. Water in wetland areas should be maintained as fresh as possible because oxygen depletion in shallow, stagnant waters leads to aquatic animal die-offs. Any factors that may increase deaths in susceptible wetlands, such as overhead power lines, should be removed or avoided.

The possibility for transmission of botulism from birds to their predators may exist. Coincidence of avian outbreaks with botulism in omnivorous animals has been documented. For instance, Weiss *et al.* (1982) reported botulism in a fox and a weasel in association with a waterfowl outbreak. In addition, there have been several reports of canine botulism in hunting breeds (Barsanti *et al.*, 1978; Richmond *et al.*, 1978; Jensen and Price, 1987). Farrow *et al.* (1983) reported the occurrence of botulism in three dogs after the consumption of a rotten duck carcass. Outbreaks of botulism (BoNT/C and D) in cattle and sheep have been associated with the feeding of contaminated poultry litter in silage (Egyed, 1987; McLoughlin *et al.*, 1988). No cases of human botulism resulting from the consumption or handling of contaminated birds have been reported, although both scenarios have likely occurred. The risk for the human acquisition of botulism from avian species appears to be limited. Although Smart *et al.* (1980) reported an outbreak of BoNT/C in nonhuman primates, humans do not appear to be susceptible to BoNT/C or D following oral exposure (Jensen and Price, 1987). Furthermore, proper cooking of poultry should denature any toxin protein and eliminate the possibility of transmission through consumption.

### Bovine botulism

Cattle are susceptible to BoNT serotypes B, C1, and D, and they acquire botulism most commonly from the

ingestion of preformed toxin in spoiled silage, carrion-laden silage, or silage contaminated with poultry litter. As with horses, toxico-infectious and wound botulism are also potential routes of intoxication in cattle. All three toxin serotypes (B, C1, and D) have been associated with clinical disease caused by the ingestion of spoiled or carrion-laden feedstuffs. Intoxication with BoNT/B is associated with the ingestion of poorly ensiled or spoiled silage, whereas BoNT/C1 is associated with the ingestion of carrion or poultry litter-laden feedstuffs. Although less frequent, BoNT/D has also been implicated with the ingestion of contaminated silage. Interestingly, intoxication with BoNT/D has also been associated with the ingestion of bones by phosphorus-deficient cattle or cattle with pica. Numerous studies have documented the association between outbreaks of bovine botulism and the ingestion of improperly ensiled silage or spoiled haylage contaminated with BoNT/B (Divers *et al.*, 1986; Yeruham *et al.*, 2003; Braun *et al.*, 2005). Wet hay or soil-contaminated hay, wrapped in plastic bags for storage, can provide the ideal moist anaerobic environment for *C. botulinum* growth. Contamination of a total mixed ration (TMR) with a cat carcass was determined to be the source of a BoNT/C1 outbreak in a herd of adult Holstein dairy cattle in California (Galey *et al.*, 2000). The practice of feeding ensiled poultry litter to cattle has also been associated with outbreaks of serotype C1 botulism, as documented in an Irish beef herd by McLoughlin *et al.* (1988). Although serotype D is less commonly associated with food-borne botulism, an outbreak occurred on a Canadian feedlot following the feeding of a TMR containing spoiled bakery waste (Heider *et al.*, 2001). A separate outbreak of BoNT/D in a Holstein dairy herd occurred in which the source was suspected, but not proven, to be contaminated haylage (Martin, 2003).

### Clinical signs, diagnosis, and treatment

Bovine botulism usually occurs in the context of a herd outbreak. The classical signs of bovine botulism are similar to those observed in horses; however, cattle exhibit a more gradual progression of clinical signs, improving the prognosis and probability of recovery in cattle (Whitlock *et al.*, 1989; Whitlock and Williams, 1999). Furthermore, at least one study has reported that ruminal microbes degrade BoNT, decreasing the absorption of active toxin in cattle compared to horses (Allison *et al.*, 1976). The clinical course ranges from 2 to 30 days, depending on exposure dose and duration and the administration of treatment. Early botulism may be confused with milk fever because generalized muscle weakness, increased ataxia, and muscle tremors may occur in both conditions. Cattle with botulism also exhibit depression, dysphagia, decreased tongue and

jaw tone, hypersalivation, dehydration, decreased tail tone, decreased pupillary light responses, and mydriasis. Rumen contractions decrease, and constipation may develop. Diarrhea and/or putrid-smelling feces may also be noted. Cattle with botulism tend to spend significant amounts of time in sternal recumbency. At terminal stages of botulism, cattle are laterally recumbent, exhibit abdominal breathing patterns, and finally succumb from respiratory failure. Vital signs are often normal in early stages of botulism; however, as the disease progresses, increased heart and respiratory rates may be noted, whereas body temperature may decrease.

A syndrome resembling equine dysautonomia has been described in German cattle, and a link to BoNT has been proposed. These cattle may present with a subclinical to chronic "visceral" disease. Nonspecific symptoms such as weight loss, decreased milk production, depression, alternating constipation and diarrhea, edema, laminitis, ataxia, retracted abdomen, emaciation, tachypnea, and unexpected death are associated with this syndrome (Böhnel *et al.*, 2001). In cattle exhibiting these symptoms, Böhnel and associates demonstrated the presence of both *C. botulinum* and BoNT in lower GI tract contents. Furthermore, neither BoNT nor *C. botulinum* was isolated from asymptomatic herds. This study hypothesized that small levels of *C. botulinum* colonized the lower intestinal tract and created a low-level, chronic exposure of BoNT. This low level of toxin may not reach the systemic circulation, and thus toxin may only disrupt nearby parasympathetic ganglionic innervation of the GI tract, altering intestinal function.

In cases of bovine botulism, clinical pathology may reveal signs of dehydration such as increases in packed cell volume and total plasma protein. Bicarbonate loss from excessive ptyalism may lead to a metabolic acidosis. Increases in muscle enzymes such as aspartate transaminase and creatinine kinase may be present due to muscle atrophy or trauma resulting from prolonged lateral recumbency. Electrolyte abnormalities and hyperglycemia may also be detected. One study documented indicators of renal failure in a herd poisoned by BoNT/B; increased  $\gamma$ -glutamyl transpeptidase, urea, creatinine, and phosphorus were also detected.

As with other species, there are no definitive gross pathological or pathognomonic histological signs of botulism. Aspiration pneumonia and pulmonary emphysema are the most frequent sequelae of botulism in cattle (Galey *et al.*, 2000; Heider *et al.*, 2001; Braun *et al.*, 2005). Other lesions, such as gastric ulcerations, thickened intestinal mucosa, hepatic lipidosis, suppurative rumenitis, and renal failure, have been documented in concurrence with botulism; however, these findings are not consistent in all cases of bovine botulism.

Botulism in cattle is usually a presumptive field diagnosis made on the basis of clinical signs and the ruling

out of other diseases. Differential diagnoses include hypocalcemia, hypomagnesemia, hypokalemia, hypophosphotemia, listeriosis, lead poisoning, polioencephalomalacia, ionophore toxicity, nutritional or plant toxin-induced myopathies, molds, organophosphate poisoning, and tick paralysis. Clinical diagnosis is usually made through the detection of neurological deficiencies in light of relatively unremarkable laboratory diagnostic findings. The neurological examination should assess cranial nerve responses, gait, posture, and attitude. Specifically, a tongue tone test, tongue stress test, and a jaw tone test should be performed. The tongue stress test is performed by placing a hand at the base of the cow's tongue and putting pressure on the tongue followed by an assessment of muscular tone. The tongue tone test is performed as in the horse. Cattle with botulism will exhibit weak tongue strength. The jaw test is performed by grasping the mandible near the symphysis and attempting to move the mandible laterally. This test assesses the strength of the masseter muscles. A "loose" jaw is suggestive of botulism.

A definitive diagnosis is made by identifying toxin in the patient's serum, ruminal fluid, or tissues. Identification of BoNT or *C. botulinum* in suspect feedstuffs previously consumed by clinically ill animals may further support a diagnosis. Isolation of BoNT from the rumen may prove difficult because the toxin is often diluted by rumen contents and/or degraded by ruminal microbes. Similar to botulism in other species, the MBA is the gold standard for a definitive diagnosis in cattle; however, as in horses, the MBA is often not sensitive enough to detect the low levels of toxin in the general circulation. The MBA may also be used to detect toxin in rumen contents, the liver and other organ tissues, milk, or feedstuffs. Due to the relatively slower progression of clinical signs in cattle, diagnostic samples are often obtained long after ingestion of toxin. Thus, the level of toxin in these samples may have fallen below the level of detection. Specimens may also be cultured to isolate *C. botulinum*. An ELISA test has been developed to detect BoNT/C and D in cattle; however, this test is considered less sensitive than the MBA. ELISA tests for the detection of antibodies to BoNT/C and D in cattle have also been developed.

Supportive care is the core of therapy for bovine botulism, and treatment should only be pursued in standing cattle. Affected cattle should be kept in confinement to minimize movement and exertion. Dehydration, electrolyte deficiencies, acid-base abnormalities, and glucose deficiencies should be managed with fluid therapy. Fluids can be administered orally (via an orogastric tube) or i.v. Mineral oil or sodium sulfate can be administered with care as cathartics to treat ileus; however, magnesium sulfate should be avoided because it may potentiate muscle weakness. Rumen transfaunation may also

be performed. Alfalfa gruels may be administered via an orogastric tube to maintain caloric intake. Equine origin polyvalent antiserum may be administered to cattle. However, antitoxin therapy may be less efficacious in cattle because most of the toxin will have been internalized into the neuron or degraded by the time the diagnosis is made. Antibiotics may be administered for secondary complications such as aspiration pneumonia; as in horses, those that produce muscle weakness should be avoided. Although toxoid vaccinations for serotypes B, C, and D are administered to cattle in other countries, there are no U.S. Food and Drug Administration-approved vaccinations for cattle in the United States.

### Public health

The Food Safety Act of the United States (1990) requires that meat or milk products be withheld from market for a minimum of 14 days after the onset of the last clinical case of botulism in an affected herd (Cobb *et al.*, 2002). However, the public health concern for transmission of BoNT through milk appears to be minimal. No cases of human botulism acquired from the consumption of meat or milk from botulism-affected cattle have been reported; furthermore, it does not appear that calves acquire botulism through nursing from affected cows. Only a single study to date has been able to detect BoNT in milk from a dairy cow affected with botulism (Böhnel *et al.*, 2005). In this study, BoNT/B was isolated in milk collected from one udder quarter that was simultaneously affected with mastitis. The toxin concentration in the milk was determined to be approximately  $10^4$  mouse LD<sub>50</sub>s. However, the milk did not test positive for *C. botulinum* bacteria. It is likely that the concurrent mastitis infection enhanced the passage of the rather large toxin protein (150 kDa) across the normally protective blood:milk barrier by altering its permeability. This is supported by a much earlier report from Moberg and Sugiyama (1980), who isolated BoNT in milk using an infected rat model. Other studies have not been able to detect BoNT in milk from affected cows using either ELISA or MBA techniques (Galey *et al.*, 2000; Cobb *et al.*, 2002; Moeller *et al.*, 2003). Regardless, the pasteurization process would likely denature any toxin protein that was able to pass into milk, reducing the risk to the consumer. Note, however, that the potential for BoNT contamination of milk may be more relevant in regions where unpasteurized milk is available for public consumption.

### Canine and feline botulism

Although carnivores are thought to be more resistant to the development of botulism, cases of canine botulism have been documented in the United States, Great Britain,

continental Europe, and Australia. Most reported cases of botulism in dogs result from the ingestion of BoNT/C1-contaminated carrion; however, a few cases of serotype D have been documented in Senegal (Barsanti, 1990, 2006). Barsanti *et al.* (1978) described an outbreak of type C1 botulism in a hunting colony of American foxhounds; however, the source of the toxin was not identified. Farrow *et al.* (1983) described type C1 botulism in three young Australian cattle dogs following the ingestion of rotting duck carcasses found in a local Sydney park. Canine botulism has also been associated with the ingestion of contaminated raw meat (Darke *et al.*, 1976).

Until recently, the only documented cases of feline botulism were experimentally induced; however, Elad *et al.* (2004) described a natural outbreak of botulism in eight cats that ingested parts of a pelican carcass contaminated with BoNT/C1. Interestingly, BoNT/C1 botulism has also been reported in lions (Critchley, 1991).

### Clinical signs, diagnosis, and treatment

The onset of canine botulism can occur within hours or as late as 6 days post-exposure. Severe cases are associated with an earlier onset of clinical signs. The course of the disease usually ranges from 12 to 24 days. In the clinical report of an outbreak of feline botulism, clinical symptoms were first noted 3 days post-ingestion of contaminated pelican muscle (Elad *et al.*, 2004). Although 50% of the exposed cats died, those that survived recovered significantly by 6 days post-intoxication.

Lower motor neuron dysfunction and, to a lesser extent, cranial nerve and autonomic nervous system deficits are observed in canine botulism. Paresis begins in the hind limbs and progresses cranially, ultimately resulting in flaccid muscle paralysis and quadriplegia. Interestingly, dogs with botulism maintain the ability to wag their tail. Tremors of the masseter and temporal muscles may be noticed. Muscle atrophy is variable throughout the course of the disease. Mydriasis, decreased pupillary light response, decreased palpebral reflexes, and decreased or weak vocalizations may occur. Hyperemic conjunctiva and decreased Schirmer tear tests may be noted. Heart rates and respiratory patterns are variable; however, as abdominal muscle tone diminishes, diaphragmatic breathing may be noted. Regurgitation, megaesophagus, urinary retention, and constipation are also observed. Secondary complications include aspiration pneumonia, bilateral keratoconjunctivitis sicca, and urinary tract infections. If paralysis progresses to the respiratory muscles, death may occur from respiratory failure; however, death may also result from progressive secondary pneumonia or urinary tract infections. If secondary complications do not arise, the prognosis for canine botulism is good. Recovery occurs in the reverse order from that of the onset of paralysis; cranial

nerve function and motor function of the neck and limbs return. In the one case study of natural botulism in cats, clinical signs were similar to those of dogs. Motor deficits and paresis were noted; however, cranial nerve reflexes were normal. Depression, anorexia, mild dehydration, tachycardia, and urinary retention were also noted.

As with EGS in the horse, there has also been speculation of an association between feline dysautonomia (Key-Gaskell disease) and BoNT/C. Clinical signs for feline dysautonomia include depression, anorexia, vomiting, regurgitation, mydriasis, constipation, and urinary retention; however, the somatic lower motor neuron paralysis characteristic of classical botulism is not observed. Histological evidence of neuronal degeneration in autonomic ganglia confirms the diagnosis of dysautonomia. Interestingly, BoNT/C was detected in feces, ileal contents, and foodstuffs of cats displaying symptoms of dysautonomia (Nunn *et al.*, 2004). Furthermore, affected cats had higher levels of anti-BoNT/C and *C. botulinum* surface antigen IgA in their feces compared to control cats. Additional studies are warranted to determine the potential role of BoNT/C in feline dysautonomia.

With the exception of dehydration or secondary infection, the CBC count, blood chemistry, urinalysis, and CSF analysis are usually within normal limits in canine and feline botulism. Thoracic radiographs may reveal a megaesophagus and aspiration pneumonia. Electromyographic (EMG) findings may indicate lower motor neuron disease in clinically ill animals. Decreases in the amplitudes of compound muscle action potentials and motor unit potentials are often detected. Furthermore, fibrillation potentials and decreases in nerve conduction velocity may also be detected. In order to make a definitive diagnosis, toxin must be identified in serum, vomitus or gastric contents, feces, or food samples from animals showing clinical signs. The gold standard MBA appears to have adequate sensitivity for the detection of toxin in canine and feline biological samples or in carrion. Note that the isolation of *C. botulinum* bacteria through cultures of feces, GI contents, or viscera is not a definitive diagnosis because this bacterium can be isolated from the GI tract and viscera of healthy dogs.

Differential diagnoses for canine botulism should include tick paralysis, polyradiculoneuritis (coonhound paralysis), myasthenia gravis, coral snake envenomization, and the dumb form of rabies. Both the lower motor neuron deficits and EMG findings are similar to those of tick paralysis and polyradiculoneuritis; however, due to its action on cholinergic terminals, botulism also causes cranial nerve and autonomic deficits. The nature of botulism outbreaks to affect multiple animals further differentiates the disease from other causes of lower motor neuron dysfunction.

Treatment of canine botulism consists mainly of supportive care (Critchley, 1991; Barsanti, 2006). If the

ingestion of toxin-contaminated food has been recent, gastric lavage, cathartics, and enemas may be used to decrease toxin absorption from the GI tract. However, as in other species, magnesium sulfate should be avoided. Supplemental fluids should be administered as needed to maintain hydration. Nutritional support via orogastric or parenteral administration may also be needed. Animals should be monitored for aspiration pneumonia due to megaesophagus and decreased gag reflexes. If constipation develops, enemas and stool softeners may be administered. Manual expression of the bladder may be required to decrease the occurrence of urinary tract infections. Topical ophthalmic ointments should be used to prevent corneal ulcers, which may result from diminished palpebral tone and tear production. Adequate bedding and frequent repositioning are necessary to prevent the development of decubital ulcers. In cases in which respiration is compromised, mechanical ventilation may be necessary. Antimicrobial therapy may be needed for secondary infections; however, as in other species, aminoglycosides, tetracycline, procaine penicillin, metronidazole, aminopyridines, and guanidines should be avoided.

Administration of the equine antitoxin in small animals is controversial. By the time clinical signs are noted, antitoxin is likely to be ineffective because most of the toxin is already bound to the nerve cell or has translocated into the neuron. Only the trivalent antitoxin vaccine for serotypes A, B, and E is available in the United States; this antitoxin is less useful for dogs and cats, which are usually affected by serotype C (Barsanti, 2006). However, the heptavalent antitoxin is available in other countries (Byrne and Smith, 2000; Arnon *et al.*, 2001). Because adverse reactions to antitoxin may occur, and patients with mild disease often recover with supportive care alone, antitoxin administration is usually reserved for severe cases.

# Enterotoxins

Larry J. Thompson

## INTRODUCTION

The term food poisoning can be used to describe the result of eating pathogenic organisms or toxins in contaminated food. The list of causative agents for food-borne illness can be quite lengthy, including infectious agents (e.g., bacteria, viruses, and parasites), natural toxins (e.g., bacterial toxins, mycotoxins, shellfish poisons, and plant poisons), and other contaminants (Mead *et al.*, 1999). Veterinarians and owners often use the term garbage intoxication or garbage poisoning to describe the situation in which animals, especially dogs, eat discarded or otherwise poorly preserved foodstuffs and subsequently develop a syndrome composed mainly of severe vomiting and diarrhea. This chapter is focused on the effects of enterotoxins, which are defined as those bacterial exotoxins that are specific for the intestinal tract causing vomiting, diarrhea, and abdominal pain. Although many organisms produce enterotoxins (Vaishnavi, 1996; Fasano, 2002), those produced by *Staphylococcus aureus* and *Bacillus cereus* are stressed in this chapter. Botulism is discussed separately in the previous chapter. In contrast to enterotoxin, the term endotoxin is used to describe a cell-associated bacterial toxin, usually a lipopolysaccharide complex that is found on the outer membrane of gram-negative bacteria. Endotoxins essentially remain associated with the cell wall until the destruction of the bacteria by autolysis, external lysis, or phagocytic digestion. Although all animals can be affected by endotoxin, the horse is especially prone to disease complications due to endotoxemia (Werners *et al.*, 2005).

## BACKGROUND

This chapter focuses on the most common situations associated with enterotoxin exposures in veterinary medicine, namely dogs ingesting garbage, carrion, or other spoiled foodstuffs. Dogs readily consume a wide variety of such material, and owners often are unaware when their animal has had access to or has consumed foodstuffs of doubtful origin. Many owners have the mistaken opinion that dogs (and other animals) are not susceptible to food poisoning and thus may feed their pets foods that humans would rather not ingest. Discarded foodstuffs are often high in proteins and carbohydrates and serve as excellent substrates for the rapid growth of bacteria, often with enterotoxin release. Instances of garbage intoxication increase during warm weather and during major holidays when increased food is prepared and discarded. Under conditions of warm temperatures and adequate moisture, these discarded foodstuffs can have an almost explosive growth of bacteria, especially *S. aureus* and *B. cereus*, which are the most common causes of enterotoxin-related food poisonings in the human. Although a great deal of time and energy has been expended by public health officials in the pursuit of the origin and control of food poisonings in humans, there is a paucity of specific information concerning animals.

## PHARMACOKINETICS AND MECHANISM OF ACTION

*Staphylococcus aureus* is a facultative anaerobic gram-positive coccus that may be single, paired, or in a

grape-like cluster. *Staphylococcus aureus* does not form spores and thus contamination may be avoided by proper heat treatment of food to kill the bacteria. *Staphylococcus aureus* is able to grow in a wide range of temperatures (7–48.5°C), with an optimum range from 30 to 37°C. *Staphylococcus aureus* can also grow over a wide pH range (4.2–9.3) and can tolerate sodium chloride concentrations of up to 15%. These characteristics allow it to grow in a wide variety of foodstuffs and in situations of discarded food. *Staphylococcus aureus* is an important infective pathogen as well and can easily be found in the nostrils and on the skin of most mammals (Le Loir *et al.*, 2003). At least 14 different staphylococcal enterotoxin (SE) types have been found, and they are best described as short proteins secreted by the cell into the growth matrix (Balaban and Rasooly, 2000). All SE types are water soluble, very heat resistant, and resist most proteolytic enzymes, such as trypsin and pepsin, which make it possible for them to travel through the digestive tract to their site of action. Thus, all SE types resist the conditions that could easily destroy the bacteria that produced them. SEs are thought to have a direct effect on the intestinal epithelium and on the vagus nerve to cause stimulation of the emetic center as well as increasing peristalsis. Foods that are frequently associated with staphylococcal food poisoning include meat and meat products; poultry and egg products; salads such as egg, tuna, chicken, potato, and macaroni; bakery products such as cream-filled pastries; and milk and other dairy products. An example of a proverbial high-risk food is the potato salad at a summer picnic left out for several hours without refrigeration.

*Bacillus cereus* is in the family Bacillaceae, which are all gram-positive rod-shaped bacteria that form endospores. The family has two main divisions: the anaerobic spore-forming bacteria of the genus *Clostridium* and the aerobic or facultatively anaerobic spore-forming bacteria of the genus *Bacillus*. *Bacillus cereus* is a primary inhabitant of soils and contaminates almost all agricultural products. It is also routinely involved in the contamination and spoilage of food products. *Bacillus cereus* can also be involved in wound, eye, or systemic infections. *Bacillus cereus* food poisoning is generally described as having two types of illness caused by different metabolites. The diarrheal type of illness is caused by one or several heat-labile, high-molecular-weight proteins, whereas the vomiting (emetic) type of illness is believed to be caused by a low-molecular-weight, heat-stable peptide that has been named cereulide (Schoeni and Wong, 2005). In the human, the diarrheal syndrome is thought to be the consequence of a food-borne infection with enterotoxigenic *B. cereus* following the observation that the diarrheal enterotoxins are produced during the vegetative growth of *B. cereus* in the small intestine. *Bacillus cereus* food poisoning has been classically associated with fried rice

and other cooked rice dishes because the bacteria is frequently present in uncooked rice and heat-resistant spores may survive cooking. If cooked rice is subsequently held at room temperature, vegetative forms multiply, and a heat-stable toxin is produced that can survive brief heating, such as stir frying. *Bacillus cereus* food poisoning can also be associated with meat- or vegetable-containing foods after cooking where the food was held above room temperature for a prolonged period of time.

## TOXICITY

The symptoms of staphylococcal food poisoning occur in humans when as little as 100ng of enterotoxin is ingested (Bennett, 2005). There is a paucity of information on the dose of individual enterotoxins that will cause clinical signs in common domestic animals. The first and most common clinical sign in dogs is vomiting, which usually occurs within 2 or 3h following ingestion. This can often suffice to remove enough contaminated food from the gastrointestinal tract to prevent the development of more severe clinical signs. However, vomiting can be protracted and lead to fluid and electrolyte abnormalities. Diarrhea can often develop within 2–48h following ingestion of contaminated food and can be severe, sometimes bloody. The combination of both vomiting and diarrhea in the affected animal can quickly lead to profound fluid and electrolyte abnormalities. The animal may exhibit tenderness to the abdomen or the stomach and the intestinal tract can be distended with gas (Coppock and Mostrom, 1986).

The emetic form of *B. cereus* food poisoning is characterized in the human by an acute attack of nausea and vomiting, which occurs within 1–5h after consumption of contaminated food. Diarrhea is not a common feature in this type of illness. In the human, the diarrheal syndrome is characterized by abdominal pain, abdominal cramping, and diarrhea that often can be very watery. There is an incubation period of 4–16h, and clinical signs can persist for 12–24h. Nausea may accompany the diarrhea, but vomiting rarely occurs.

## TREATMENT

It is important to remember three factors when a food-borne problem is included in the differential diagnosis: the presenting clinical signs, the possible exposure to foodstuffs not normally included in the animal's diet, and the interval between exposure and onset of clinical problems. Some of these may not be known at the time of initial presentation but should be explored as the case is developed.

In general, treatment of garbage intoxication in animals should be directed at correcting the fluid and electrolyte abnormalities along with considerations of acid–base balance. As mentioned previously, non-complicated cases will often resolve within hours of presentation with only supportive care. However, because the clinical signs can be similar to those of more serious conditions, a more thorough diagnostic workup (e.g., survey abdominal radiographs) and close observation should always be considered. Because cases most often present following several vomiting episodes, the use of emetics is usually not indicated. In the case of protracted vomiting, the judicious use of antiemetics should be considered. Administration of activated charcoal is not required for known garbage intoxications, but many clinicians will use it as part of a general approach to these cases. Activated charcoal should not be given to dehydrated animals unless fluid administration is also initiated. Antibiotics are not indicated in uncomplicated cases of garbage intoxication.

## CONCLUDING REMARKS

This chapter describes garbage intoxication with emphasis on preformed enterotoxins as the causative agents.

The great number of other types of food-borne illnesses, including infectious agents and toxins, require other diagnostic and treatment considerations.

# Cyanobacterial (blue-green algae) toxins

Birgit Puschner and Amber Roegner

## INTRODUCTION

Freshwater cyanobacterial blooms hold the potential to significantly impact the health of both animal and human populations utilizing surface waters for drinking water, daily living, and recreation worldwide. In addition to the often visually stunning nature of these proliferations of cyanobacterial species, the blooms can result in the production of a variety of compounds, from malodorous ones that affect the taste of the water to dermal and gastrointestinal irritants and severe neurotoxins, gastrointestinal toxins, and hepatotoxins. Among the 2000 species identified through morphological criteria, more than 80 are known to be toxigenic, and as assays for detection and toxicity continue to improve, this number will continue to grow. George Francis first reported a toxigenic bloom in the journal *Nature* in 1878. He reported a “poisonous Australian lake” with “a thick scum like green oil paint” and vividly described acute intoxications of sheep, horses, dogs, and pigs. Analysis of archaeological evidence coupled with evolving understanding of modern blooms have begun to implicate the role of cyanotoxin poisoning in more widespread mammalian die-offs dating back to the Pleistocene age (i.e., approximately 150,000 years BC; Braun and Pfeiffer, 2002), and even a controversial hypothesis about the role of cyanobacteria in the various mass extinction events has begun to emerge (Castle and Rodgers, 2009).

Since Francis’ publication in 1878, numerous case reports describing animal morbidity and mortality after exposure to cyanotoxins have been published (Fitzgerald and Poppenga, 1993; Naegeli *et al.*, 1997; Puschner *et al.*, 1998, 2008, 2010; Gugger *et al.*, 2005; Nasri *et al.*, 2008;

Wood *et al.*, 2010). The frequency of blue-green algae poisoning in animals is likely underreported due to lack of methods to confirm exposure; in addition, geographical distribution of these case reports is likely biased by available resources. Diagnostic confirmation of suspect blue-green algae poisoning cases of humans and animals requires extensive effort from both toxicologists and clinicians, and resources are often not readily available. New algal toxins are continuously being discovered, and oral bioavailability and toxicity data are often unavailable. It is probable that blue-green algae poisonings are more common in animals than in humans due to animals’ greater direct dependence and contact with surface waters.

Pursuant to several major human intoxications in Australia, Europe, and Brazil (Falconer and Humpage, 2005), in 1998 the World Health Organization (WHO) proposed a guidance value for the maximum permissible concentration in potable water sources for microcystin-LR, the most commonly reported cyanotoxin worldwide. Water sanitation agencies in many countries in Europe, North America (Canada), South America (Brazil), and Oceania (Australia and New Zealand) adopted these guidelines. In addition, as a result of a tragedy in 1996 in which more than 100 patients at a hemodialysis clinic received inadequately treated drinking water (Azevedo *et al.*, 2002), most of whom developed acute liver failure as a result of being exposed to cyanotoxins, Brazil has adopted more comprehensive and stringent guidelines to include other cyanotoxins (Burch, 2008). Awareness of imminent health risks for wild and domestic terrestrial vertebrates has increased during approximately the past decade, in part due to veterinary case reports; however, the extent and

heterogeneity of the impact are still far from understood. Veterinarians thus have the opportunity to substantially deepen the understanding of the impact of these cyanotoxins on animal and human populations alike.

## BACKGROUND

Nutrient-rich runoff into surface waters – particularly nitrogen- and phosphorus-rich fertilizers, soaps, and waste products – has led to significant eutrophication worldwide (>40% in Europe, Asia, and America) (Bartram *et al.*, 1999; Smith, 2003). As a major consequence of shifting nutrient additions, previously nutrient-limited photosynthetic microorganisms proliferate. Depending on the limitations of the system and the types of nutrients added, a few species (generally one or two) outcompete the others, thereby considerably reducing the heterogeneity of the phytoplankton community. In such conditions, cyanobacteria often predominate through adaptive processes, and substantial shifts in the microscopic and macroscopic food web may occur. Anoxic conditions can also result in fish kills, and falling debris from blooms can have profound impacts on the invertebrates in the sediment below (Pearl *et al.*, 2001; Havens, 2008).

Among the oldest microorganisms, these oxygenic photosynthetic prokaryotes may be organized as individual cells (e.g., *Synechococcus*), filaments (e.g., *Planktothrix*), or colonies (e.g., *Microcystis*). More than 2000 cyanobacterial species belong to four orders based on morphological and morphometric criteria in botanical code (Anagnostidis and Komarek, 1985); however, classification based on bacterial code defines five sections through combined use of genetic data, morphological criteria, and cellular fission (Rippka *et al.*, 1979).

Both pelagic (suspended in the water column) and benthic (along the bottom) cyanobacteria can proliferate into blooms. Pelagic blooms, which are easier to visually detect because of the evident scum formation at the surface, usually occur in mesotrophic and eutrophic ecosystems (concentrations in phosphorus >30 µg/L), during the summer, in water temperatures greater than 20°C, and in low turbulence. Proliferations of benthic species generally occur during the summer on the surfaces of sediments, stones, or macrophytes in small oligotrophic rivers or in oligotrophic lakes (Mez *et al.*, 1997).

In the past, most cases were diagnosed by positive identification of the algae in the suspect water source along with the occurrence of consistent clinical signs and pathological findings. However, new analytical methods can now be applied to detect toxins in biological specimens of animals or humans with suspect exposure to toxic algal blooms Figure 72.1 illustrates the wide variety

in chemical structures of cyanotoxins and the need for specific detection methods. (Yuan *et al.*, 2006; Humbert, 2010). These capabilities will allow for in-depth diagnostic investigations and a better estimate of the true frequency of blue-green algae poisonings in livestock, pets, and wildlife. Table 72.1 provides an overview of cyanobacterial species known to produce a large number of toxins. Some species can produce a variety of cyanotoxins and thus it is difficult to predict the nature and the level of the toxin production during a bloom event. This chapter focuses on the several types of cyanotoxins known to have the greatest impact on veterinary species and presents the current understanding of their toxic mechanisms, toxicokinetics, and diagnostic and therapeutic approaches with a focus on veterinary medicine.

## MICROCYSTINS

Produced by multiple cyanobacteria, including species within the genera *Microcystis*, *Anabaena*, *Planktothrix*, *Nostoc*, *Oscillatoria*, and *Anabaenopsis*, microcystins have been detected worldwide (Fromme *et al.*, 2000; Hitzfeld *et al.*, 2000; Ballot *et al.*, 2004; Briand *et al.*, 2005; Karlsson *et al.*, 2005a; Ndeti and Muhandiki, 2005; Agrawal *et al.*, 2006). Not all strains are capable of producing microcystins. In recent years, a useful diagnostic tool to test for the presence of toxin-producing genes has emerged (Hisbergues *et al.*, 2003). Although the reason for production is not understood, environmental factors, such as pH, nutrient concentrations, and water temperature, clearly trigger production, increasing with water temperature, elevated concentrations of phosphorus and nitrogen, iron limitation, and globally with the growth rate (Briand *et al.*, 2005; Downing *et al.*, 2005; Sevilla *et al.*, 2008). Microcystin concentrations may be highest when the growth of the cyanobacteria is high, but toxin concentrations do not necessarily correlate with cell count, and toxins may occur any time of the year. Although predominantly found in freshwater, microcystin-producing blooms have also been described in saline ecosystems (Atkins *et al.*, 2001; Carmichael and Li, 2006).

Potent cyclic heptapeptides causing acute hepatotoxicosis in mammals, microcystins have also been demonstrated to be toxic to reptiles, amphibians, and aquatic species, as well as invertebrates and even plant species (McElhiney *et al.*, 2001; Malbrouck and Kestemont, 2006; Nasri *et al.*, 2008; Amado and Monserrat, 2010). In freshwater, the toxins are retained inside the cyanobacteria and only released upon cell damage, lysis, and death; destruction of algal mats (either naturally or through the application of herbicides) may result in a pulse of microcystin release following destruction of the individual cell walls. After oral exposure to microcystin-containing

FIGURE 72.1 Structural formulas of cyanobacterial toxins.

algae, the acidic environment of the stomach can result in the release of microcystins. Commercially available blue-green algae food supplements also present a potential route of oral exposure (Schaeffer *et al.*, 1999; Dietrich and Hoeger, 2005).

More than 80 different structural variants of microcystins have been identified from various genera of cyanobacteria (Luukkainen *et al.*, 1994; Lawton *et al.*, 1995; Welker and von Döhren, 2006). The shared structure involves an amino acid called ADDA

TABLE 72.1 Potential toxins produced by the different cyanobacterial species

Cyanobacterial species	Toxins	Cyanobacterial species	Toxins
<i>Anabena bergii</i>	Cylindrospermopsin	<i>Nodularia spumigena</i>	Nodularins
<i>Anabaena circinalis</i>	Anatoxin-a, saxitoxins, microcystins	<i>Nostoc linckia</i>	Microcystins

		<i>Woronichinia naegeliana</i>	Anatoxin-a

(3-amino-9-methoxy-2,6,8-trimethyl-10-phenyldeca; 4,6-dienoic acid) and six other amino acids, including two variable positions that designate the congener. The most extensively studied, microcystin-LR, has been found worldwide and has caused acute, lethal hepatotoxicoses in farm animals (Carbis *et al.*, 1994; Mez *et al.*, 1997; Puschner *et al.*, 1998) and hepatic injury in humans (Azevedo *et al.*, 2002; Rao *et al.*, 2002).

### Pharmacokinetics/toxicokinetics

Despite the abundant literature on microcystins, understanding of pharmacokinetics remains limited,

particularly with regard to potential species variations. Most studies have been conducted in mice after intravenous (i.v.) and intraperitoneal (i.p.) administration of cyanobacteria, their filtrates, and, in some instances, purified microcystins. After i.v. and i.p. administration in mice and rats, microcystins are rapidly distributed to the liver (Falconer *et al.*, 1986; Robinson *et al.*, 1991). Plasma half-lives of microcystin-LR in mice after i.v. administration were 0.8 and 6.9 min for the alpha and beta phases of elimination (Robinson *et al.*, 1991). Interestingly, the hepatic concentration of <sup>3</sup>H-microcystin-LR remained constant throughout the 6-day study, indicating accumulation in this target organ. This study also demonstrated that approximately 9 and 14% of the dose was

excreted in urine and feces, respectively, after 12 h, with 60% of it being excreted unchanged. Additional studies in swine have also indicated that the majority is excreted unchanged, with only two metabolites detected; biliary excretion is also noted after less than 1 h of i.v. administration (Stotts *et al.*, 1997). The exact route of metabolism is yet to be defined, but glutathione and cysteine conjugation have been identified and may represent major detoxification pathways (Kondo *et al.*, 1996; Pflugmacher *et al.*, 1998). Other metabolites have been identified *in vivo* and *in vitro*, but further work is needed to define their roles.

Data on bioavailability for microcystins are needed to better evaluate risk from oral ingestion. Absorption occurs in the small intestine (Ito *et al.*, 2000); thus, the integrity of the intestinal mucosa can significantly impact the degree of absorption (Zeller *et al.*, 2011). Altered cell permeability of the small intestine in aged mice lends them more susceptible than young animals (Ito *et al.*, 1997). Once absorbed, microcystins are rapidly distributed to the liver (Runnegar *et al.*, 1981; Fischer *et al.*, 2000), but they can also reach lung, heart, and capillaries (Ito *et al.*, 2000). Based on radiolabeled experiments in which microcystins were administered i.v. in Wistar rats, uptake into the kidney appears to be important for excretion. Results of uptake experiments with radiolabeled dihydro-MC-LR demonstrated that OATP1B1 (organic anion transporter protein) and OATP1B3 are involved in uptake of MC-LR (Seithel *et al.*, 2007). Studies in fish (i.v.) have demonstrated that the liver is the primary target, followed by kidney and gonads, although uptake does occur into muscle tissue and cardiovascular effects are observed (Malbrouck and Kestemont, 2006). Absorption of microcystin via the respiratory route (Ito *et al.*, 2001) has been demonstrated to lead to lethality in mice and also induce damage to nasal epithelium at lower exposures (Benson *et al.*, 2005), thus posing a threat from aerosolization of the compound.

## Mechanism of action

Specifically toxic to liver, microcystins cause severe hepatomegaly macroscopically and progressive centrilobular hepatocyte rounding, dissociation, and necrosis microscopically. Breakdown of the sinusoidal endothelium and intrahepatic hemorrhage ultimately result in death (Hooser *et al.*, 1991a; Falconer and Yeung, 1992). Unable to permeate cell membranes, microcystins enter hepatocytes via the bile acid transporter mechanism (Hooser *et al.*, 1991b). Once inside the hepatocytes, microcystins are potent inhibitors of protein phosphatases 1 and 2A (Falconer and Yeung, 1992; Runnegar *et al.*, 1993). The disruption of the cytoskeletal components and the associated rearrangement of filamentous

actin within hepatocytes account for the morphological changes, although other mechanisms play a role in the development of liver lesions. Microcystins induce apoptosis of hepatocytes via induction of free radical formation and mitochondrial alterations (Ding and Ong, 2003). A single-dose i.v. in rats demonstrated an increase in liver sphingolipid levels at higher doses (implicating ceramide-mediated apoptosis), a dose-dependent decreased PP2A expression, and ultimately a dose-dependent decreased expression of Bcl2 family proteins, involved in cell cycle/apoptosis regulation (Billam *et al.*, 2008). The role of oxidative stress has become increasingly apparent, and the ultimate toxic effect may depend on the ability of antioxidant pathways to counter the stressors (Ding and Ong, 2003; Jayaraj *et al.*, 2006; Xiong *et al.*, 2010). In addition, microcystins are classified as tumor-promoting compounds (Humpage and Falconer, 1999). Investigations have indicated the role of protooncogenes in this tumorigenesis, hypothesized to be a sequelae of dysregulation of phosphorylation (Li *et al.*, 2009). Several studies have demonstrated the ability of microcystins to induce DNA damage in liver cells (Zegura *et al.*, 2011).

Clinical signs of microcystin poisoning have been described in a number of reports in livestock, humans, and wildlife in the United States (DeVries *et al.*, 1993; Fitzgerald and Poppenga, 1993; Galey *et al.*, 1987; Puschner *et al.*, 1998) and other countries (Done and Bain, 1993; Van Halderen *et al.*, 1995; Mez *et al.*, 1997; Naegeli *et al.*, 1997; Azevedo *et al.*, 2002; Ballot *et al.*, 2004; Ndeti and Muhandiki, 2005; Handeland and Østensvik, 2010; Wood *et al.*, 2010). Interestingly, laboratory animals select water with microcystin-producing strains of cyanobacteria over a water source with nontoxic strains (Lopez Rodas and Costas, 1999), suggesting an increased risk for toxicosis in animals due to behavioral preferences. Microcystin intoxication should be suspected in cases of acute hepatotoxicosis with clinical signs of diarrhea, vomiting, weakness, pale mucous membranes, and shock. Although most animals die within a few hours of exposure, some animals may live for several hours and develop hyperkalemia, hypoglycemia, nervousness, recumbency, and convulsions. Animals that survive the acute intoxication may develop hepatogenous photosensitization. Nephrotoxic effects have been described in laboratory animals after chronic microcystin exposure (Milutinovic *et al.*, 2003). Evidence suggests potential suppression of immune function at sublethal exposures (Shi *et al.*, 2004). In humans, primary liver cancer as well as colorectal cancer have been associated with microcystin-contaminated drinking water (Ueno *et al.*, 1996; Zhou *et al.*, 2002). In mice, subchronic exposure i.p. of microcystin-LR (20 µg/kg) causes the appearance of hepatic nodules, a characteristic not observed after oral subchronic administration (Ito *et al.*, 1997).

## Toxicity

The lethal doses 50 ( $LD_{50}$ s) for microcystins vary between 50  $\mu\text{g/kg}$  and 11  $\text{mg/kg}$ , depending on the microcystin analog, the species affected, and the route of administration. In mice, the oral  $LD_{50}$  value for microcystin-LR is 10.9  $\text{mg/kg}$ , whereas the i.p.  $LD_{50}$  is 50  $\mu\text{g/kg}$ . Because most blooms contain a number of structural variants of microcystins, it is difficult to estimate the toxicity potential of a bloom. The no-observed-adverse-effect level for orally administered microcystin LR to mice is 40  $\mu\text{g/kg/day}$  (Fawell *et al.*, 1994). In pigs, the lowest-observed-adverse-effect level for microcystin-LR is 100  $\mu\text{g/kg/day}$  (Falconer *et al.*, 1994), and in rat it is 50  $\mu\text{g/kg/day}$  (Heinze, 1999). WHO set the tolerable daily intake (TDI) for human ingestion of microcystin-LR at 0.04  $\mu\text{g/kg/day}$  (Kuiper-Goodman *et al.*, 1999). The potential risk to humans by ingesting food products derived from animals exposed to microcystins was evaluated in beef (Orr *et al.*, 2003) and dairy cattle (Orr *et al.*, 2001). Based on these studies, it is unlikely that consumption of milk, meat, or liver poses a significant health risk to humans. It might be prudent to establish specific guidelines for nonlethal, chronic microcystin exposure in livestock.

## Treatment

No specific antidote for microcystins exists. The rapid onset of acute hepatotoxicosis renders therapeutic intervention quite difficult, and mortality rates are very high. In addition, despite the evaluation of numerous treatment options, no specific therapy has been proven to be effective. The most promising strategy appears to be prevention of uptake into hepatocytes through the administration of compounds that may compete for the specific transporters associated with microcystin uptake; administration of the antibiotic rifampin (i.p.) in mice effectively reduced mortality after exposure (i.p.) to microcystin-LR (Hermansky *et al.*, 1991). By contrast, other compounds, such as glutathione, silymarin, and cyclosporine A, were only beneficial if administered as a prophylactic (Hermansky *et al.*, 1991; Rao *et al.*, 2004). These compounds may help reduce microcystin toxicity in chronic exposure scenarios. Due to the role of oxidative stress, antioxidants such as vitamin E, selenium, and green tea polyphenols also appear to be beneficial prophylactically (Gehring *et al.*, 2003a,b; Jayaraj *et al.*, 2007; Xu *et al.*, 2007). Although the adsorption of microcystins by activated charcoal was used successfully to decontaminate drinking water (Warhurst *et al.*, 1997), this decontamination procedure was not protective in mice dosed with microcystins (Mereish and Solow, 1989); no data are available for other species.

Diagnosis of microcystin toxicosis is corroborated by identification of microcystin-containing water in the environment of the animal. Identification of algae material in water and gastric contents is an important component of the diagnostic workup but does not confirm intoxication. As described previously, the toxicity of the cyanobacteria is strain specific, and morphological observations alone cannot predict the hazard level, but polymerase chain reaction detection of microcystin-producing genes can help identify a potentially culpable species. Detection of microcystins in gastric contents is confirmatory, but these tests are not routinely available at diagnostic laboratories and are limited to a few structural variants. In the past, the mouse bioassay was used to determine the toxicity of crude algal biomass in suspicious blue-green algae poisonings. Although many assays are available to analyze water samples for microcystins (Maizels and Budde, 2004; McElhiney and Lawton, 2005; Frias *et al.*, 2006), there are only limited methods available to reliably and accurately detect microcystins in biological specimens collected from animals suspected to have died from microcystin intoxication (Bogialli *et al.*, 2005; Karlsson *et al.*, 2005b; Chen *et al.*, 2009). An electrospray ionization liquid chromatography–mass spectrometry method has been developed to determine the bound microcystin concentrations in animal tissues, which provides an estimate of the total microcystin burden in exposed animals (Ott and Carmichael, 2006).

Differential diagnoses in animals with a clinical presentation of liver failure include other toxic ingestions, such as amanitins, cocklebur, cycad palm, aflatoxin, xylitol, certain heavy metals, and acetaminophen overdose. Careful evaluation of the history, feed, and environment of the animal can help eliminate most of the toxicant differentials on the list.

## ANATOXINS

Anatoxins are mainly produced by cyanobacteria in the *Anabaena* genus (Beltran and Neilan, 2000) but also by other genera, such as *Plankthrix*, *Oscillatoria*, *Microcystis*, *Aphanizomenon*, *Cylindrospermum*, and *Phormidium*. Unfortunately, specific data on factors resulting in anatoxin-a production are lacking, which makes toxin production unpredictable. Although anatoxin-a is considered unstable in the environment, certain environmental conditions are known to result in continuous toxin production. Reports of anatoxin poisoning are less frequent than those of microcystin toxicosis; however, poisoning has occurred worldwide (Edwards *et al.*, 1992; Gunn *et al.*, 1992; Beltran and Neilan, 2000;

Fromme *et al.*, 2000; Gugger *et al.*, 2005; Yang and Boyer, 2005; Wood *et al.*, 2007; Puschner *et al.*, 2008, 2010). Anatoxins are neurotoxins and can generally be divided into anatoxin-a, homoanatoxin-a, and anatoxin-a(s). Anatoxin-a is a secondary amine and has been detected in blooms worldwide. Homoanatoxin-a is a methyl derivative of anatoxin-a and has been identified in blooms in Japan (Namikoshi *et al.*, 2004), Ireland (Furey *et al.*, 2003), Sweden (Skulberg *et al.*, 1992), and New Zealand (Wood *et al.*, 2007). Anatoxin-a(s) is a unique N-hydroxyguanidine methyl phosphate ester that has been detected in the Americas (Monserrat *et al.*, 2001) and Europe (Henriksen *et al.*, 1997). Commercially available blue-green algae dietary supplements also represent a potential source (Rellán *et al.*, 2009).

### Pharmacokinetics/toxicokinetics

Definite data on the toxicokinetics of anatoxin-a, homoanatoxin-a, and anatoxin-a(s) have not been established. Based on the rapid onset of clinical signs after oral exposure, rapid absorption of the toxins is suspected. Anatoxin-a has been detected in the urine and bile of a poisoned dog, confirming that anatoxin-a is, at least in part, excreted unchanged in urine and bile (Puschner *et al.*, 2010).

### Mechanism of action

Anatoxin-a is a potent cholinergic agonist at nicotinic acetylcholine receptors in neurons and at neuromuscular junctions (Thomas *et al.*, 1993). Anatoxin-a has two enantiomers, with (+)anatoxin-a having a higher binding affinity than the (–) form (Spivak *et al.*, 1980; Zhang and Nordberg, 1993). Compared to nicotine, anatoxin-a is approximately 20 times more potent than acetylcholine. After continuous electrical stimulation at the neuromuscular junctions, a nerve block may follow and result in death due to respiratory paralysis. Furthermore, anatoxin-a has modulatory action at presynaptic neuronal nicotinic acetylcholine receptors, which can lead to dopamine as well as noradrenaline release (Barik and Wonnacott, 2006; Campos *et al.*, 2010). Clinical signs of anatoxin-a poisoning include a rapid onset of rigidity and muscle tremors followed by convulsions, paralysis, respiratory failure, cyanosis, and death. Death usually occurs within minutes to a few hours. Anatoxin-a poisonings have been reported in dogs in Europe (Edwards *et al.*, 1992; Gunn *et al.*, 1992; James *et al.*, 1997; Gugger *et al.*, 2005) and the United States (Puschner *et al.*, 2008, 2010). Anatoxin-a is also considered a contributing factor in the deaths of Lesser Flamingos in Kenya (Krienitz *et al.*, 2003). Homoanatoxin-a is a methyl derivative of

anatoxin-a with similar pharmacological and toxicological properties (Wonnacott *et al.*, 1992), and it has been implicated in dog deaths in New Zealand (Wood *et al.*, 2007). In addition to being a nicotinic agonist, homoanatoxin-a can increase the release of acetylcholine from peripheral cholinergic nerves through opening of endogenous voltage-dependent neuronal L-type  $\text{Ca}^{2+}$  channels (Aas *et al.*, 1996).

Anatoxin-a(s) is different from anatoxin-a and homoanatoxin-a. This neurotoxin has a unique chemical structure and is a naturally occurring irreversible acetylcholinesterase inhibitor. The increased concentrations of acetylcholine in the synapse lead to persistent stimulation, followed by a neuronal muscular block (Cook *et al.*, 1990; Hyde *et al.*, 1991). The mechanism of toxic action is similar to that of organophosphorus and carbamate insecticides, as well as some chemical warfare nerve agents (Patocka *et al.*, 2011). However, one of the main differences is that anatoxin-a(s) acts only in the periphery, whereas the insecticides inhibit acetylcholinesterase in the brain and retina (Cook *et al.*, 1989). Animals poisoned with anatoxin-a(s) show a rapid onset of excessive salivation (“s” stands for salivation), lacrimation, diarrhea, and urination. Clinical signs of nicotinic receptor overstimulation including tremors, incoordination, convulsions, recumbency, and respiratory arrest are most commonly observed in cases with a lethal outcome. Animals often die within 30 min of exposure. Animals that die from anatoxin-a, homoanatoxin-a, or anatoxin-a(s) toxicosis do not show specific gross or microscopic lesions. Anatoxin-a(s) poisoning has been reported in pigs, birds, dogs, and calves in the United States and Europe (Mahmood *et al.*, 1988; Cook *et al.*, 1989; Onodera *et al.*, 1997). Because of the lack of specific detection methods for anatoxin-a(s), the natural occurrence of this neurotoxin has not been fully evaluated.

### Toxicity

In mice, the i.p.  $\text{LD}_{50}$  of anatoxin-a is 200  $\mu\text{g}/\text{kg}$  (Stevens and Krieger, 1991), whereas the i.v.  $\text{LD}_{50}$  is estimated to be less than 100  $\mu\text{g}/\text{kg}$ . The oral toxicity of anatoxin-a is much higher, with an oral  $\text{LD}_{50}$  in mice reported to be greater than 5 mg/kg. Several studies have shown that there are significant species differences with regard to anatoxin-a toxicity. Whereas an anatoxin-a containing *Aphanizomenon flos-aquae* bloom was toxic to sheep after i.p. administration, oral administration failed to induce toxicity (Runnegar *et al.*, 1988). In contrast, calves developed toxicity after oral administration of an anatoxin-a containing *A. flos-aquae* bloom (Carmichael *et al.*, 1977). The i.p.  $\text{LD}_{50}$  of homoanatoxin-a in mice is 250  $\mu\text{g}/\text{kg}$  (Skulberg *et al.*, 1992). Anatoxin-a(s) is much more toxic than anatoxin-a or homoanatoxin-a, with an i.p.  $\text{LD}_{50}$  in mice of 20  $\mu\text{g}/\text{kg}$  (Briand *et al.*, 2003).

## Treatment

There is no specific antidote for anatoxin-a. Because of the rapid onset of clinical signs, emesis is not likely to be useful. Although no studies have evaluated the efficacy of specific decontamination procedures, administration of activated charcoal has been recommended. In addition, artificial respiration may be of benefit along with general supportive care. Specific measures to control seizures include benzodiazepines, phenobarbital, or pentobarbital. If given, they may cause central nervous system and respiratory depression, and careful monitoring of the animal is necessary. In any seizing animal, control of body temperature is an important part of the symptomatic care.

Treatment of animals poisoned with anatoxin-a(s) is primarily symptomatic and supportive. Decontamination procedures can be considered but have not been evaluated. It has been shown that 2-PAM is not able to reactivate the inhibited acetylcholinesterase and is therefore not recommended (Hyde and Carmichael, 1991). Atropine should be given at a test dose to determine its efficacy in animals with life-threatening clinical signs. After the test dose, atropine can be given repeatedly until cessation of salivation. It is important to carefully monitor the animal for anticholinergic effects and to reduce or discontinue atropine if adverse effects develop.

As with other cyanobacteria toxins, toxicity is strain-specific, and identification of the cyanobacteria alone cannot predict the toxicity level. Therefore, detection of anatoxin-a in biological specimens is confirmatory, but these tests are not routinely available (James *et al.*, 1998; Puschner *et al.*, 2010). Anatoxin-a was confirmed in stomach content, liver, urine, and bile of dogs (Gugger *et al.*, 2005; Puschner *et al.*, 2010). In suspect cases, environmental and biological samples should be saved for toxicological and phylogenetic analysis.

Diagnosis of anatoxin-a(s) toxicosis is aided by the determination of blood acetylcholinesterase activity. However, organophosphorus and carbamate insecticides can also inhibit acetylcholinesterase, and additional diagnostic workup is needed to establish a firm diagnosis. This includes the determination of brain acetylcholinesterase postmortem (unchanged in cases of anatoxin-a(s) poisoning), screening of gastrointestinal contents for insecticides, examination of stomach contents (possible identification of cyanobacteria), and a careful evaluation of the environment (access to freshwater and access to insecticides). Detection methods for anatoxin-a(s) are rare. A biosensor method has been developed that allows the quantitation of anatoxin-a(s) in environmental samples (Devic *et al.*, 2002). New analytical methods for anatoxin-a(s) are necessary to better document the distribution of this neurotoxin in freshwater worldwide. Phylogenetic analysis of 16S rRNA gene sequences will help in the species identification.

## MISCELLANEOUS FRESHWATER CYANOBACTERIAL TOXINS

Although microcystin and anatoxin poisonings comprise the majority of cases reported in animals, other cyanotoxins are of concern. Saxitoxins and derived forms belong to the group of paralytic shellfish poisoning (PSP) toxins and have been produced by a number of freshwater cyanobacteria, including *A. flos-aquae*, *Cylindrospermopsis raciborskii*, *Anabaena circinalis*, *Lyngbya wollei*, *Planktothrix* sp., and *Aphanizomenon gracile* (Carmichael *et al.*, 1997; Kaas and Henriksen, 2000; Molica *et al.*, 2005; Ballot *et al.*, 2010). All saxitoxin analogs have high toxicity in mammals by blocking voltage-gated sodium channels, leading to respiratory arrest, neuromuscular weakness, and cardiovascular shock. Whereas intoxications of birds and cats have been associated with ingestion of PSP contaminated fish and clams (Landsberg, 2002), there is only one confirmed report of PSP toxin-associated mortality from exposure to contaminated freshwater (Negri *et al.*, 1995). Fourteen sheep showed signs of trembling, recumbency, and death in Australia after exposure to toxic concentrations of PSPs produced by *Anabaena circinalis*. Because PSP toxins are produced by several species of freshwater cyanobacteria, terrestrial animals and humans are at risk of being exposed to these toxins. Thus, it is important to reliably evaluate animals with neurologic signs after access to freshwater for possible PSP exposure because the risk certainly exists.

Another cyanotoxin, the alkaloid cylindrospermopsin, has caused deaths in cattle (Saker *et al.*, 1999) and severe gastrointestinal disease in humans. Cylindrospermopsin is a potent inhibitor of protein synthesis and can lead to various degrees of injury to the liver, kidneys, adrenal gland, intestine, lung, thymus, and heart (Griffiths and Saker, 2003). Furthermore, this cyanotoxin is of particular concern because of its mutagenic and possibly carcinogenic activities. Cylindrospermopsin has been found in Europe, Australia, New Zealand, and Asia (Hawkins *et al.*, 1997; Saker and Griffiths, 2001; Fastner *et al.*, 2003), but it should be considered a potential worldwide problem. Cylindrospermopsin and deoxycylindrospermopsin have been produced by *C. raciborskii* (Ohtani *et al.*, 1992), and 7-epicylindrospermopsin has been produced by *Aphanizomenon ovalisporum* (Banker *et al.*, 1997). After oral exposure, the LD<sub>50</sub> of cylindrospermopsin obtained with culture extracts of *C. raciborskii* ranged from 4.4 to 6.9 mg/kg in equivalent cylindrospermopsin (Seawright *et al.*, 1999; Shaw *et al.*, 2000).

Nodularins are cyclic pentapeptides that lead to severe hepatotoxicosis in the same way as microcystins (Harding *et al.*, 1995). In addition, nodularin is a more potent tumor promoter than microcystin (Sueoka *et al.*, 1997). The only cyanobacterium species known to

produce nodularin is *Nodularia spumigena*. This cyanobacterium can form extensive blooms in the Baltic Sea and in brackish waters in the summer (Francis, 1878; Sivonen *et al.*, 1989). The risk of nodularin intoxication is twofold because toxin exposure can occur not only through recreational or drinking water but also via contamination of seafood (Van Buynder *et al.*, 2001). In cases of acute hepatotoxicity, exposure to microcystins as well as nodularins must be considered.

$\beta$ -N-methylamino-L-alanine (BMAA), a neurotoxic amino acid, has been confirmed to be produced by a newly discovered cyanobacterial species associated with avian vacuolar myelinopathy (Bidigare *et al.*, 2009). The algal species is in the order Stigonematales and is found on the surface of *Hydrilla verticillata*, aquatic vegetation commonly found in wetlands in the southeastern United States (Wiley *et al.*, 2007). BMAA is a neurotoxic amino acid that has been associated with the pathogenesis of human amyotrophic lateral sclerosis–parkinsonism–dementia complex of Guam (Guam ALS-PD) and lathyrism. Birds with avian vacuolar myelinopathy develop ataxia, tilting, weakness, and death, and they have characteristic postmortem lesions of bilateral symmetrical vacuolation of the white matter of the brain and spinal cord (Thomas *et al.*, 1998). Characterization of BMAA provides a critical tool to study the impact of this cyanobacterial toxin on animals (and humans) and to develop control strategies.

## CONCLUDING REMARKS AND FUTURE DIRECTIONS

The frequency and extent of harmful cyanobacterial blooms appears to increase with the addition of nutrients to surface freshwater ecosystems throughout the world. As demonstrated in Table 72.1, numerous cyanobacterial species have the potential to produce a number of toxins with a range of target organs, but for each cyanobacterial species, it is very difficult to predict the nature and the level of the toxin production for a specific bloom. Although newer detection methods allow for better monitoring of potentially harmful blooms, there is still a need to apply these existing methods spatially and temporally and to develop lower cost, field-ready alternatives accessible to even remote areas. It is also important to develop more sophisticated methods that allow testing for a wider range of cyanotoxins and matrices in order to reliably confirm intoxications and improve overall risk assessment. Some recently developed methods have been useful in analyzing biological specimens in order to confirm a diagnosis of poisoning, but due to lack of availability and high cost, they are rarely pursued

in suspect cases. The lack of methods to confirm exposure is most likely responsible for the low number of reported cases in the veterinary literature during the past 20–30 years. The incorporation of new analytical methods into diagnosis should provide insight into the true frequency of cyanotoxin poisoning in animals. For example, in the United States, several dog intoxications due to anatoxin-a have recently been identified in different regions in relation with the development of an analytical method using high-performance liquid chromatograph–mass spectrometry analysis (Puschner *et al.*, 2008, 2010). In addition, information is needed on the efficacy of therapeutic measures. Similar to advisories for human populations, it is advisable to take preventative measures to avoid contact with surface waters containing visible blooms for all veterinary species, particularly when the water is utilized for a drinking source or for bathing.

## Terrestrial zootoxins

Sharon M. Gwaltney-Brant, Eric Dunayer and Hany Youssef

### INTRODUCTION

The Animal Kingdom is populated by a vast variety of creatures whose main focus in life is to live to see tomorrow. To this end, many animals have developed chemical means of defense and/or food procurement. Every phylum within the Animal Kingdom contains species that produce poisons or venoms. Poisons are compounds produced in nonspecialized tissues as secondary products of metabolism that accumulate in the host animal or that accumulate in predators following ingestion of prey. Poisonous animals, therefore, lack means of actively delivering these chemical compounds to others – exposure generally requires oral contact (rarely dermal) in order for another animal to become poisoned. In contrast, venoms are produced in specialized tissues or glands, and venomous animals have developed a variety of venom apparatuses (stingers, teeth, etc.) to deliver their venom to target animals – a process termed envenomation.

Most venoms and poisons are not composed of a single chemical substance but, rather, are mixtures of a variety of chemical compounds that often act synergistically to produce their toxic effect. Typical constituents include peptides, amines, serotonin, quinones, polypeptides, and enzymes (Russell, 2001). These compounds are collectively termed toxins (the science of the study of toxins is termed toxinology), and toxins produced by members of the Animal Kingdom are collectively termed zootoxins.

Not every exposure to a poisonous or venomous animal will necessarily result in a toxicosis (Meier, 1995). Variations in size, age, sex, season, toxin composition, and geographic location can result in zootoxins with relatively more or less toxicity. Similarly, the animal exposed to the zootoxin may be more or less susceptible

to toxicosis based on its age, weight, sex, and degree of exposure.

Compared to other means of injury or illness in animals, envenomation or poisoning from zootoxins are relatively rare causes for presentation of domestic animals to their veterinarians, due largely to the protection afforded by animal owners. Wildlife, on the other hand, probably face potential exposure to zootoxins on a nearly daily basis. Bites and stings from arthropods and snakes certainly can occur in any species, and the potential for oral exposure to animals such as poisonous toads, snakes, or insects will vary with the region and environment. Recent studies suggest that zootoxins can affect various vital organs, such as nervous, cardiovascular, and reproductive and developmental systems (Dorce *et al.*, 2009; Gwaltney-Brant, 2011; Troncone *et al.*, 2011).

In managing known or suspected zootoxicoses, veterinarians should be mindful to “treat the patient, not the poison.” Patient assessment and stabilization, along with supportive care, are critical in managing these patients. Although antivenins are available for treatment of some types of envenomation, financial and availability issues may limit their use in many instances.

### ARTHROPODA

#### ARANEAE: SPIDERS

##### Introduction

There are at least 30,000 species of spiders distributed throughout the world (Goddard, 2003). Spiders are

characterized by a two-segmented body: a head/thorax (prosoma or cephalothorax) and the abdomen (opisthosoma). They have eight segmented legs (Lucas and Meier, 1995b). Venom is stored in two glands located in the cephalothorax and empties through fangs (chelicerae) located at the rostral end of the prosoma (Lucas and Meier, 1995b). With the exception of spiders in the family Ulobiridae (found in Australia), all spiders are capable of inflicting an envenomating bite via fangs. Most spider envenomations, however, are likely to cause few signs other than local swelling and pain. Anaphylaxis and other allergic reactions to venom components are possible (Goddard, 2003). Although there is disagreement in the literature, it appears that fewer than 100 spider species can inflict a bite of medical significance (Lucas and Meier, 1995b).

## WIDOW SPIDERS (*LATRODECTUS* SPP.)

### Background

Spiders of this genus are found throughout the world. The spiders are identified by a red, yellow, or orange hourglass-shaped marking on the ventral abdomen of the female. Males and immature females are brown; the immature females do not have the hourglass marking. The fangs of the male are considered too short to inflict an envenomating bite to humans or other mammals (Lucas and Meier, 1995b). In the United States, there are five major species of widow spiders (Goddard, 2003):

1. *Latrodectus mactans* (black widow spider): These spiders are found throughout the United States but especially in the southern United States. Black widow spiders prefer dark places, especially under debris such as leaf litter or cardboard.
2. *Latrodectus hesperus* (western black widow spider): Common black widow of the western United States.
3. *Latrodectus variolus* (northern black widow spider): This species is common in the northern United States. The hourglass mark is not joined.
4. *Latrodectus bishopi* (red widow spider and red-legged widow spider): These spiders are found in palmetto fronds of the sandy, scrub-pine region of central and southern Florida. They are brightly colored.
5. *Latrodectus geometricus* (brown widow spider): The hourglass is orange in this species. These spiders are an introduced species to the United States found mainly in Florida.

Widow spiders are found mostly outside of living spaces, preferring dark secluded areas such as piles of debris and densely growing plants. Inside houses, they prefer dark, rarely disturbed spaces and will often settle

under appliances and cabinets. Adult spiders are most active in the warm months and will die during the colder months if not in a heated space. They build webs to ensnare prey. In general, widow spiders are shy and do not bite larger animals unless provoked (Goddard, 2003).

### Mechanism of action

Widow spider venom is a complex mixture of approximately six neuroactive proteins; there are also some proteolytic enzymes. The principal toxin for mammals is  $\alpha$ -latrotoxin, a polypeptide that causes a large release and then depletion of acetylcholine and norepinephrine at postganglionic sympathetic synapses (Lucas and Meier, 1995b).

### Toxicity

The venom of widow spiders is extremely potent. For instance, the LD<sub>50</sub> for whole venom of *L. mactans tridecimguttas* (European black widow) in guinea pigs is 0.0075 mg/kg and for mice is 0.9 mg/kg (White *et al.*, 1995).

The syndrome caused by widow venom is called latrodectism. Following a widow spider bite, the venom is taken up by lymphatics and then enters the bloodstream (White *et al.*, 1995). Clinically, there may be short-lived, localized pain at the bite site. Then, in approximately 30–120 min, myalgia and muscle cramps near the site of envenomation will begin. The pain begins to spread to the large muscles groups of the legs, thorax, back, and abdomen, peaking in approximately 2 or 3 h. Mild to moderate hypertension and tachycardia are common. In most cases, signs resolve in 48–72 h, but signs such as weakness, fatigue, and insomnia may persist for weeks to months (White *et al.*, 1995; Goddard, 2003).

Cats are very sensitive to the effects of widow venom. In one study, 20 of 22 cats died after widow spider bites, with an average survival time of 115 h. Paralysis occurs early in the course; severe pain is evidenced by howling and other vocalizations. Hypersalivation, restlessness, vomiting, and diarrhea were common. Muscle tremors, cramping, ataxia, and inability to stand may precede an atonic paralysis. Cheyne–Stokes respiratory pattern may develop prior to death (Peterson and McNalley, 2006a).

### Treatment

Treatment is largely symptomatic, with control of pain by opioids and use of muscle relaxants such as diazepam and methocarbamol to control the muscle rigidity. Calcium gluconate, which was once used for treatment

of widow envenomation, is no longer recommended because it was found to be less effective at controlling pain than opioids and muscle relaxants (Clarke *et al.*, 1992; Peterson and McNalley, 2006a). An equine-origin antivenin (Lycovac, available in the United States from Merck and Co.) has been used in humans. It is generally administered to high-risk patients (the very young or old) or in those whose signs are progressing despite other medical care. The antivenin is extremely effective; in one study, all 58 patients receiving the agent had resolution of signs within 30 min (Clarke *et al.*, 1992). In one case report (Twedt *et al.*, 1999), a cat with suspected lactrodectism was treated with antivenom approximately 26 h after signs began. The cat rapidly recovered neurologic function.

## RECLUSE OR VIOLIN SPIDERS (*LOXESCELES* SPP.)

### Background

Although there are at least 50 species of *Loxosceles*, few are capable of inflicting a medically significant envenomation known as loxoscelism. In the United States, where several *Loxosceles* species occur, the brown recluse spider (*L. reclusa*) is considered the only one of medical importance. *Loxosceles reclusa* is found principally in Missouri, Arkansas, Oklahoma, Kansas, and Tennessee, but its range extends from the southern Gulf states and southern Atlantic states through Indiana and Illinois. Other species of *Loxosceles* are found principally in the southwest United States and California. In South America, *L. laeta* and *L. gaucho* have been associated with severe loxoscelism in Brazil, Chile, Argentina, Peru, and Uruguay (White *et al.*, 1995). (*L. laeta* appears to have been introduced into the Los Angeles area (Goddard, 2003).) Although species of *Loxosceles* may occur in other regions of the world, significant morbidity and mortality have not been associated with these spiders (White *et al.*, 1995). Brown recluse spiders (*L. reclusa*) are nocturnal, nonaggressive spiders. They are recognizable by the “fiddle”-shaped marking on the dorsal surface of the cephalothorax.

### Mechanism of action

The venom of the recluse spider contains several necrotizing enzymes, including hyaluronidase, esterases, and alkaline phosphatases. Sphingomyelinase D, a phospholipase, appears to be the most important component; it binds to cell membranes and causes migration and activation of neutrophils in the area of the

envenomation. In addition, the venom inactivates serum hemolytic complement, leading to intravascular coagulation, occlusion of small capillaries, and tissue necrosis; systemic depletion of clotting factors (VII, IX, XI, and XII) can also occur (White *et al.*, 1995; Goddard, 2003; Peterson and McNalley, 2006b). Platelet activation can also be seen (Peterson and McNalley, 2006b). In the presence of calcium and C-reactive protein, sphingomyelinase D can cause hemolysis. Finally, lipases can cause free lipids in the blood that may act as inflammatory mediators and/or cause embolization (Peterson and McNalley, 2006b).

### Toxicity

In one study (Denny *et al.*, 1964), dogs injected intravenously with brown recluse venom developed thrombocytopenia, absence of reticulocytes, and evidence of hemolysis with decreased hematocrit. Necropsy showed widespread petechial and ecchymotic hemorrhage, dehydration, and hypocellular bone marrow with depression of the erythroid and platelet cell lines. Another study (Futrell *et al.*, 1979) of *in vitro* hemolysis found that human and pig erythrocytes were far more susceptible to lysis from brown recluse venom than those of dogs.

Initially, the bite may produce little pain or local reaction. Approximately 3–8 h after envenomation, the site becomes red, swollen, and tender; this is a so-called “bull’s-eye” lesion. A vesicle may form and be replaced by a black scab or eschar. Tissue around the bite may slough, leaving a 1- to 25-cm ulcer. Distribution may occur in areas dependent to the bite due to gravity. Healing is slow and may take months, often leaving a large scar (Goddard, 2003). Diagnosing a brown recluse bite may be difficult if the bite is not witnessed. In many cases, a brown recluse bite is “blamed” for necrotic lesions due to other causes (Mullen, 2002b). Systemic signs, although uncommon, can be seen with a brown recluse bite; they may develop 48–72 h after exposure. Hemolysis with anemia and hematuria, tachycardia, pyrexia, myalgia, vomiting, dyspnea, disseminated intravascular coagulation, and coma have been reported but are rare (Goddard, 2003).

### Treatment

For the necrotic lesion, local wound care including chemical debridement with Burrow’s solution (aluminum acetate) or hydrogen peroxide and bandaging should be performed. Pruritus may be controlled with diphenhydramine (2.2 mg/kg q8h). Antibiotics, especially if infection is evident, should be administered. Analgesics for

pain (NSAIDs for mild pain and opioids for severe pain) may be required. Surgical excision, used in the past, is no longer recommended (Peterson and McNalley, 2006b).

Dapsone (4,4'-diaminodiphenylsulfone) may be helpful in limiting the severity of the necrotic lesion because it inhibits neutrophil migration. In dogs, a dose of 1 mg/kg/day for 14 days has been used experimentally. Dapsone can cause methemoglobinemia as well as hemolysis in individuals with glucose-6-phosphate dehydrogenase deficiency (Peterson and McNalley, 2006b).

Antivenins are available for South American *Loxosceles* species. Experimental antivenins for *L. reclusa* have been developed. These have been shown to be effective if given within 4 h of envenomation. However, these antivenins are not currently commercially available (Mullen, 2002b).

## HOBO SPIDERS (*TEGENARIA AGRETIS*)

### Background

Hobo spiders are native to Europe but were introduced in the Pacific Northwest in the 1930s. They occur mainly in Washington, Oregon, and Idaho, but their range includes central Utah through western Canada to the Alaskan panhandle. In the 1980s, the appearance of necrotic spider bites in the Pacific Northwest was initially blamed on *L. reclusa*, but later the bites were correctly attributed to *T. agretis* (Goddard, 2003).

Hobo spiders are poor climbers and build a funnel web at ground level or in basements. Males will leave their web at night in search of females and may enter houses while doing so. Males are more venomous than females and are more likely to bite (Mullen, 2002a,b; Goddard, 2003).

### Toxicity

In most cases, the bite is initially painless. Within 30 min, a localized expanding area of erythema may occur; the lesion may eventually reach 15 cm in diameter. Then, in approximately 15–35 h, the area ruptures and there is a serous discharge from the wound. The wound may require 3 years to heal, especially if it is in fatty tissue (Goddard, 2003).

In humans, systemic signs may occur in approximately 45% of bites, and approximately one-third of these may require hospitalization. Signs may include headache (which can last for days), nausea, weakness, and vision changes. The signs may progress to vomiting (often intractable), watery diarrhea, and bone marrow

destruction resulting in anemia, pancytopenia, and thrombocytopenia. Fatalities are rare (Mullen, 2002b).

### Treatment

Treatment of the hobo spider bite is supportive and symptomatic.

## FUNNEL WEB SPIDERS (*ATRX* AND *HADRONYCHE* SPP.)

### Background

There are approximately 35 species of funnel web spiders. They are all found in Australia, principally distributed along the southeast coastal region. Although all may potentially be dangerous to mammals, the Sydney funnel web spider (*A. robustus*) is considered the most dangerous because this is the only species for which human fatalities have been recorded (White *et al.*, 1995). *Atrax robustus* is found within 160 km (100 miles) of the center of Sydney. They are large, aggressive black spiders (Sutherland and Tibballs, 2001).

### Mechanism of action

The toxic component of the funnel web spider's venom is the neurotoxin robustoxin, a 42-amino acid protein. The toxin binds to the presynaptic neuron and both inhibits central nervous system (CNS)-mediated neurotransmitter release and increases spontaneous release of neurotransmitters; the toxin affects both the autonomic nervous system and skeletal muscles. Other species of funnel web spiders contain structurally similar neurotoxins that are less potent than robustoxin (White *et al.*, 1995).

### Toxicity

There is a wide variation of reaction in different species of animals; the sex of the spider also affects toxicity of the bite. For instance, rats, rabbits, and cats are unaffected by the bite of a female spider, whereas 20% of mice and guinea pigs died after the bite of a female. When mice or guinea pigs are bitten by a male spider, most die. The male funnel web spider's venom appears to be six times more potent than that of the female based on minimum lethal dose determinations. However, in dogs and cats, male funnel web spider bites cause mild transient effects. Humans and other primates appear

to be extremely sensitive to the venom of this spider (Sutherland and Tibballs, 2001).

## TARANTULAS

Tarantulas are large, ground-dwelling spiders. During mating season, males wander in search of females and may be more aggressive at these times. In most cases, the bite of the tarantula causes little more than localized pain that develops slowly but usually resolves within 30 min. There are approximately 12 genera of tarantulas that may deliver a potentially life-threatening bite. These spiders occur in the tropical regions of South America, Africa, and Australia. Their venom contains a neurotoxin; there may also be a necrotoxin and hemolytic toxin. Following envenomation, muscle spasms, edema, hemoglobinuria, jaundice, and circulatory shock may develop (Mullen, 2002b).

Tarantulas of the family Theraphosidae (bird-eating or whistling spiders) are often kept as pets in Australia and Asia. In one Australian study (Isbister *et al.*, 2003), the bite of these spiders was found to cause only local effects in humans. However, seven dogs bitten by spiders of the genera *Phlogiellus* and *Selenocosmia* died rapidly, often within 2 h of the envenomation. (In two cases, the dogs and their owners were bitten by the same spider.) The spiders are also considered highly poisonous for cats. The exact cause of death was not discussed, but based on experimental data, apnea and cardiac arrhythmias may occur.

Species of tarantula living in the United States are not capable of delivering serious envenomation. However, many of these species have urticating hairs on their abdomen that possess spines and barbs that can penetrate skin. When threatened, these tarantulas can stroke their abdomen and flick the urticating hairs at their attacker. The hairs can cause severe inflammation of the skin, eyes, mouth, and respiratory tract. The effect is purely mechanical because there is no toxin associated with the hairs. Urticaria, edema, and vasodilation may occur in the skin. In the eyes, swelling of the lids and corneal abrasions are common (Mullen, 2002b). Dogs or cats attempting to ingest tarantulas may gag or vomit.

## SCORPIONES: SCORPIONS

### Background

Scorpions are arachnids with two body divisions: the combined head and thorax, referred to as the prosoma or cephalothorax, and the abdomen or opisthosoma.

**TABLE 73.1** Scorpions of medical importance: species and location

Location	Species
India	<i>Buthotus tamulus</i>
Mexico and Central America	<i>Centruroides</i> spp.
Middle East	<i>Androctonus</i> spp. <i>Buthus</i> spp. <i>Hemiscorpion lepturus</i> <i>Leiurus quinquestriatus</i> <i>Mesobuthus gibbosus</i>
South Africa	<i>Parabuthus</i> spp. <i>Buthus minax</i>
South America	<i>Tityus</i> spp. <i>Centruroides gracilis</i>
United States	<i>Centruroides sculpturatus</i>
West Indies (Trinidad)	<i>Tityus trinitatis</i>

Adapted from Lucas and Meier (1995a) and Keegan (1980).

They possess large paired claws or pincers known as pedipalps and four pairs of legs. At the caudal portion of the abdomen, scorpions have a tail that terminates in the telson – a barbed appendage that houses two venom glands that exit via a stinger at the end of the telson. Scorpions are nocturnal hunters; they may spend the day in burrows or hiding under rocks or vegetation. They may also hide in blankets, shoes, and clothing; this a common way for humans to be exposed to them (Keegan, 1980).

There are approximately 1400 species of scorpions occurring on all continents except Antarctica (Goddard, 2003). Most occur in tropical or temperate regions (Lucas and Meier, 1995a). Table 73.1 lists locations and species of scorpions capable of inflicting life-threatening envenomations in humans. The main genera of scorpions found in North America are the bark scorpions (*Centruroides* spp.). They are found primarily in Central America, Mexico, and the southern through southwest United States (Mullen and Stockwell, 2002). In the United States, only *Centruroides exilicauda* (Arizona bark scorpion) is considered capable of inflicting a life-threatening sting (Goddard, 2003).

### Mechanism of action

All scorpions can deliver an envenomating sting (Keegan, 1980). Scorpion venom components vary greatly between genera and may even differ based on geographic location within species (Mullen and Stockwell, 2002). The venom consists of a mixture of low-molecular-weight polypeptides. At least two potent neurotoxins have been identified:  $\alpha$ -scorpion toxin found in *Androctonus*, *Leiurus*, and *Buthus* spp. and  $\beta$ -scorpion toxin found in *Centruroides* spp. Both toxins can be found in the venom of *Tityus* spp. These

venoms block the voltage-sensitive sodium and potassium channels in nerves (Mullen and Stockwell, 2002).

## Toxicity

Scorpion stings cause instant, sharp pain at the site of envenomation. Some stings will cause localized pain that resolves over hours. Localized edema and pruritus are common. Regional lymph nodes may enlarge, and there may be an allergic reaction characterized by swelling of the eyelids, tongue, and vomiting. Sloughing of the skin at the site of envenomation can also occur (Mullen and Stockwell, 2002). Signs usually resolve within 24h (Keegan, 1980). Systemically, signs can vary but generally include numbness of face, myalgia, tachycardia or bradycardia, respiratory depression, and seizures; however, there is a lack of evidence that scorpion envenomation in dogs and cats is a serious concern (Mullen and Stockwell, 2002).

## Treatment

In most cases, the treatment of scorpion stings consists of analgesics and local wound care. Systemic signs are treated symptomatically with control of hypertension, heart rate changes, and neurologic signs. Some antivenoms in the United States are produced locally; however, because these are not approved by the U.S. Food and Drug Administration, they cannot legally be transported to other states (Goddard, 2003). In addition, their use in veterinary patients is considered controversial (Dalefield and Oehme, 2006).

# IXODIDA: TICKS

## Background

Ticks are well known as being vectors for a large number of human and animal diseases, with the first reports of tick paralysis originating in Australia in 1890 and British Columbia in 1912 (Sonenshine *et al.*, 2002). Worldwide, 43 species of ticks from nine different genera have been associated with tick paralysis: *Amblyomma*, *Argas*, *Dermacentor*, *Haemaphysalis*, *Hyalomma*, *Ixodes*, *Ornithodoros*, *Otobius*, and *Rhipicephalus* (Dipeolu, 1976; Fowler, 1993). Tick paralysis has been reported in North America, Europe, Africa, Australia, and the former Soviet Union.

## Mechanism of action

The exact mechanism(s) of action of tick toxins is not well known, but in most tick species it is suspected that the toxin interferes with the synthesis and/or release of

acetylcholine at the neuromuscular junctions, resulting in lower motor neuron paresis and paralysis very similar to that produced by botulinum toxin (Fowler, 1993; Grattan-Smith *et al.*, 1997). The Australian tick, *Ixodes holocyclus*, toxin may differ because it appears to have more of an effect on central nerve centers rather than on peripheral (Fowler, 1993).

## Toxicity

Tick paralysis has been reported in a large variety of animal species, including dogs, cats, cattle, sheep, goats, llamas, poultry, wild antelope, bison, foxes, wolves, mice, ground hogs, black-tailed deer, and several species of wild birds (Daly *et al.*, 1992; Fowler, 1993; Beyer and Grossman, 1997; Sonenshine *et al.*, 2002). In North America, most cases of tick paralysis in livestock occur in the Pacific Northwest due to *Dermacentor andersoni*, whereas most cases in dogs are due to *D. variabilis* (Fowler, 1993; Sonenshine *et al.*, 2002). *Dermacentor occidentalis* occasionally causes tick paralysis in cattle, ponies, and deer but not dogs (Sonenshine *et al.*, 2002). In the southeastern United States, *I. brunneus* has been associated with tick paralysis in wild passerine birds (Luttrell *et al.*, 1996). In Australia, tick paralysis is caused by *I. holocyclus*, whereas *I. rubicundus* and *Rhipicephalus evertsi* are the primary species responsible for tick paralysis in Africa (Sonenshine *et al.*, 2002). Tick paralysis in Europe and Asia has been reported due to bites from *Hyalomma punctata* and *I. ricinus*.

Tick paralysis has occurred following the bite of as few as one tick, and heavily infested animals may succumb quickly (Fowler, 1993). Clinical signs include an ascending ataxia that progresses to paresis and flaccid paralysis. Early in the intoxication, animals remain bright, alert, and able to eat and drink if properly supported. Eventually, paralysis of the respiratory muscles leads to respiratory failure and death. Paralysis produced by *I. holocyclus*, the Australian tick, generally occurs more rapidly and tends to persist following removal of the tick.

## Treatment

The main goal of treatment is to remove the ticks and provide supportive care (especially respiratory support) until recovery occurs. Recovery can occur quite rapidly following complete removal of the ticks, or it may take a few days (Fowler, 1993). The use of topical insecticides may aid in the removal of ticks and can be especially helpful in cases in which numerous ticks are embedded. Heavily coated animals may need to be shaved to ensure that all embedded ticks are found and removed. Removal of embedded ticks should be performed carefully to avoid expressing additional toxin into the wound or leaving the head embedded in the skin. Forceps may be used to grasp

the tick as close to the skin as possible, and gentle traction should be used to remove the tick. In most cases in which ticks are removed before bulbar paralysis has occurred, the prognosis for full recovery is very good. A short-term immunity develops following recovery from tick paralysis. In Australia, a polyclonal dog antiserum has been developed to treat tick paralysis, but it is only effective in the early stages of paralysis (Masina and Broady, 1999).

## MYRIAPODA: CENTIPEDES AND MILLIPEDES

Centipedes and millipedes are distantly related to lobsters, crayfish, and shrimp. These arthropods are widely distributed throughout the world, and they are characterized by a long, flat, multisegmented body with one (centipede) or two (millipede) legs emerging from each body segment. Although most centipedes and millipedes are less than 1.5 in. long, centipedes from the genus *Scolopendra* may grow to be 4–6 in. long. All centipedes have a pair of modified front legs (forcipules) that serve as fangs and that are connected to venomous glands directly under the head (Norris, 2004). Larger centipedes have the ability to inflict painful bites resulting in local swelling, erythema, and lymphangitis (Stewart, 1985). In addition, the legs of *Scolopendra* spp. are tipped with sharp claws that are capable of penetrating skin, and toxin produced at the attachment point of each leg may drop into these wounds, causing inflammation and irritation.

Centipede venom has been poorly studied, but components identified in various centipedes include serotonin, a cytotoxin, a hemolysin, and a vesicating agent (Deng *et al.*, 1997; Norris, 2004). In most cases, systemic toxicosis is not expected, although local necrosis may occur (Russell, 1996); a single case report exists of a human fatality from the bite of *Scolopendra subspinipes* (Norris, 2004). Signs generally subside within 48h and rarely require more than symptomatic care (e.g., analgesics). Millipedes do not bite but can emit irritating and foul-smelling secretions from repugnatorial glands; some species can spray these fluids over distances of several inches. These secretions are irritating to mucosal surfaces, particularly the eyes, and corticosteroids have been recommended to decrease the inflammatory response (Russell, 1996).

## INSECTA: INSECTS

### Introduction

Insect and insect-related problems are common in domestic and wild animals. Insects such as lice, fleas, deerflies, horseflies, sand flies, mosquitoes, blackflies,

and biting midges may cause severe annoyance to animals because of biting behavior. Members of several groups of insects can inject venom when they bite or sting, most notably bees, wasps, and ants. Bites or stings from insects such as lice, fleas, bees, ants, wasps, mosquitoes, and chiggers may cause direct effects from the venoms or may result in allergic host reactions resulting from overresponsive host immune systems. Contact allergies may occur when certain beetles or caterpillars touch the skin. Other insects, such as blister beetles and certain caterpillars, produce toxins that can cause adverse reactions when they are touched or ingested (Durden and Mullen, 2002). Respiratory allergies can result from inhaling allergic air-borne particles from cockroaches, fleas, or other arthropods (Durden and Mullen, 2002). Some insects invade the body tissues of their host. Various degrees of invasion may occur, ranging from subcutaneous infestations to invasion of organs such as the lungs and intestine (Durden and Mullen, 2002). Table 73.2 provides a list of nine orders of insects that are of particular interest to veterinary entomologists.

## COLEOPTERA: MELOIDAE (BLISTER BEETLES)

### Background

More than 300,000 species of beetles have been described, representing 30–40% of all known insects. Approximately 25,000 species of beetles occur in the United States and Canada (Krinsky, 2002). Fewer than 100 species of beetles worldwide are known to be of public health or veterinary importance. Most of these are in the suborder Polyphaga. The species that have the greatest impact on the health of human and domestic animals are in the following families: Melidae (blister beetles), Oedemeridae (false blister beetles), Staphylinidae (rove beetles), Tenebrionidae (darkling beetles), Dermestidae (larder beetles), and Scarabaeidae (scarab or dung beetles) (Krinsky, 2002).

Most blister beetles are in the family Melidae, although some are in the Staphylinidae family. Blister beetles are elongate, soft-bodied specimens in which the pronotum (section between head and wings) is narrower than the head or wings. Two of the common blister beetle species are potato beetles, one with orange and black longitudinal stripes and one black with gray wing margins (Goddard, 2003). Members of the genus *Mele* are called oil beetles because they exude an oily substance from their legs when disturbed. Oil beetles are approximately 20–25mm long and black with no hind wings, giving the appearance that their wings are too short (Goddard, 2003).

TABLE 73.2 Insects of veterinary importance

Order	Common names	Clinical significance
Coleoptera	Beetles	Toxic beetles (e.g., blister beetle); vectors for pathogenic organisms; intermediate host for nematodes, flukes, cestodes, acanthocephalans
Dictyoptera	Cockroaches	Intermediate hosts for nematodes, flukes, cestodes, acanthocephalans; vectors for pathogenic organisms
Diptera	Flies, mosquitoes	Vectors for pathogenic organisms; myiasis; decreased production due to annoyance or anemia from biting/sucking insects
Hemiptera	True bugs	Transmission of infectious agents (e.g., trypanosomiasis); decreased production due to anemia from blood-sucking bugs
Hymenoptera	Wasps, hornets, ants, bees	Envenomation, allergy from bites or stings; poisonous insects (e.g., sawfly larvae)
Lepidoptera	Moths, butterflies	Urticaria, irritation, ulceration from urticating hairs; poisonous insects (e.g., monarch butterfly)
Phasmida	Stick insects, leaf insects	Irritation from secretions of walking sticks
Phthiraptera	Lice	Decreased production due to annoyance or anemia; vector for pathogenic organisms
Siphonaptera	Fleas	Decreased production due to annoyance or anemia; vector for pathogenic organisms

Species that pose problems in the United States include the striped blister beetle (*Epicauta vittata*) (Figure 73.1), the black blister beetle (*E. pennsylvanica*), the margined blister beetle (*E. pestifera*), and the three-striped blister beetle (*E. lemniscata*), as well as *E. fabricii*, *E. occidentalis*, and *E. temexa*. Of these, the most common species associated with toxicosis are *E. occidentalis* and *E. temexa* (Stair and Plumlee, 2004).

Mechanism of action

The toxic principle in melioid beetles, cantharidin, has the formula  $C_{10}H_{12}O_4$  and is a bicyclic terpenoid (Goddard, 2003; Stair and Plumlee, 2004). The concentration of cantharidin present in beetles varies from 1 to 5% of the dry weight of the beetle. Males always have a higher concentration because the male produces the cantharidin and transfers a quantity to the female during copulation (Krinsky, 2002). Cantharidin is present in the hemolymph as well as in the clear, yellow secretion that is exuded at the joints of the legs of these beetles by reflex bleeding (Figure 73.2).

The mechanism of action of cantharidin may involve interference with enzyme systems responsible for active transport across mitochondrial membranes, resulting in membrane disruption and permeability changes. Mitochondrial damage results in cellular disruption, acantholysis, and vesicle formation. Cantharidin has also been shown to inhibit protein phosphatase 2A, resulting in disruption of signal transduction and cell metabolism (Stair and Plumlee, 2004).

Purified, crystalline cantharidin is a potent vesicating agent that is readily absorbed through the gastrointestinal mucosa and, to a lesser degree, the skin. It is eliminated unchanged through the kidneys (Krinsky, 2002).

FIGURE 73.1 An adult striped blister beetle (*E. vittata*). (Photo courtesy of James E. Appleby, University of Illinois.)

FIGURE 73.2 An adult blister beetle (*Epicauta*), with hemolymph droplets containing cantharidin. (Photo courtesy of Dr. Maria Eisner, Cornell University.)

## Toxicity

Adult blister beetles feed on flowering foliage, especially blooming alfalfa (*Medicago sativa*). Blister beetles in alfalfa fields contain enough cantharidin to provide lethal doses to livestock that feed on forage when it is used as hay. Modern methods of hay harvesting, especially crimping, decrease the opportunity of blister beetles to vacate the foliage before it is incorporated into hay, thereby increasing the likelihood of blister beetles being trapped in the hay (Stair and Plumlee, 2004). Cantharidin released from crushed adult blister beetles may contaminate hay without visual evidence of insect parts. Cantharidin is very stable and may persist in hay for long periods of time. Because in the United States alfalfa is most widely grown in the South, cantharidin toxicosis is most commonly found in the southern states; however, due to interstate transport of alfalfa hay throughout the country, cantharidin toxicosis could potentially occur in any state.

Horses are the species in which cantharidin toxicosis is most commonly reported. However, the following hosts have also been poisoned in natural or experimental situations: cattle, sheep, goats, rabbits, rats, hedgehogs, dogs, and emus. Poisoning in human beings has been noted for decades and is usually the result of either improper medicinal use of cantharides or malicious poisoning (Krinsky, 2002). Horses are considered to be particularly susceptible to the effects of cantharidin (Stair and Plumlee, 2004). The estimated lethal dosage of cantharidin for the horse is approximately 0.5–1 mg/kg, and as little as 4 g of dried beetles may be lethal to a horse (Krinsky, 2002). The oral experimental lethal dosage of crystalline cantharidin for dogs and cats was 1.0–1.5 mg/kg, and it was 20 mg/kg for rabbits. It is estimated that the lethal dosage for a human is less than 1.0 mg/kg.

Cantharidin produces an intense, direct irritant effect on the skin and mucous membranes of the esophagus, stomach, and intestines. Once absorbed, the toxin may affect many different organs. Excretion is via the kidneys, resulting in transfer of the irritant effect to the urinary tract, particularly the bladder and urethra (Krinsky, 2002).

Clinical signs vary with the dose ingested. Massive doses may cause shock and death within 4 h (Krinsky, 2002). Smaller doses may cause gastroenteritis, nephrosis, cystitis, and/or urethritis; thus, signs may include anorexia, soft feces, mucoid to bloody feces, intestinal atony, colic, dysuria (frequent, painful urination, or oliguria to anuria), and hematuria. The body temperature may elevate to 106°F (41.1°C). Other signs observed include depression, weakness, muscle rigidity, collapse, prostration, dehydration, and sweating (Krinsky, 2002). Animals frequently become dyspneic, and rales may be detected on auscultation due to pulmonary edema. Myocarditis may initiate cardiovascular signs including tachycardia, congested mucous membranes,

and decreased capillary refill time. Synchronous diaphragmatic flutter and muscle fasciculations have been reported in horses and are thought to be a result of hypocalcemia (Stair and Plumlee, 2004). Ulceration of the oral mucosa membranes may be observed, and animals may be seen dipping their muzzles into water without drinking (Krinsky, 2002). Diarrhea may be observed in animals that live for a few days. The course of the disease may be as short as 4 h, with massive dose ingestion, to 5 days in lethal poisoning. In horses, the mortality rate is approximately 50%, with horses surviving more than 1 week having a favorable prognosis (Krinsky, 2002).

In both field cases and experimental cantharidin poisoning, there are elevations in serum protein and packed cell volume caused by dehydration and shock. The damaged gastrointestinal mucosa allows rapid invasion of enteric bacteria, resulting in bacteremia and leukocytosis. There may be mild elevation in serum urea nitrogen. Profound hypocalcemia (5.9 mg/dL; normal, 12.8 ± 1.2 mg/dL) and hypomagnesemia (0.7–1.8 mg/dL; normal, 2.5 ± 0.3 mg/dL) have been reported. Specific gravity of urine is low in the early stages of the disease, and erythrocytes are usually present in the urine, yielding a positive occult blood reaction.

Gross lesions may be minimal with massive dose ingestion. In more protracted cases, oral ulcers, vesication and desquamation of patches of the distal esophagus, erosions and ulceration of the gastrointestinal tract, mucus in the renal pelvis, and renal cortical hemorrhages may be seen. Hyperemia and hemorrhages are seen in the urethra and bladder mucosa. Ventricular myocarditis, pulmonary edema, petechial hemorrhages of serosal surfaces, hepatomegaly, and splenomegaly may also be present.

The initial microscopic lesion is acantholysis of mucosa of the gastrointestinal tract, epithelium of the urinary tract, and endothelium of vessels (Krinsky, 2002). Other microscopic lesions include myocarditis, renal tubular nephrosis, and degenerative changes in the kidneys and digestive tract.

Cantharidin may be detected in urine, tissue (kidney and blood), gastrointestinal contents, and the dried beetles themselves by high-pressure liquid chromatography or gas chromatography–mass spectrometry. Cantharidin is excreted rapidly and may not be present in detectable amounts after 4 or 5 days following ingestion (Krinsky, 2002).

## Treatment

There is no specific treatment. The administration of either activated charcoal or mineral oil (but not together) via a gastric tube may aid animals that have consumed a small dose or are in the early stages of poisoning.

General supportive therapy should include correction of fluid loss and electrolyte imbalances, particularly hypocalcemia and hypomagnesemia (Krinsky, 2002).

Broad-spectrum antimicrobial therapy may be necessary to counter secondary bacterial invasion from the gastrointestinal tract. Aminoglycoside antibiotics and others that are potentially nephrotoxic or that are excreted via the kidney should be avoided because nephrosis is a potential effect of cantharidin.

## COLEOPTERA: FIREFLIES

### Background

Fireflies of the genus *Photinus* have been reported to cause death when fed to captive reptiles and amphibians (Knight *et al.*, 1999).

### Mechanism of action

Lucibufagins, steroidal pyrones structurally related to cardiotoxic bufodienolides of toads, have been isolated from the bodies of *Photinus*. It is suspected that lucibufagins have cardiotoxic effects similar to those of bufodienolides – that is, they inhibit sodium–potassium ATPase activity in the myocardial cell membrane in a mechanism similar to digitalis (Brubacher *et al.*, 1999).

### Toxicity

It is likely that the lucibufagins protect the fireflies from predation from birds and spiders (Knight *et al.*, 1999). Reported cases of firefly toxicosis have occurred when captive reptiles and amphibians were fed the fireflies by their owners. As few as one firefly has caused death in lizards. Toxicosis has been reported in bearded dragons (*Pogona* spp.), an African chameleon (*Chamaleleo* spp.), White's tree frogs (*Litoria caerulea*), and a *Lacerta derjugini* lizard.

Within 5–90 min of being fed fireflies, affected lizards displayed head shaking, oral gaping, dyspnea, skin color change to black, and regurgitation, with death occurring as rapidly as 15 min post-ingestion (Knight *et al.*, 1999). No gross lesions were reported in animals presented for postmortem.

### Treatment

Because of the rapid onset of signs and rapid progression to death, no veterinary care could be instituted in the reported cases (Knight *et al.*, 1999). Treatment for affected

animals would include management of any cardiac arrhythmias and general supportive care. Because the lucibufagins are similar in structure to bufodienolides, in theory one would expect that digoxin-specific Fab fragments (e.g., Digibind) might be of benefit in treating animals with firefly toxicosis (Brubacher *et al.*, 1999). However, given the rapid development and progression of clinical signs following ingestion of fireflies, the prognosis in most cases will be poor.

## COLEOPTERA: OTHER TOXIC BEETLES

Ingestion of rove beetles, *Paederus fuscipes* (Staphylinidae), has resulted in toxicosis in horses and cattle in Southeast Asia (Krinsky, 2002). Pederin, a toxin more potent than *Latrodectus* spider venom, can cause severe vesicular damage to the mucosa of the alimentary tract. Ingestion of the rose chafer (*Macrodactylus subspinosus*), a member of the Scarabaeidae, has been associated with deaths in chickens, ducklings, goslings, and young turkeys in North America, although modern confinement poultry production operations have largely reduced the risk of toxicosis.

In Michigan, a dog that ingested large numbers of Asian ladybeetles (*Harmonia axyridis*) developed severe shock, cyanosis, rapid pulses, and lateral recumbency (Hoenerhoff *et al.*, 2002). The dog subsequently died, and on postmortem large numbers of partially digested and intact Asian ladybeetles were detected in the small and large intestines associated with severe hemorrhage and thickening and ulceration of the jejunum and ascending colon. There was a pungent odor to the gastrointestinal contents that mirrored the foul-smelling fluid that Asian ladybeetles can produce when disturbed. Asian ladybeetles were introduced as a biologic control agent and are spreading rapidly throughout the United States.

## HYMENOPTERA: BEES, WASPS, AND HORNETS

### Background

Bee and wasp stings caused approximately 23 human deaths per year in the United States during the 1950s (Akre and Reed, 2002). During that same period, approximately 13 individuals per year died of snakebite. No statistics are available for fatal bee or wasp stings in animals. More than 20,000 species of bees are distributed throughout the world (Fowler, 1993). The honeybee, *Apis mellifera*, is one of two domesticated insect species (the other is the silk worm, *Bombyx mori*). Native honeybees in tropical Southeast Asia

were the source of the domestic honeybee. When early American colonists imported European strains of the honeybee to the Virginia Colonies, the bees became known as European honeybees. Africanized honeybees (*A. mellifera scutellata*) are a subspecies of the common honeybee native to Africa that has spread from South and Central America into south Texas, New Mexico, Arizona, Nevada, California, and Puerto Rico (Akre and Reed, 2002).

### Mechanism of action

There are numerous variations in the venom apparatus of members of Hymenoptera (Fowler, 1993). The stinger is a modification of the ovipositor apparatus and is found only in female bees and wasps. Venom secreted from specialized cells in the acid glands is transported to the venom sac reservoir via small tubules. One-way valves in the bulb of the venom apparatus control the flow of venom during envenomation. At the time of venom injection, the alkaline gland contributes a secretion that enhances the toxicity of the venom. The stinger of the honeybee is covered with retrograde barbs that cause the stinger to remain impaled in thick-skinned victims. When this occurs and the bee attempts to withdraw, the entire stinger apparatus is pulled from the bee, resulting in death of the honeybee.

Honeybee venoms are complex mixtures of proteins, peptides, and small organic molecules (Akre and Reed, 2002). Phospholipases and hyaluronidases present in the venom account for the majority of allergic responses to bee venoms in humans and likely other animals as well. Phospholipase A<sub>2</sub> is one of the most lethal peptides in honeybee venom (Schmidt, 1995). Mellitin is a membrane disruptive compound that increases the susceptibility of cell membranes to the damage caused by phospholipases within the venom (Akre and Reed, 2002). Mellitin can also cause pain, trigger hemolysis, increase capillary blood flow, increase cell permeability, and enhance spread of venom constituents within tissue. Mellitin, in combination with phospholipase and a mast cell degranulating peptide, triggers the release of histamine and serotonin. In mice, mellitin was found to be the primary lethal component of honeybee venom (Schmidt, 1995). Apamin is a neurotoxin that blocks calcium-activated potassium channels and has been associated with transient peripheral nerve effects in humans after bee stings (Saravanan *et al.*, 2004). In cats, bee venom can cause contraction of bronchiolar muscles.

Like honeybees, vespid wasps (including yellow jackets and hornets) produce venoms containing peptides, enzymes, and amines designed to trigger pain (Akre and Reed, 2002). The primary pain-inducing substances are kinins; however, other compounds present in vespid venom, such as serotonin, histamine, tyramine,

catecholamines, and acetylcholine, can contribute to the pain as well as local vasoactivity. Several of the constituents of vespid venom can act as allergens and trigger allergic reactions. Some vespid venoms contain neurotoxins or alarm pheromones that alert the swarm to an intruder.

### Toxicity

Honeybees can inflict only a single sting, but an animal attacked by a swarm or hive of bees may sustain multiple stings and the cumulative envenomation may be lethal. The Africanized honeybee (*A. mellifera scutellata*) presents a special case. Although its venom is no more toxic than that of the domestic honeybee, the aggressive behavior of the African honeybee increases the likelihood of multiple stings occurring by swarms of these bees (Akre and Reed, 2002). Wasps and hornets either lack a barbed stinger or the barbs are small and do not prevent withdrawal of the stinger. Therefore, a single wasp may inflict multiple stings. Also, because many wasps are highly social, multiple stings are commonplace.

A sting by a single bee or vespid rarely causes more than a transient, painful prick in animals, in contrast to humans, where sensitive individuals may die peracutely from a single sting. However, death following a single bee sting has been reported in a dog (Fowler, 1993). Deaths following attacks on livestock by Africanized bees have been reported, although the majority of interactions between livestock and bees or wasps result in only local reactions. Yellow jacket envenomation leading to skin lesions and death has been reported in a group of pigs (Fowler, 1993).

Local reactions to single bee, hornet, or wasp stings consist of swollen, edematous, and erythematous plaques at the site of the sting (Fowler, 1993). Most small animal patients present with facial, periorbital, and/or aural edema. Honeybee stingers will occasionally be located embedded in the area, and a small abscess may form at the site. In the Middle East, the German wasp, *Vespula germanica*, has been observed to injure the teats and udders of dairy cattle, causing lesions that can lead to mastitis. Apparently, the wasps served as a vector in spreading *Streptococcus dysgalactiae* infection in the herds (Yeruham *et al.*, 1998).

Multiple stings may produce numerous wheals, urticaria, and in severe cases may cause severe systemic responses as direct toxic effects of the venom. Systemic effects reported in dogs following multiple stings from bees or vespids include prostration, convulsions, CNS depression, shock, hyperthermia, bloody diarrhea, bloody vomiting, leukocytosis, intravascular hemolysis, disseminated intravascular coagulopathy, and elevations of blood urea nitrogen and alanine transaminase, suggesting renal and hepatic involvement (Wysoke *et al.*, 1990; Cowell *et al.*, 1991; Fowler, 1993). Hepatic injury in

cats has also been reported following exposure to hornet venom. Acute lung injury similar to the human acute respiratory distress syndrome developed in a dog following envenomation by more than 100 bees (Walker *et al.*, 2005).

The classic anaphylactoid response to bee and vespid venoms that is not uncommon in humans has not been documented in livestock, but anaphylaxis in dogs due to bee stings has been reported (Akre and Reed, 2002). Immune-mediated hemolytic anemia secondary to bee envenomation developed in two dogs (Noble and Armstrong, 1999). Clinical signs included lethargy, hematuria, ataxia, and seizures, and one dog died. Clinicopathologic data included nonregenerative anemia, spherocytosis, positive results for Coomb's test, and occult hematuria. Treatment included oral administration of corticosteroids at immunosuppressive dosages and supportive care. The surviving dog initially responded to corticosteroids, but hemolysis recurred as the dosage was tapered. Hemolysis resolved with prolonged administration of corticosteroids.

## Treatment

Ideally, when an insect has stung an animal, identification of the insect should be attempted. Most often, stings occur in areas that are free of hair or have short hair. For bee stings, the site should be examined to determine if any part of the stinger remains. Retained stingers should be scraped away from the injection site; grasping the stinger with forceps may result in more venom being expressed into the injection site. Cold compresses may be used as first aid to relieve pain and swelling. Antihistamines and corticosteroids are thought to have questionable value once lesions have developed, but they are not contraindicated (Fowler, 1993). Patients should be monitored for development of systemic or anaphylactic reactions, which need to be treated promptly and aggressively. Epinephrine may be used in cases in which anaphylaxis is suspected. In cases of true systemic toxicosis, aggressive intravenous fluid therapy is recommended using balanced fluid solutions. Other treatments that have been recommended include corticosteroids, antihistamines, oxygen for dyspnea, and diazepam as needed for convulsions (Fowler, 1993). Renal and hepatic function should be monitored in animals that develop systemic reactions. In most cases, exposure to single stings from bees and vespids is rarely fatal.

## HYMENOPTERA: ANTS

### Background

There are more than 10,000 species of ants, some of which bite, some of which sting, and others that both bite and sting. Some ants that lack a sting have the

ability to spray formic acid, which can cause local irritation to the victim if it gets in the eyes or wounds produced by the ant's mandibles.

Multiple stings from venomous ants have resulted in the death of pets, livestock, and wild animals in North, Central, and South America (Fowler, 1993). The red imported fire ant, *Solenopsis invicta*, is the most important species in terms of envenomation of animals. This ant was native to Brazil but entered the United States in the 1940s, where it has become a serious pest in the southeast as far west as Texas.

### Mechanism of action

Ant venoms, like bee venoms, are complex mixtures of compounds that can induce a variety of adverse effects in animals. Fire ant venoms consist largely of alkaloids, with less than 1% proteinaceous component (Akre and Reed, 2002). The alkaloids consist of solenopsins (methyl-*n*-alkylpiperidines) and a piperidine that cause dermal necrosis when injected in skin. These alkaloids have cytotoxic, hemolytic, fungicidal, insecticidal, and bactericidal properties.

### Toxicity

Animals most likely to be severely affected by fire ants tend to be those that are unable to move away from a colony, including those that are neonatal, juvenile, or disabled. Attacks of fire ants resulting in deaths of newborn game animals such as rabbits and deer have been reported (Akre and Reed, 2002). Nesting bird chicks and newly hatched quail and poultry have been killed (and often eaten) by fire ants (Fowler, 1993).

Clinical effects of fire ant envenomation include intense pain at the site of the sting. In humans, within minutes of a sting there is formation of an urticarial wheal, which progresses to a vesicle and then a pustule within 24 h (Fowler, 1993). Within a few days, the pustule will rupture, resulting in a crusting lesion. Dogs do not appear to develop the pustules described in humans; instead, they develop erythematous pruritic papules that generally resolve within 24 h (Rakich *et al.*, 1993). There are no reports of anaphylaxis in animals secondary to fire ant stings (Akre and Reed, 2002). Multiple stings may result in systemic signs similar to those of multiple bee or wasp stings.

### Treatment

Single bites from fire ants generally require no treatment. Multiple envenomations resulting in severe systemic

reactions or anaphylaxis should be managed similarly to systemic reactions to bee stings (i.e., fluids, corticosteroids, and supportive care).

## HYMENOPTERA: SAWFLIES

### Background

Sawflies are primitive hymenopterans that belong to the suborder Symphyta and are widely distributed throughout the world. Sawfly poisoning has been reported in livestock in Denmark by *Arge pullata*, in Australia by *Lophotoma* spp., and in Uruguay by *Perreyia flavipes* (Fowler, 1993; Thamsborg *et al.*, 1996; Dutra *et al.*, 1997).

### Mechanism of action

Sawfly larvae harbor D-amino acid-containing peptides that are considered the toxic principle in sawfly larvae poisoning, which results in hepatic, and occasionally renal, degeneration and also necrosis (Oelrichs *et al.*, 1977). Lophyrotomin, an octapeptide structurally similar to cyclic peptide hepatotoxins from *Amanita* mushrooms (Thamsborg *et al.*, 1996), is the major toxin found in the Australian and Danish sawfly larvae (Oelrichs *et al.*, 1999). The bile acid transport system is important in the hepatocellular uptake of lophyrotomin, which causes a periportal hemorrhagic necrosis of the liver (Oelrichs *et al.*, 2001; Chong *et al.*, 2002). Pergidin, a heptapeptide containing a phosphoserine residue, is the major toxin found in the South American sawfly. In contrast to lophyrotomin, pergidin causes a periacinar coagulative necrosis in the liver (Oelrichs *et al.*, 2001).

### Toxicity

In natural outbreaks, deaths have occurred in livestock, primarily sheep and cattle, when large numbers of sawfly larvae have been ingested. In Australia, outbreaks have occurred in Queensland, where large forests of silver-leaf iron bark trees (*Eucalyptus melanophloia*) provide sustenance for *Lophorotoma interrupta* (Dutra *et al.*, 1997). Large piles of larvae accumulate on the ground under the trees and are ingested by cattle and sheep. In Denmark, a similar outbreak in sheep and goats involving the sawfly *Arge pullata* occurred associated with birch trees (*Betula pendula*) heavily infested with larvae. Outbreaks of sawfly poisoning of cattle, sheep, and pigs in Uruguay were associated with masses of *Perreyia flavipes* crawling through grass in orderly columns. In

Uruguay, sheep were reported to be less frequently affected than cattle. Mortality rates on affected farms have been reported to range from 1.3 to 28% (Dutra *et al.*, 1997).

Minimum lethal dosages of lophyrotomin and pergidin when dosed intraperitoneally in C57/B16 male mice were 8 and 32 mg/kg, respectively (Oelrichs *et al.*, 2001). Administration of intact *P. flavipes* larvae to pigs, calves, and lambs resulted in mortality (Dutra *et al.*, 1997). Deaths occurred in pigs and calves at dosages of 40 g of larvae per kilogram body weight. Sheep administered 10, 20, and 40 g of larvae per kilogram body weight died at 68, 43, and 14 h, respectively. One calf administered 9 g of larvae per kilogram body weight developed diarrhea and became depressed, anorexic, and ataxic but recovered 10 days following dosing. The toxicity of live and dead larvae is equivalent.

Livestock ingesting sawfly larvae may be found dead without prodromal signs (Dutra *et al.*, 1997). Clinically, affected cattle may develop weakness, muscle tremors, depression, agitation, aggression, stupor, and death within 2–7 days. Icterus and mild photosensitization were reported in some cattle that survived. In sheep and goats, clinical signs included depression, anorexia, ataxia, recumbency, and death (Thamsborg *et al.*, 1987).

Clinical laboratory abnormalities associated with sawfly larvae poisoning include elevations in liver enzymes aspartate aminotransferase, alanine aminotransferase, alkaline phosphatase, and  $\gamma$ -glutamyltransferase (Thamsborg *et al.*, 1996).

Massive hepatic necrosis was the primary postmortem lesion found in cattle and sheep, whereas renal tubular degeneration was occasionally identified in sheep (Thamsborg *et al.*, 1987; Dutra *et al.*, 1997). Lesions secondary to hepatic failure included widespread hemorrhage, icterus, and photosensitization (Dutra *et al.*, 1997).

### Treatment

Management of sawfly larvae poisoning would include removing animals from the source of the larvae and providing symptomatic and supportive care. Administration of silymarin (44–58 mg/kg intravenously) in combination with penicillin (200,000 IU/kg intravenously) and glucose (20 g/lamb) at 7 and 24 h following dosing with sawfly larvae prevented clinical signs of toxicosis and significant liver enzyme changes in experimental lambs (Thamsborg *et al.*, 1996). Lambs receiving larvae along with glucose and penicillin without silymarin developed a milder course of clinical illness and lower liver enzyme changes than did untreated control lambs administered sawfly larvae.

## LEPIDOPTERA: BUTTERFLIES AND MOTHS

Caterpillars of many species of moths and butterflies may possess hairs and spines on their surfaces that can trigger urticarial reactions in humans and animals (Mullen, 2002a). Necrosis and partial sloughing of the tongue was reported in three dogs in Israel following exposure to the pine processionary moth (*Thaumetopoea wilkinsoni*); early signs included vomiting, swelling of the tongue, dyspnea, hyperthermia, tachypnea, cyanosis, lingual edema, labial angioedema, ptyalism, bilateral submandibular lymphadenopathy, and conjunctivitis (Bruchim *et al.*, 2005). All dogs survived following symptomatic care. Caterpillars of monarch butterflies that feed on milkweed plants may accumulate the cardiotoxic glycosides from the plant into their bodies (Fowler, 1993). Upon metamorphosis into monarch butterflies, the glycosides are localized to the wings, and predatory animals such as birds, lizards, and small mammals may be poisoned if they ingest the monarchs.

## PHASMATODEA: WALKING STICKS

Ulcerative keratitis has been reported when dogs encountered the two-striped walking stick (*Anisomorpha buprestoides*). These insects are distributed through Florida and the Gulf coastal plain west to Texas, and they possess defensive glands that produce a lachrymogenic and irritation substance. When annoyed, the walking stick will spray this secretion at its harasser (Dziezyc, 1992).

## AMPHIBIA, ANURA: TOADS

### Introduction

Poisonous amphibians include frogs, salamanders, and toads, but only toads have been associated with toxicosis in domestic animals. Poisonous frogs belong to the Dendrobatidae family and are popular aquarium pets due to their vivid, gem-like coloration. Poisonous frogs have been found to have nearly 500 different bioactive alkaloids in their skin secretions, some of which have been used for food procurement by Central and South American aboriginals who live in areas that these frogs inhabit (Daly, 1980; Daly *et al.*, 2002; Takada *et al.*, 2005). Most of these alkaloids are not thought to be synthesized *de novo* by the frogs but, rather, originate from insects that make up the frogs' diets; the alkaloids are absorbed from the insects and sequestered in the glands

to produce the skin secretions (Daly, 1995a,b; Donnelly, 2002; Saporito *et al.*, 2004). Captive dendrobatids tend to lack these toxic alkaloids in their skin secretions, most likely due to the difference in diets. The remaining discussion focuses on poisonous toads.

### Background

Members of the genus *Bufo* are found throughout the world, and all are considered to produce zootoxins capable of causing clinical effects in animals. However, only the larger toads, specifically *B. marinus*, *B. alvarius*, *B. regularis*, and *B. blombergi*, are considered to produce sufficient poison to cause serious toxicosis (Fowler, 1993). *Bufo marinus* is found in Florida, Texas, Hawaii, the Caribbean, Central and South America, Fiji, Australia, the Philippines, and the Marianas. *Bufo alvarius* is found in the Imperial Valley of California and the Colorado River basin between Arizona and California. *Bufo blombergi* is found only in Colombia, and *B. regularis* is found in Ethiopia (Fowler, 1993).

Toads possess mucous glands, which are widely distributed over the skin and produce a slimy secretion that keeps the skin moist and lubricated. The mucus secretions may aid in defense through their objectionable odor and/or taste to predators. Toads produce their toxic secretions from granular glands, modified mucous glands, throughout the head, shoulders, and dorsolateral areas of their skin. The more toxic toad species possess a parotid gland, which is an aggregation of granular glands located caudal and lateral to the ear (Fowler, 1993).

### Toxicokinetics

Dogs are the species most commonly involved in toad toxicosis. Mouthing of toads stimulates release of toxins from the parotid gland into the mouth, with absorption occurring across the mucous membranes in the mouth (Roder, 2004). Toad secretions contain a variety of compounds, including bufogenins, bufotoxins, and bufotenines.

### Mechanism of action

Bufogenins inhibit sodium–potassium ATPase activity in a manner similar to cardiac glycosides such as digitalis, ultimately causing increased intracellular calcium in myocardial cells that results in cardiac arrhythmias (Eubig, 2001). Bufotoxins are bufogenins conjugated with suberyl arginine, and they have a similar mechanism of action as bufogenins. Bufotenines are indolalkylamines such as serotonin and 5-hydroxytryptophan; in combination with catecholamines present in *Bufo* toxin, these

agents may be responsible for many of the neurologic and gastrointestinal effects of *Bufo* toxins (Eubig, 2001).

## Toxicity

The relative potency of *Bufo* toxins varies with species of toad, geographic location, and size of the toad (Fowler, 1993). Smaller patients may show more severe signs when exposed to toad secretions (Eubig, 2001). *Bufo* toads in Florida appear to be more toxic than those in Hawaii and Texas, based on mortality rates of dogs exposed to the toads (Roder, 2004). One hundred milligrams of crude *Bufo* toxin is said to be toxic for dogs weighing 9–14 kg.

Clinical effects of toad poisoning include hypersalivation, anxiety, and vomiting, which can occur almost immediately following exposure; also, death may occur as rapidly as 15 min following exposure (Eubig, 2001). Other signs, including hyperemic mucous membranes, recumbency, collapse, and tachypnea, may also be present. Neurologic effects are common and include convulsions, ataxia, nystagmus, stupor, or coma (Fowler, 1993; Roder, 2004). A variety of cardiac arrhythmias have been reported, including bradycardia, sinus tachycardia, and sinus arrhythmias (Eubig, 2001). Pulmonary edema, hyperthermia, and hyperkalemia have also been reported (Fowler, 1993).

## Treatment

On-the-spot decontamination of the oral cavity by copious water lavage is recommended in cases in which no signs beyond ptyalism and gagging have occurred (Eubig, 2001). Patients displaying more severe signs should be transported to a veterinary facility for stabilization prior to oral lavage. If an entire toad has been ingested, emesis under veterinary supervision is indicated for dogs when no signs beyond hypersalivation have occurred. Endoscopic or surgical removal of the toad from the stomach may be required in cases in which signs have developed, but it is important to stabilize the patient prior to attempts to remove the toad. Alternatively, multiple doses of activated charcoal with a cathartic may be used when entire toads are ingested (Eubig, 2001).

Patients displaying severe signs of toxicosis should be treated symptomatically and aggressively. Seizures may be managed with diazepam or a barbiturate. Intravenous fluid therapy is essential to aid in cardiovascular support. Arrhythmias should be managed as they develop. Bradycardia may be treated using atropine, whereas propranolol or esmolol may be used to treat tachycardia (Eubig, 2001). Correction of potassium imbalances should be performed as needed. Animals experiencing severe hyperkalemia, severe neurologic signs, or severe

arrhythmias unresponsive to therapy may be treated with digoxin-specific antigen-binding fragments (digoxin immune Fab); however, the high cost of this product often makes its use in veterinary medicine unfeasible (Eubig, 2001).

The prognosis for patients exposed to small toads and/or showing mild clinical signs is good. Animals developing advanced neurologic or cardiac signs have a more guarded prognosis.

## REPTILIA

Venomous reptiles come from the order Squamata, which includes the lizards and the snakes. Outbreaks of poisonings from consumption of the flesh of certain turtles and tortoises have occasionally been reported in humans, but the incidence is fairly low; reports in the veterinary literature of chelonitoxism are lacking.

## SNAKES

### Introduction

Of the 35,001 species of snakes in the world, approximately 400 are venomous (Russell, 2001). Venomous snakes are widely distributed throughout the world, with the exception of certain islands, such as Hawaii, Ireland, and New Zealand (Fowler, 1993). Venomous snakes come from the families Colubridae, Crotalidae, Elapidae, Hydrophiidae, Laticaudidae, and Viperidae; only members of the Crotalidae and Elapidae are represented in the Western Hemisphere.

## CROTALIDS

### Background

The crotalids are also known as pit vipers, so named for the indented, heat-sensing pits located between the nostrils and eyes. Other features of this family include elliptical pupils, triangular-shaped heads, retractable and hollow front fangs, and a single row of subcaudal scales distal to the anal plate (Peterson, 2004). Rattlesnakes have special keratin “rattles” on the ends of their tails and are members of the genera *Crotalus* and *Sistrus*. Other crotalids native to North America include water moccasins, also known as cottonmouths (*Agkistrodon piscivorus*) and copperheads (*A. contortrix*).

At least 29 subspecies of rattlesnakes are found throughout the United States, whereas copperheads and water moccasins are distributed through the eastern and central United States. The approximate distributions of some of the more common species are illustrated in Figure 73.3. Because of their tendency to associate near areas of human habitation, copperheads are responsible for the majority of human (and likely animal) snakebites in the United States. However, the majority of animal and human deaths in the United States are attributed to rattlesnakes, due to their more potent venoms. It is estimated that from 150,000 to 300,000 animals are bitten every year by pit vipers within the United States (Peterson, 2004; Wallis, 2005).

### Toxicokinetics

Pit vipers inject their venom by rotating their retractable fangs downward and forward in a stabbing motion (Peterson, 2004). Contraction of muscles in the venom glands then forces the venom through the hollow fangs and into the tissues of the victim. Snakes can control the amount of venom delivered to the victim by regulating the muscular contraction of the venom glands.

### Mechanism of action

Crotalid venoms are complex combinations of enzymes, cytotoxins, neurotoxins, cardiotoxins, hemolysins, coagulants/anticoagulants, lipids, nucleosides, nucleotides, organic acids, and cations such as zinc (Fowler, 1993; Peterson, 2004). Most venoms contain a minimum of 10 of these different components. In North American rattlesnakes, three general venom types have been defined (Peterson, 2004). "Classic" diamondback venom causes marked tissue destruction, coagulopathy, and hypotension. Mojave A venom causes little tissue destruction or coagulopathy but causes severe neurotoxicosis. The third venom class contains components of both classic and neurotoxic venoms.

Hyaluronidase ("spreading factor") and other enzymes break down collagen and other connective tissues, allowing for rapid penetration of venom components throughout the victim's tissues. Low-molecular-weight myotoxins open sodium channels in the muscle cell membrane, leading to myocyte necrosis. Phospholipase A stimulates hypercontraction of myocyte membranes, resulting in myofibril rupture (Peterson, 2004). Alteration of blood coagulation may lead to either hyper- or hypo-coagulation through either direct effects on clotting factors or induction of hyperfibrinolysis, resulting in dissolution of clots as they are forming. Some diamondback rattlesnake venoms contain cardiotoxic agents

(myocardial depressant factors) that cause profound hypotension unresponsive to fluid therapy. Neurotoxic components bind the presynaptic nerve membrane, inhibiting neurotransmitter release and causing paralysis (Fowler, 1993).

### Toxicity

Dogs are the domestic species most commonly bitten by pit vipers. In a study of prairie rattlesnake bites in dogs, most bites occurred between May and September during the late afternoon (Hackett *et al.*, 2002). Most bites involved young dogs (median age, 3.7 years) and were located on the head.

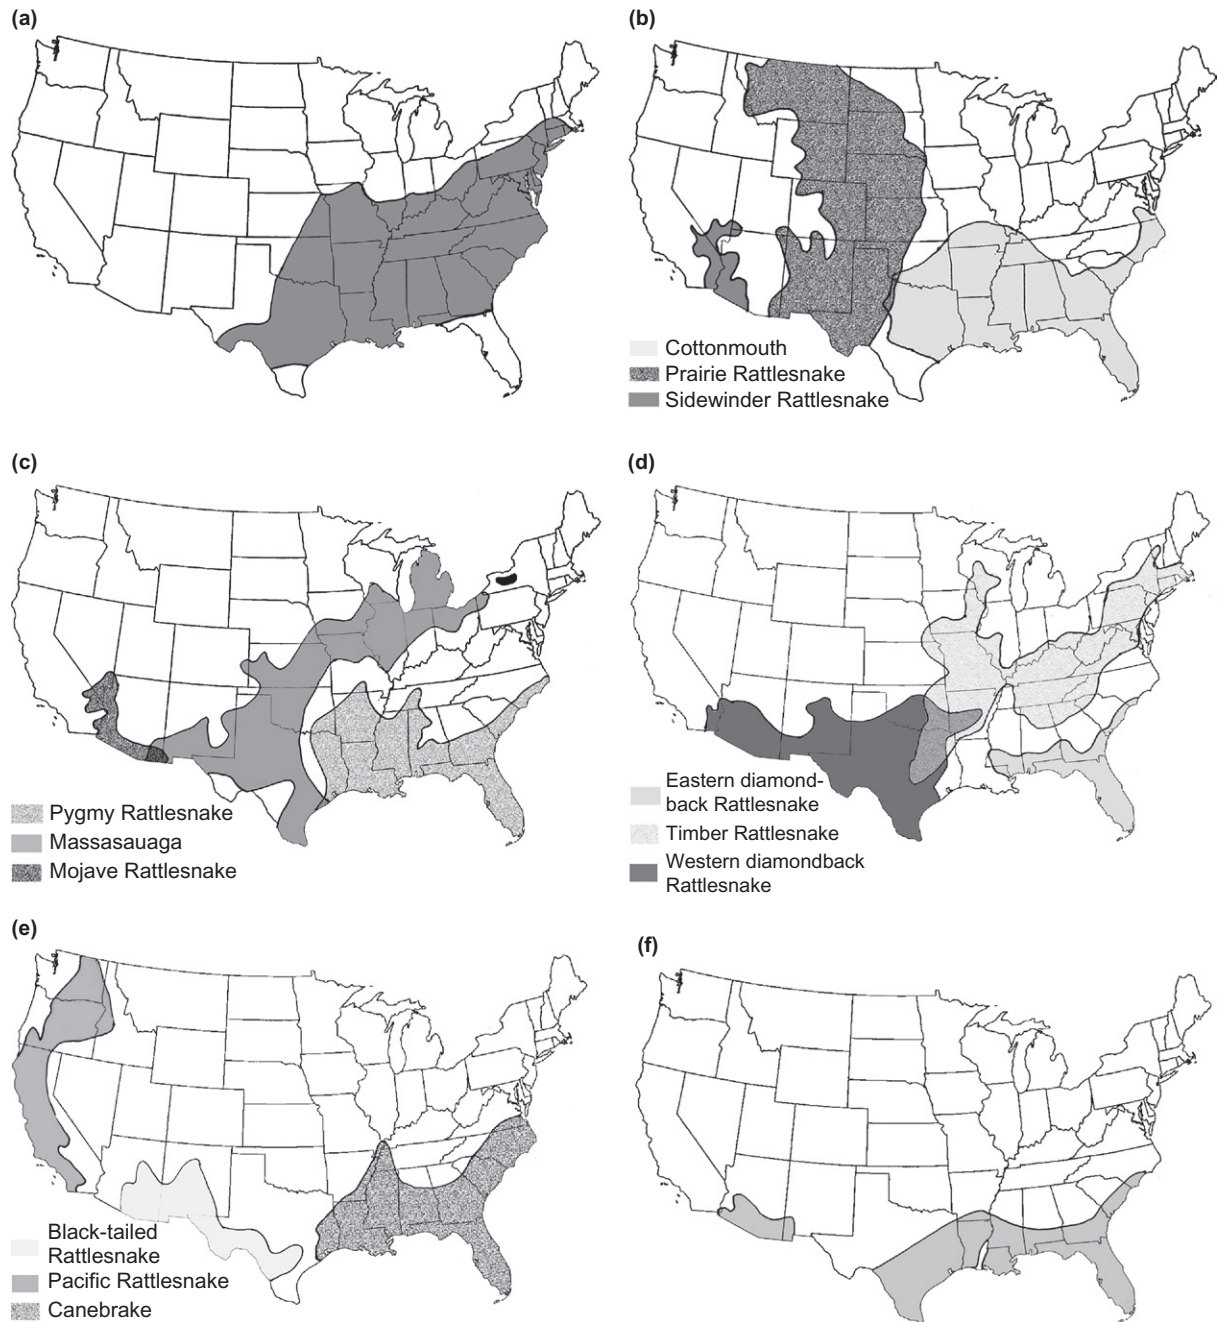

Dogs are most commonly bitten on the front legs and head, horses are most commonly bitten on the muzzle, and cattle are more commonly bitten on the tongue or muzzle (Peterson, 2004). Cats are considered more resistant to pit viper venom, but cats are often presented in more severe clinical conditions due to their small body size, tendency to be struck on the torso, and, often, delay in obtaining veterinary care when they run and hide following a bite. Bites to the thoracic wall allow for more rapid and complete venom absorption, whereas bites to the tongue are essentially equivalent to intravenous envenomations.

The toxicity of any given crotalid bite will depend on both victim and snake factors. The species of the victim is an important factor because some species of animals have a degree of natural immunity to snake venoms. In addition, the victim's size, pre-existing health, interval until medical care is obtained, and site of the bite are victim-related factors that can influence the severity of the snakebite. Snake factors that affect toxicity include species, size and age of the snake, as well as the time of year, time since the snake's last bite, and whether the bite was defensive or offensive. "Dry" bites, those in which no venom is injected, may occur in up to 25% of snakebites (Peterson, 2004). Snakes that have recently fed may be depleted of venom and thus inject less (Fowler, 1993). Older snakes may have more potent venom, and larger snakes may harbor larger volumes of venom to deliver.

Analysis of venoms from a variety of North American pit vipers indicates that the ranking of relative toxicity of venoms, from highest to lowest, is Mojave A rattlesnake (*Crotalus scutulatus*), eastern diamondback (*C. adamanteus*), western diamondback (*C. atrox*), timber rattlesnake (*C. horridus*), cottonmouth (*A. picivorus*), and copperhead (*A. contortrix*).

### Clinical effects

In most cases of snakebite, the initial signs are usually local pain and swelling, followed by petechiation,

**FIGURE 73.3** Distribution of venomous snakes in the United States. (a) Distribution of copperheads (*Agkistrodon contortrix*). (b) Distribution of cottonmouths (*Agkistrodon piscivorus*), prairie rattlesnakes (*Crotalus viridis*), and sidewinder rattlesnakes (*Crotalus cerastes*). (c) Distribution of pygmy rattlesnakes (*Sistrurus miliarius*), massasauga rattlesnake (*Sistrurus catenatus*), and Mojave rattlesnake (*Crotalus scutulatus*). (d) Distribution of the Eastern diamondback rattlesnake (*Crotalus adamanteus*), timber rattlesnake (*Crotalus horridus*), and Western diamondback rattlesnake (*Crotalus atrox*). (e) Distribution of the black-tailed rattlesnake (*Crotalus molossus*), Pacific rattlesnake (*Crotalus atrox*), and canebrake rattlesnake (*Crotalus horridus atricaudatus*). (f) Distribution of coral snakes (*Micruroides euryxanthus* and *Micrurus fulvius*). (Adapted from Fowler, *Veterinary Zootoxicology*, CRC Press, and Professional Pest Control Products website, <http://www.pestproducts.com/snakeinfo.htm>.)

ecchymosis, and discoloration of the skin in the region of the bite. Swelling and/or the haircoat of the victim may mask bite wounds. Bites from snake species that possess only neurotoxic venom may show little local swelling.

Several hours may elapse before more significant clinical signs develop. Hypotension, shock, tachycardia or other arrhythmia, vomiting, diarrhea, shallow respiration, lethargy, nausea, obtundation, muscle fasciculations,

ptyalism, and pain and enlargement of regional lymph nodes may occur (Peterson, 2004). Local tissue necrosis may be severe, especially in areas with minimal muscle mass. Local swelling from bites to the head or front legs in dogs may result in regional circulatory alterations that reduce venom uptake (Peterson, 2004). Horses or llamas bitten on the muzzle may succumb to asphyxiation due to occlusion of the nares due to tissue swelling. Horses develop pitting edema that frequently progresses to involve the entire head and neck or limb, but tissue necrosis is uncommon (Fowler, 1993). Hemolysis, rhabdomyolysis, thrombocytopenia, and coagulopathy may occur.

## Treatment

Historically, a variety of first aid measures have been described for managing snakebites in humans and animals, including suction, electric shock, ice packs, and tourniquets (Bush, 2004; Peterson, 2004). However, most of these measures are of questionable value, and they waste precious time that could be used to transport the patient to a veterinary medical facility. Initial first aid should be focused on keeping the animal quiet (exertion will hasten the spread of venom factors into the tissues) and attempting to keep the bitten area below heart level.

The haircoat around the bite area should be clipped in order to fully visualize the bite. Use of a permanent marker to delineate the margins of local edema and/or circumferential measurements above, at, and below the bite site will allow objective evaluation of the progression of local tissue involvement (Fowler, 1993; Peterson, 2004). Vital signs, including blood pressure, should be monitored closely for the first several hours; all patients should be monitored for a minimum of 24h before being released (Fowler, 1993). Tracheostomy may be required in cases in which severe swelling in the head or neck region results in respiratory compromise or in cases of obligate nasal breathers (e.g., horses and llamas) that are bitten on the muzzle. Intravenous crystalloid therapy is recommended to manage hypotension or hypovolemia. Coagulopathy and hemolysis should be managed using blood or platelet transfusions. Conditions such as muscle tremors, seizures, cardiac arrhythmias, and pulmonary edema should be managed as they develop using standard medical therapies. Corticosteroid use is controversial in snakebites, with some indicating that corticosteroids have no place in management of snakebite (Peterson, 2004), whereas others suggest that judicious use of corticosteroids may be of benefit (Fowler, 1993). In horses, topical application of dimethyl sulfoxide to the bite site should be avoided because it enhances systemic absorption of venom (Peterson, 2004). Diphenhydramine may be useful for its sedative effect. Broad-spectrum antibiotics are advocated by some to aid in prevention of

infection (Peterson, 2004), and horses should receive tetanus antitoxin or toxoid (Fowler, 1993).

The use of intravenous antivenin in crotalid snakebites can result in the reversal of potentially life-threatening problems such as coagulopathy, thrombocytopenia, and paralysis (Peterson, 2004). Antivenin cannot reverse tissue necrosis or secondary effects such as renal damage. One study on prairie rattlesnake bites in dogs suggested that antivenin administration was not significantly associated with clinical outcome, and the value of its use in prairie rattlesnake envenomation was questioned (Hackett *et al.*, 2002).

Equine-origin polyvalent antivenin has historically been used to manage snakebites in animals. More recently, polyvalent immune Fab fragments (CroFab and Protherics) have become available to treat snakebites in humans and animals. Advantages of the crotalid Fab antivenin over the equine-origin antivenin include decreased antigenicity (and therefore decreased potential for allergic reaction), more rapid elimination, increased stability, and more rapid reconstitution (Gwaltney-Brant and Rumble, 2002). The crotalid Fab antivenin has been shown to be effective in management of canine snakebite (Peterson, 2004). Administration of either antivenin should be begun as early as possible, and patients should be closely monitored for signs of anaphylaxis during antivenin administration. Studies in dogs have shown that single vial doses of crotalid Fab antivenin are sufficient to manage most cases of canine snakebite envenomation. Coagulation parameters should be monitored, and additional vials of antivenin should be administered if deterioration is noted.

The prognosis for recovery from snake envenomation is dependent on the type of snake involved, the severity of the envenomation, and the rapidity and aggressiveness of veterinary intervention.

A rattlesnake vaccine (*Crotalus Atrox* Toxoid, Red Rock Biologics) has been developed and marketed with the aim of reducing the morbidity and mortality of dogs due to crotalid snakebites (Wallis, 2005). The vaccine is designed to elicit an immune response to the major protein fractions of *Crotalus atrox* (western diamondback rattlesnake) that may also cross-react to the major protein fractions of some other rattlesnake venoms. The vaccine does not induce neutralizing antibodies against Mojave neurotoxin. The vaccine is administered as two injections (three for dogs exceeding 100 pounds of body weight) spaced 4 weeks apart. Titers peak in 4–6 weeks and decline after approximately 6 months, and twice-yearly vaccination is recommended for dogs that have potential to be exposed to rattlesnakes year-round. The manufacturer emphasizes that the vaccine does not eliminate the need to seek veterinary care in the event that a venomous snake bites a vaccinated dog. In clinical trials, vaccinated dogs experiencing mild envenomations from

subsequent snakebites frequently had their swelling receding within hours of the bite, compared to unvaccinated dogs, which may have swelling progress and persist for 1 or 2 days following a mild envenomation. Vaccinated dogs that are severely envenomated may still require treatment with antivenom, although the amount of antivenom required may be reduced in vaccinated dogs (Wallis, 2005). The vaccine has been on the market for only a few years, and additional time and study are required to determine its overall efficacy and value.

## ELAPIDS

### Background

In North America, there are two species of venomous elapid snakes: the Sonoran coral snake (*Micruroides euryoxanthus*) and several subspecies of *Micrurus fulvius*, including the Texas coral snake (*M. f. tenere*), the eastern coral snake (*M. f. fulvius*), and the south Florida coral snake (*M. f. barbouri*) (Peterson, 2004). The Sonoran coral snake is found in central and southeastern Arizona and southwestern New Mexico. The Texas coral snake is found from eastern and south-central Texas north into Louisiana and southern Arkansas. The eastern coral snake is present from eastern North Carolina south to central Florida and west through Alabama and Mississippi. The south Florida coral snake is located in southern Florida.

North American coral snakes tend to be shy, nonaggressive, and nocturnal, making interactions between them and domestic animals less common than interactions with pit vipers (Peterson, 2004). These snakes are brightly colored, with alternating bands of black, red, and yellow, and they have small heads and round pupils. The venom delivery apparatus of coral snakes includes short, fixed (nonhinged) front fangs that are partially covered by a membrane (Fowler, 1993). During the bite, the membrane is pushed away and the venom duct empties at the base of the fang, bathing the fang with venom that runs down grooves in the fang. During the bite, coral snakes hold onto the victim and chew, delivering additional venom to the wound.

### Toxicokinetics

Like crotalid venom, coral snake venom is composed of a variety of compounds, mostly small polypeptides and enzymes. Neurologic signs following envenomation may be delayed in onset for up to 12 h, and the duration of effects is prolonged (Peterson, 2004). Total clearance of venom from the body may take up to 14 days.

### Mechanism of action

Neurotoxic peptides in coral snake venom cause a nondepolarizing postsynaptic neuromuscular blockade similar to the effects of curare (Peterson, 2004). Binding of neurotoxins to postsynaptic receptors appears to be irreversible. Enzymes within the venom can cause local tissue necrosis, myoglobinemia in cats, and hemolysis in dogs.

### Toxicity

As with crotalid envenomations, the severity of the bite is related to the size of the victim and the amount of venom delivered. The amount of venom injected is related to the duration of the bite, intensity of chewing, and reason for the bite (offensive versus defensive). Clinical signs vary with the species of the victim. In cats, the signs are primarily neurologic, including progressive ascending flaccid paralysis, decreased nociception, CNS depression, and diminished spinal reflexes (Peterson, 2004). Hypotension, respiratory depression, anisocoria, myoglobinemia, and hypothermia have also been described in cats. In dogs, depression of the CNS, decreased spinal reflexes, muscle weakness, and respiratory depression may occur. Vomiting, hypersalivation, hypotension, dyspnea, dysphagia, muscle fasciculation, tachycardia, and hemolysis have also been reported in dogs. Potential complications include dysphagia leading to aspiration pneumonia. Death is due to respiratory paralysis.

### Treatment

Management of coral snake envenomations in animals should entail immediate transport for veterinary care. Because onset of clinical signs may be delayed up to 12 h, patients that have been bitten should be closely monitored for a minimum of 24 h. Baseline serum chemistry and complete blood count values should be obtained, and respiratory function should be closely monitored. Ventilatory support may be required if clinical signs progress to the point where respiration is compromised; ventilation may be required for 72 h or more (Peterson, 2004). Administration of specific *Micrurus* antivenin should be considered if neurologic signs begin to develop; early administration is recommended because the antivenin is considered poorly effective at displacing venom components bound to receptor sites (Peterson, 2004). As with crotalid antivenin, anaphylaxis is a potential complication of *Micrurus* antivenin administration. Broad-spectrum antibiotics and symptomatic wound care may be indicated. Recovery periods of 7–10 days

have been reported in cats envenomated by coral snakes (Chrisman *et al.*, 1996).

The prognosis for coral snake envenomations in animals is generally good provided prompt and aggressive veterinary care is obtained.

LIZARDS

Background

Venomous lizards are found only in North and Central America and are members of the genus *Heloderma*. *Heloderma suspectum* and *H. cinctum* are commonly referred to as Gila monsters, whereas *H. horridum* is known as the Mexican beaded lizard. The Gila monsters are found in Arizona and areas of Utah, New Mexico, Nevada, and Southern California, whereas the Mexican beaded lizard is found in Mexico from Sonora to the Pacific Coast and into Guatemala (Cantrell, 2003; Peterson, 2004).

Venomous lizards are large and heavily bodied, with blunt, rounded tails, powerful jaws, and short legs with clawed, hand-like feet. The colorful, bead-like scales form a reticular pattern of dark brown to black on a yellow, orange, pink, and/or cream background. Gila monsters, which can reach 55 cm in length, are smaller than Mexican beaded lizards, which can grow up to 1 m in length and weigh up to 2 kg (Cantrell, 2003; Peterson, 2004).

*Heloderma* spp. possess venom glands in the lower jaw at the base of the teeth, and venom is delivered through grooves in the teeth via capillary action as the lizard masticates. These lizards are generally considered to be docile, but when provoked they can be aggressive biters that can hang on tenaciously to their victim, often requiring prying the jaws open to release the victim (Cantrell, 2003). The teeth are loosely attached and brittle, and they may break off into the wound. The venom is considered a defensive weapon rather than one for procuring food (Peterson, 2004).

Mechanism of action

*Heloderma* venom is composed of a complex mixture of proteins and enzymes, many of which are similar to those found in snake venoms, including hyaluronidase, phospholipase A<sub>2</sub>, serotonin, and a variety of enzymes (Cantrell, 2003). Hyaluronidase (“spreading factor”) catalyzes the cleavage of internal glycoside bonds of acid mucoglycosides, resulting in decreased viscosity of hyaluronic acid, which in turn increases tissue permeability and allows deeper penetration of venom into tissue. Phospholipase A<sub>2</sub> uncouples oxidative phosphorylation, which inhibits cellular respiration, causes cell

TABLE 73.3 Contents and effects of various *Heloderma* spp. venom components

Component	Effects	References
Gilatoxin	“Lethal factor,” kallikrein-like activity, pain, hypotension	Fowler (1993), Utainsincharoen <i>et al.</i> (1993)

Helothermine	Lethargy, paresis, hypothermia	Peterson (2004)
Hyaluronidase	“Spreading factor,” degrades connective tissue	Peterson (2004)
Phospholipase A <sub>2</sub>	Inhibition of platelet aggregations	Huang and Chiang (1994)

membrane destruction, and inhibits platelet aggregation (Huang and Chiang, 1994; Peterson, 2004). Various proteolytic enzymes result in local tissue damage as well as aid in the spread of venom through the tissue. In addition, *Heloderma* venoms contain several unique components that have a variety of clinical effects; these are summarized in Table 73.3. Gilatoxin is considered to be the major lethal factor in *Heloderma* venom (Fowler, 1993).

Toxicity

The toxicity of *Heloderma* venoms is dependent on the amount of venom delivered to tissues, which in turn is dependent on the duration and severity of the bite. Due to their inquisitive nature and tendency to harass wildlife that they encounter, dogs are the species most likely to have a significant encounter with *Heloderma* spp. Although rare, *Heloderma* bites to dogs and cats have occurred, and the death of at least one dog has been reported (Fowler, 1993; Peterson, 2004).

The clinical effects of *Heloderma* envenomation include intense local pain, edema, and hemorrhage at the site of the wound (which may contain fractured teeth). Regional lymphangitis and local ecchymoses may occur, although tissue necrosis is not common. Systemic signs described in humans include weakness, dizziness, tinnitus, muscle fasciculations, hypotension, and tachycardia. In dogs and cats, signs may include tachypnea, vomiting, polyuria, salivation, and lacrimation. Aphonia has been reported in cats (Peterson, 2004). Hypotension, tachycardia, and respiratory distress have been reported in dogs and cats injected with boluses of *Heloderma* venom, although reports of these conditions in natural exposures are lacking.

## Treatment

Management of *Heloderma* bites in small animals includes initial first aid followed by assessment and monitoring. The first course of action is often disengaging a lizard that is still attached to the victim because these lizards may hold on tenaciously once they bite. Removal should be attempted as quickly as possible because the amount of venom delivered is proportional to the duration of the bite. Suggested means of removal of the lizard include applying a flame from a match or cigarette lighter to the underjaw of the lizard, prying the jaws open with a metal bar, or killing the lizard by incising the jugular vein with a knife. Attempts to pull the lizard off the victim or to strike the lizard in the head may enlarge or deepen the wounds at the site of the bite (Fowler, 1993). Once the lizard is removed, a veterinarian should evaluate the patient. The bite site should be irrigated with 2% lidocaine and the wound probed with a 25-gauge needle to detect any embedded tooth fragments (Peterson, 2006). Diazepam, 0.1–0.5 mg/kg intramuscularly, may be helpful in sedating agitated or highly painful animals. Analgesics should be administered as needed, and the animal should be monitored for several hours for the development of hypotension or shock; if either develops, appropriate medical treatment including intravenous fluid therapy is indicated. Broad-spectrum antibiotics should be administered to prevent infection from the myriad of potentially pathogenic bacteria that have been reported to frequent the mouth of reptiles (Peterson, 2006). General wound care should be instituted, and the wound should be examined daily for evidence of infection. Envenomation of pets by *Heloderma* spp. is rare, and in most cases, a favorable outcome can be expected provided prompt and appropriate veterinary care is obtained.

## AVES

Two genera of passerine birds native to New Guinea, *Pitohui* and *Ifrita*, have poisonous secretions on their feathers, most likely as means of defense against predators (Dumbacher *et al.*, 1992; Weldon, 2000; Dumbacher and Fleischer, 2001). The toxins are present in highest concentrations in the contour feathers of the belly, breast, and legs, with lesser amounts on the head, back, tail, and wing feathers (Weldon, 2000). Several steroidal alkaloids have been isolated from the feathers of these birds, including batrachotoxin and homobatrachotoxin as well as derivatives of these compounds; similar compounds are present on the skin of poison dart frogs (Dendrobatidae) from Central and South America (Daly, 1995b).

The origin of the toxins found in *Pitohui* ("rubbish bird") and *Ifrita* ("bitter bird") is thought to be through accumulation from insects ingested by the birds rather than by *de novo* synthesis (Dumbacher *et al.*, 2004). High levels of batrachotoxins have been found in beetles of the genus *Choresine* (family Melyridae) that serve as part of the diet of *Pitohui* species. The beetles themselves are unable to synthesize steroidal skeletons and likely accumulate the base steroids from plant phytosterols that they ingest. The beetles then convert the steroids to the steroidal alkaloids and accumulate them within their bodies.

Batrachotoxins act through the opening of sodium channels in nerve and muscle cells, resulting in depolarization and paralysis (Dumbacher *et al.*, 2004). However, exposure of humans to the feathers of *Pitohui* and *Ifrita* species primarily results in respiratory irritation; allergic-type responses; and burning sensations of the eyes, skin, and oral mucosa (Dumbacher *et al.*, 2000).

## MAMMALIA

Only a handful of mammals are poisonous or venomous, and toxicosis from exposure to these animals is uncommon. Poisonous mammals include certain carnivores (e.g., polar bears) and pinnipeds (e.g., walrus and seals), whose livers contain high levels of vitamin A; ingestion of these livers may result in acute or chronic hypervitaminosis A (Cleland and Southcott, 1969; Fishman, 2002). In addition, the meat of marine mammals such as whales may accumulate high levels of organotins, mercury, and other agents that can pose a toxicologic hazard if ingested in sufficient quantity (Endo *et al.*, 2005). Impairment in cell-mediated immunity was found in sled dogs from Greenland that were fed the blubber of minke whales (*Balaenoptera acutorostrata*) (Sonne *et al.*, 2006).

Venomous mammals belong to the orders Monotremata and Insectivora (Fowler, 1993). Venomous monotremes are the platypus and echidna, of which only the platypus is considered to be of toxicologic significance because the venom gland in the echidna is nonfunctional. The male platypus possesses a curved, grooved, conical, sharp spur on the medial aspect of the tarsus. The spur is normally kept retracted against the leg, but when stimulated, muscles cause the spur to project perpendicularly to the leg. The venom gland is kidney shaped and located on the medial aspect of the thigh, and venom is first transported to a reservoir near the spur and then moved through a duct to the spur. Envenomation occurs when the platypus kicks the spur into the victim. Although poorly studied, components

identified in platypus venom include a protein similar to natriuretic peptide, a defensin-like peptide, a hyaluronidase, 5-hydroxytryptophan, and histamine (Hodgson, 1997; Torres *et al.*, 2006). Based on reports of human envenomation by platypus, expected signs include intense pain and numbness at the site of the wound and local swelling that may progress proximally (Fowler, 1993). Regional lymph nodes may become enlarged and painful. Humans have reported a feeling of faintness. No reports of human or animal fatality from platypus exist. There are infrequent anecdotal reports of dogs being envenomated by platypus.

Venomous insectivores include various shrews and solenodons and possibly some moles and hedgehogs (Dufton, 1992). The European hedgehog (*Erinaceus europaeus*) has been noted to mix its frothy saliva with toad toxins and smear this mixture over its forward spines. Some moles will store "paralyzed" worms and slugs away, with the paralysis thought to be due to paralytic toxins within the mole's saliva. Studies of the American short-tailed shrew (*Blarina brevicauda*), the Haitian solenodon (*Solenodon paradoxus*), the European water shrew (*Neomys fodiens*), and the Mediterranean shrew (*N. anomalus*) have obtained more definitive evidence of the presence of venoms. These mammals possess three pairs of salivary glands: parotid, retrolingual, and submaxillary. The submaxillary glands are thought to contribute to the bulk of the venom in these species. The Haitian solenodon has grooved incisors that direct the venom to the wound, whereas the shrews have teeth with concave inner surfaces that may play a similar role as grooves.

Envenomation is achieved by biting and chewing the victim, accompanied by copious salivation. Insectivore venoms contain a variety of peptides and enzymes, and a compound isolated from *Blarina* venom has been shown to have kallikrein-like activity (Kita *et al.*, 2005). The venom of *Blarina* appears to be the most toxic, with that of *N. fodiens*, *N. anomalus*, and *Solenodon* being 1/3, 1/6, and 1/20 as toxic, respectively (Dufton, 1992). There is considerable species variation in sensitivity to the venom in shrew and solenodon venom, with voles and rabbits being most sensitive to the effects and mice, cats, and humans being relatively more resistant (Dufton, 1992). In most natural exposures, the primary effects of shrew and solenodon venoms are related to neurotoxicity. Mice bitten by *Blarina* rapidly develop depression and immobility. When submaxillary gland extracts are injected into experimental animals, depression, irregular respiration, dyspnea, ptosis, rear limb paralysis, convulsions, and death occur. Intravenous injection of 7 mg/kg of *Blarina* toxin extract in a cat resulted in decreases in respiratory and heart rates with a concomitant decrease in blood pressure. These effects resolved within 15 min but returned with subsequent doses of 2.5 and 7 mg/kg. Apparent recovery following the final dose was followed

by acute respiratory depression and cardiac arrhythmia, and the cat subsequently died. In humans, symptoms of bites from shrews or solenodons result in localized burning sensation surrounding the lower jaw tooth puncture sites and localized swelling. The burning sensation may persist for several days. Systemic toxicosis has not been reported in natural exposures to the bites of shrews or solenodons in humans or domestic animals.

## CONCLUSIONS

Every phylum of the Animal Kingdom contains animals capable of producing toxic effects, either through envenomation or through poisoning. However, only a small number of these animals are sufficiently toxic to be of importance to veterinary clinicians. Arachnids, insects, toads, and snakes cause the most clinically significant problems for domestic and wild animals. Although in some cases specific antidotes (i.e., antivenins) exist for exposures to venomous animals, availability and cost of these antidotes often make their use in veterinary medicine unfeasible. Therefore, most cases of zootoxicosis in animals will be managed with symptomatic and supportive care.

## Mare reproductive loss syndrome

Sharon M. Gwaltney-Brant

### INTRODUCTION

In April 2001, an outbreak of abortions and early fetal losses among horse farms in central Kentucky resulted in the loss of more than 4500 equine pregnancies (Sebastian *et al.*, 2008). The losses hit particularly hard within the Thoroughbred industry, in which more than 3500 early and late-term abortions accounted for an overall loss of 17% of all pregnancies, with some farms experiencing more than 60% early fetal losses compared to typical losses of 3–5% during the same time interval in other years (Potter *et al.*, 2005). Losses also occurred in other breeds (including approximately 1000 Paint horse and Quarter horse foals) in Kentucky, and smaller numbers of similar fetal losses were reported in surrounding states of Ohio, West Virginia, Tennessee, Illinois, and Indiana (Cohen *et al.*, 2003b; Bernard *et al.*, 2004; Sebastian *et al.*, 2008). In 2002, a similar outbreak occurred that was approximately one-third that of 2001 (McDowell *et al.*, 2010). The total economic loss to the thoroughbred industry in 2001 was estimated to be more than \$330 million, and the combined 2001–2002 losses to mare reproductive loss syndrome (MRLS), as the disorder became known, were estimated to be approximately \$500 million (Sebastian *et al.*, 2008).

Attempts to identify the etiology of MRLS managed to rule out a number of infectious, nutritional, toxic, and metabolic causes. Mares bred in mid-February were found to be at greatest risk of early term abortions, whereas those bred after April 1 were at much lower risk (Cohen *et al.*, 2005). An epidemiological survey performed in the summer of 2001 revealed a temporal correlation between the presence of eastern tent caterpillars (ETC; *Malacosoma americanum*), the presence

of wild black cherry trees (*Prunus serotina*), the presence of waterfowl, and the practice of feeding hay off the ground among the farms where MRLS was reported (McDowell *et al.*, 2010). During the same time frame in which MRLS-related abortions were being investigated, there were increased reports of fibrinous pericarditis and unilateral uveitis in horses on farms in central Kentucky. Mares experiencing early or late-term abortions from MRLS did not experience any long-term effect on fertility and were able to successfully reproduce in subsequent years (Cohen *et al.*, 2005; Sebastian *et al.*, 2007).

### CLINICAL MANIFESTATIONS

The majority of fetal losses attributed to MRLS were early fetal losses occurring between 48 and 171 days of gestation that were detected during routine reproductive ultrasonographic evaluations (Sebastian *et al.*, 2007). Most mares showed no clinical signs, with less than 5% exhibiting mild colic, abdominal straining, or low-grade fevers 1–3 days prior to fetal loss (Bernard *et al.*, 2004). Examination of affected mares revealed that fetuses were absent, present but dead, present and alive with bradycardia and slow movements (these fetuses later died), or present and alive but surrounded by flocculent and cloudy amniotic fluid (some of these fetuses did survive) (Dwyer *et al.*, 2003). Culture of fetal and placental tissues most consistently resulted in growth of non- $\beta$ -hemolytic streptococci or actinobacilli.

Late-term abortions attributed to MRLS were characterized by abortion at more than 269 days of gestation,

live fetuses with slow heart rates and movements, and fetuses with amniotic fluid changes as described for early term abortions. Some foals were born weak and with signs consistent with fetal hypoxia; the majority of these foals did not survive beyond 4 days (Sebastian *et al.*, 2007). Pathologic lesions found in both early and late-term abortions included placental edema, premature placental separation, placentitis, funisitis, thyroidal follicular dysplasia, and pulmonary lesions consisting of inflammatory infiltration of pulmonary parenchyma and/or alveoli and the presence of squamous epithelial cells within alveoli (Cohen *et al.*, 2003a). Up to 40% of late-term aborted fetuses had no pathologic lesions at necropsy. As with early term abortions, non- $\beta$ -hemolytic streptococci and actinobacilli were most commonly isolated from fetal and/or placental tissues.

An outbreak of fibrinous pericarditis occurred during the same time frame as the 2001 MRLS abortions, with 34 terminal cases reported during May and September of 2001 compared to a normal prevalence of 4 cases per year (Bolin *et al.*, 2005). Horses of all ages, breeds, and sexes were represented in the population of affected horses. Nearly half of the affected horses were 2 years of age or younger, suggesting that younger horses may be at greater risk to develop pericarditis. Affected horses presented with tachycardia, pleural effusion, pericardial effusion, ascites, fever, abdominal pain, respiratory distress, weight loss, and tachypnea. Sudden death was reported in a few cases. Ultrasonographic evaluation revealed effusive and fibrinous pericarditis. Pathologic lesions detected at necropsy included cardiomegaly, fibrinous pericardial effusion, thickening of pericardium with fibrin, and restrictive pericarditis with fibrous tissue deposition on pericardial and epicardial surfaces. Culture of pericardial fluid revealed bacterial involvement in 62% of clinical and terminal cases (Bolin *et al.*, 2005). *Actinobacillus* species were the most commonly isolated bacteria from affected horses, although *Enterococcus faecalis*, *Streptococcus zooepidemicus*, and *Escherichia coli* were occasionally isolated. Most of these bacteria showed relatively broad sensitivity to antibiotics.

During the 2001 MRLS phenomenon in central Kentucky, unilateral uveitis was reported in 40 horses of varying age, breed, and sex (Sebastian *et al.*, 2007). Affected horses developed acute exudative ophthalmitis with corneal edema, exudates within the anterior and posterior chambers, and iris hemorrhages. Affected eyes progressed to blindness and global atrophy. No pathologic organisms were detected on culture, and no histopathological examination of affected globes was performed. Also during this time frame, three cases of *Actinobacillus* meningoencephalitis were diagnosed in young (<4 years of age) horses at necropsy.

In central Kentucky, the majority of cases of MRLS and associated disorders occurred during 2001, with fewer cases reported the following year and even fewer in

2003. Retrospectively, similar abortion storms occurred in Kentucky in the spring of both 1981 and 1982, but no epidemiological studies were conducted. In 2006, abortions in mares in Florida were associated with the presence of large numbers of ETC (Sebastian *et al.*, 2007). Similar episodes of equine abortions were also reported in Australia, associated with processionary caterpillars (*Ochragaster lunifer*) (McDowell *et al.*, 2010).

## MECHANISM OF ACTION

Upon initial study of the MRLS phenomenon, several hypotheses regarding the potential cause of the abortions were presented and investigated. An infectious etiology was considered, but serological and virological studies were consistently negative, and the pathological lesions were not characteristic of ascending infections. The presence of funisitis might suggest a hematogenous route of infection, but funisitis was identified in less than half of the cases of MRLS, and many cases had no evidence of infection by any route (Cohen *et al.*, 2003b,c). The bacterial organisms (*Actinobacillus* spp. and non- $\beta$ -hemolytic *Streptococcus*) that were most commonly isolated from affected tissues are common commensal organisms in the equine oral cavity and alimentary tract and are considered opportunistic, not primary, pathogens (Donahue *et al.*, 2006). Moreover, even these commensal organisms were not consistently isolated from all affected tissues, making their role as potential primary pathogens unlikely.

The lack of identification of infectious causes for MRLS stimulated a search for a potential environmental toxin that might explain the abortions (Taylor, 2002; Sebastian *et al.*, 2007). Toxicants that had been associated with abortions in the past, such as nitrates/nitrites and ergot/fescue, were quickly ruled out as potential etiologies, as were phytoestrogens and mycotoxins (Sebastian *et al.*, 2007). The association between ETC and the development of MRLS led some to hypothesize that the cyanogens from black cherry trees (the ETC's preferred food) may be responsible, and very low levels of cyanide were detected in the heart tissue from some aborted fetuses. However, further tests, including studies exposing pregnant mares to cyanide, failed to support the role of cyanide in MRLS. Nor did exposing mares to mandelonitrile, the primary breakdown product of the major cyanogen of cherry trees, induce significant illness or abortion. Other investigations attempting to link MRLS to exposure to other toxicants, including ammonia, were also unsuccessful.

Pregnant mares exposed to live ETC on pasture at a concentration of 11.3–27.5 larvae/25cm<sup>2</sup> for 6 h per day aborted within several days of exposure (Webb *et al.*, 2004). Another experimental study gavaged

pregnant mares (<102 days of gestation) with homogenized ETC, resulting in abortion in four of five mares, whereas mares administered saline or ETC frass (feces) had no fetal losses. Once the relationship between ETC and MRLS was established, studies were undertaken to determine the mechanism by which ETC induces abortion. Fractionating ETC larvae and administering the various fractions to pregnant mares revealed that the abortifacient fraction is associated with the larval exoskeleton (McDowell *et al.*, 2010). Attempts to induce abortion by feeding gypsy moth (*Lymantria dispar*) larvae, which have similar exoskeletons with numerous setae (hairs), and closely related forest tent caterpillars (*Malacosoma disstria*) demonstrated that neither of these species were abortifacient in mares. This suggested that the presence of setae alone was not sufficient to induce abortion and that some unique component of the ETC exoskeleton appears to play a role in triggering abortions (Sebastian *et al.*, 2007). Sterilization of ETC via irradiation reduced but did not completely eliminate the ETC's abortifacient properties. ETC-induced abortion has been reproduced in pigs (a species with a similar epitheliochorial type of placentation), but goats, rats, and mice appear to be resistant to the abortifacient effects of ETC.

Based on natural and experimental disease, the current hypotheses regarding the potential pathophysiology of MRLS-induced disease are focused on the setae (hairs) of the ETC exoskeleton (Tobin *et al.*, 2004; McDowell *et al.*, 2010). The first hypothesis is that the setae cause disruption of the gastrointestinal mucosal barrier, resulting in subclinical bacteremia with hematogenous spread to the pericardium, uvea, meninges, placenta, or fetus (Tobin *et al.*, 2004; McDowell *et al.*, 2010). The presence of microgranulomas surrounding setal fragments within the gastrointestinal tract of mares and pigs fed intact or fragmented ETC supports this hypothesis. Another hypothesis is that the embolization of setal or other exoskeletal fragments may directly carry opportunistic bacteria to the target tissues. However, the inability to culture bacteria from a large percentage of affected tissues tends to argue against these hypotheses. A final hypothesis is that MRLS is caused by an unidentified toxin that is produced by or carried on the ETC and is toxic to the placenta and/or fetus (Sebastian *et al.*, 2007). A dose-response relationship between exposure to ETC and time of abortion has been described that would support a toxic mechanism (Sebastian *et al.*, 2003).

## TREATMENT AND PREVENTION

Because many of the early term abortions happened abruptly, without clinical signs in the mares, treatment was often not able to be instituted. Mares that had

aborted were often treated with broad-spectrum antibiotics, and subsequent uterine cytological evaluations were normal. No long-term effect on fertility was reported in mares that aborted due to MRLS. Live foals born to mares affected by MRLS were treated with supportive care, oxygen therapy, and antibiotics, but frequently these foals failed to survive (Sebastian *et al.*, 2007). Some horses that developed fibrinous pericarditis recovered following treatment with antibiotics selected based on culture and sensitivity. Standard treatments for unilateral uveitis included systemic and topical antibiotics, anti-inflammatory drugs, atropine, tissue plasminogen activator, mycotoxin binders, and cyclosporine. Response to treatment of unilateral uveitis was poor, and many affected horses lost functional use of the affected eye.

Preventative measures suggested to minimize the effect of ETC on subsequent equine breeding seasons included removal of cherry trees from pastures, spraying of pastures and ETC nests with pyrethrin-based pesticides, and muzzling of mares when on pasture (Potter *et al.*, 2005; Sebastian *et al.*, 2007). These measures resulted in a decline in the incidence of MRLS in subsequent breeding seasons.

## CONCLUSIONS

A syndrome of early and late-term abortions, fibrinous pericarditis, unilateral uveitis, and meningoencephalitis in horses exposed to eastern tent caterpillars was reported in 2001 and 2002 in central Kentucky. The causative factor has been tentatively isolated to the exoskeleton of the caterpillar, with the setae being the exoskeleton component of greatest suspicion. Current hypotheses on pathophysiology include an unidentified abortifacient toxin and subclinical bacteremia with subsequent seeding of tissues with opportunistic bacteria.

# Chemical-induced estrogenicity

Stephen H. Safe, Shaheen Khan, Fei Wu, Xiangrong Li and Sandeep Sreevalsan

## INTRODUCTION

17 $\beta$ -Estradiol (E2) and related steroidal hormones play an important role in multiple physiological processes. However, these hormones are risk factors for hormone-dependent diseases including breast and endometrial cancer. Inappropriate exposures (high or low) to estrogens can also lead to adverse health effects. The identification of estrogenic compounds in the environment, coupled with human exposures to these compounds, has generated public, regulatory, and scientific concern regarding their potential hormonal toxicity to humans and wildlife. This chapter focuses on chemical-induced estrogenicity and the potential toxicological impacts of these compounds.

## ESTROGENS PLAY A ROLE IN NORMAL PHYSIOLOGICAL FUNCTION AND DISEASE

### Background

Estrogens regulate the development and function of the female reproductive system, and their effects are mediated through estrogen receptor  $\alpha$  (ER $\alpha$ ) and ER $\beta$ . However, estrogens are by no means only female hormones. In both males and females, estrogens play crucial physiological roles, including sex differentiation, bone development and maintenance, and central nervous system and cardiovascular function. The ER is important for mammary gland development, and ER $\alpha$

knockout ( $\alpha$ ERKO) mice are viable but sterile and are estrogen-insensitive in several estrogen target organs, including mammary glands, reproductive tracts, and gonads. The well-recognized estrogenic responses, such as uterine weight increase and vaginal cornification, are all absent in  $\alpha$ ERKO mice (Lubahn *et al.*, 1993; Korach, 1994). In  $\alpha$ ERKO mice, mammary glands undergo normal development in the prenatal period, but they fail to develop terminal end buds and are severely undertropic during adulthood (Lubahn *et al.*, 1993; Korach, 1994). Surprisingly, adult male  $\alpha$ ERKO mice are also infertile because of impaired spermatogenesis (Eddy *et al.*, 1996). In contrast to the extensive reproductive tract abnormalities in  $\alpha$ ERKO mice, ER $\beta$  knockout mice are fertile but exhibit reduced fertility (Korach, 1994; Krege *et al.*, 1998).

### Estrogens and women's health

Women have significantly lower risk of cardiovascular disease than do men, and this has been putatively attributed to the beneficial effects of estrogen on cardiovascular function (Nathan and Chaudhuri, 1997). Estrogen decreases low-density lipoprotein levels and increases high-density lipoprotein levels. Estrogen exhibits vasodilatory effects and protects against vascular injury (Pare *et al.*, 2002), and it also induces COX-2-dependent up-regulation of atheroprotective prostacyclin PGI<sub>2</sub> (Egan *et al.*, 2004). In epidemiological studies, estrogen has been linked with improved cardiovascular functions (Grodstein *et al.*, 1996). Bilateral ovariectomy before menopause elevates the risk for coronary heart disease, and the increased risk is eliminated by estrogen replacement therapy (Colditz *et al.*, 1987). However, a large

clinical trial conducted by the Women's Health Initiative reported contradictory results on the effects of estrogens because women taking hormone replacement therapies (HRTs) have an increased risk for heart diseases and stroke (Rossouw *et al.*, 2002). The relationships between estrogen and cardiovascular diseases require further assessment.

Estrogen is also important for bone development and maintenance (Cutler, 1997) and for sexual differentiation in the brain and reproductive behavior (Bakker *et al.*, 2003). In addition, sustained estrogen treatment improves learning ability, memory, and fine motor skills in animal models (Lacresse and Herndon, 2003). However, results of the Women's Health Initiative show that the use of HRTs can lead to increased risks for heart disease and stroke. There is concern that these estrogens may induce some adverse neurological responses (Shumaker *et al.*, 2003; Espeland *et al.*, 2004). The most well-characterized adverse responses of endogenous and exogenous estrogens are associated with their effects on both breast and endometrial cancer in women (Hilakivi-Clarke, 2000; Bernstein, 2002). There is also concern that fetal or early postnatal exposure of males to estrogens will affect the male reproductive tract functions in adults (Skakkebaek *et al.*, 2001).

### Risks for breast cancer: genetic factors

There are several different risk factors for breast cancer, and there is a strong interplay of genetic and environmental factors. Five to ten percent of all breast cancers are associated with the inheritance of mutations in one of the two major breast cancer susceptibility genes, BRCA1 and BRCA2 (Venkitaraman, 2002). There is an 80% chance of developing breast cancer during a lifetime in women with an inherited BRCA1 or BRCA2 mutation. BRCA1 and BRCA2 are tumor suppressor genes, and their proteins have been implicated in a multitude of different processes, including DNA repair and recombination, cell cycle control, and transcription (Venkitaraman, 2002). Several other genetic mutations also contribute to the risk for breast cancer, including genes such as p53 that also enhance risk for multiple cancers.

### Hormonal risk factors for breast cancer

Several studies have shown that prolonged exposure to the hormone estrogen increases the risk of breast cancer. Epidemiological studies have established a strong link between higher risk of breast cancer and reproductive factors that increase the overall number of menstrual cycles, such as early menarche (before age 12 years), late

menopause (after age 55 years), age of women at first birth (older than 30–35 years), and nulliparity (Russo *et al.*, 1992). Breast cancer risk is lower in women with multiple pregnancies and women with a pregnancy prior to age 24 years (Lambe *et al.*, 1996). Women who are older than 30–35 years of age at first birth are at higher risk compared to nulliparous women (Albrektsen *et al.*, 1994; Rosner *et al.*, 1994). The protective effects of pregnancy against breast cancer are explained by the induction of complete differentiation of the breast that may markedly reduce the carcinogen susceptibility of the fully differentiated mammary gland due, at least in part, to the decreased proliferative activity of parous epithelium (Russo *et al.*, 2000). Studies have shown that the use of HRTs and oral contraceptives for long time periods can also increase the risk of developing breast cancer (Althuis *et al.*, 2003). In some studies, women exposed to diethylstilbestrol (DES) were also found to be at slightly increased risk for breast cancer (Titus-Ernstoff *et al.*, 2001).

### Lifestyle and dietary risk factors

Ionizing radiation is the most well-characterized environmental risk factor for breast cancer. Radiation-induced breast cancer risk depends on various factors, including age at exposure (highest before age 30 years), the status of hormone levels, parity, and other genetic disorders (Coyle, 2004). Other risk factors include solar radiation, light, and chemicals. Solar radiation creates an active form of vitamin D that may lower the risk of breast cancer, and studies show that women who work at night are at higher breast cancer risk. This may be due to decreased vitamin D synthesis and suppression of normal nocturnal production of melatonin by the pineal gland, which increases estrogen release by the ovaries, thereby disrupting circadian patterns (Davis *et al.*, 2001; Schernhammer *et al.*, 2001).

Lifestyle factors such as diet, exercise, smoking, and alcohol consumption are related to an increased risk of developing breast cancer (Key *et al.*, 2003). Confirmation of the risk of dietary fat intake and breast cancer has not been substantiated in large epidemiology studies (Velie *et al.*, 2000; Smith-Warner *et al.*, 2001); however, a dietary pattern of high fiber and low fat intakes is associated with a lower risk of breast cancer in postmenopausal women (Mattisson *et al.*, 2004; Saadatian-Elahi *et al.*, 2004). In some studies, protective effects of some vegetable fats, vitamin E, selenium, and other antioxidants have been observed (Gerber *et al.*, 2003; Gaudet *et al.*, 2004). Decreased ovarian hormone levels decrease the risk of breast cancer in populations in Asia, and this is related to their high consumption of soya products containing significant amounts of the isoflavones

daidzein and genistein, which act as weak estrogens (Mezzetti *et al.*, 1998; Lu *et al.*, 2000).

## ESTROGENS AS RISK FACTORS FOR MALE REPRODUCTIVE TRACT PROBLEMS

Although estrogens are female steroid hormones and influence normal physiology and disease in women, there has been increasing concern regarding the potential adverse effect of estrogenic compounds on the development of the male reproductive tract (Sharpe and Skakkebaek, 1993). Support for the hypothesis that "environmental estrogens" (xenoestrogens) and other endocrine disrupting compounds are responsible for an increase in male reproductive tract problems is derived from laboratory animal, wildlife, and human studies. For example, there are numerous reports of feminized fish in river systems, particularly in the United Kingdom, and this has been linked to their exposure to endogenous estrogens (17 $\beta$ -estradiol/estrone), synthetic contraceptives (17-ethinylestradiol), and industrial byproducts such as alkylphenols (Desbrow *et al.*, 1998; Routledge *et al.*, 1998). There is evidence that nonylphenol and alkylphenols may contribute to estrogenization of fish near sewage outflows.

It has also been suggested that the major concern regarding environmental/dietary estrogens is *in utero* or early postnatal exposure during the important initial periods of male reproductive tract development (Skakkebaek *et al.*, 2001). The potent estrogenic drug DES was extensively used by pregnant women with disastrous consequences for their male and female offspring (Giusti *et al.*, 1995). Females exposed *in utero* developed a high incidence of a rare vaginal adenocarcinoma, whereas male offspring developed a range of responses including deformed genitalia. The effects of DES form one of the bases of the endocrine disruption hypothesis and the opinion that a testicular dysgenesis syndrome that includes low sperm counts, increased hypospadias and cryptorchidism, and testicular cancer may be linked to *in utero* exposure to estrogenic compounds and other endocrine disrupting compounds (Skakkebaek *et al.*, 2001). This opinion and hypothesis have been challenged (Safe, 2000; Handelsman, 2001). However, it has become increasingly clear that humans are exposed to a wide range of xenoestrogens and phytoestrogens, which constitute the major subclass of endocrine disruptors of concern. The following section describes several different structural classes of synthetic estrogenic compounds, phytoestrogens, and estrogens/antiestrogens such as DES

and tamoxifen that have been used as pharmaceutical agents. In addition, the mechanism of estrogen action and implications for risk assessment of these compounds are also discussed.

## ESTROGENIC CHEMICALS OF CONCERN

The hypothesis that environmental/dietary estrogens may play a role in male reproductive tract problems and the increased incidence of breast cancer is controversial, and the significance of these compounds on human health is not resolved. Nevertheless, this resulted in legislation in the United States requiring the U.S. Environmental Protection Agency to develop testing procedures for examining industrial compounds for their activity as estrogens/antiestrogens, androgens/antiandrogens, and thyroid hormone mimics. Initial screening studies for estrogens used the MCF-7 cell proliferation assay (E-screen) (Sonnenschein and Soto, 1998), and this was complemented by development of receptor binding and transactivation studies in various cell lines. All of these assays have advantages and disadvantages and for the most part give complementary results on the estrogenic activity of individual compounds.

Steroidal and nonsteroidal estrogens and antiestrogens have been developed as pharmacologic agents, and Figure 75.1 illustrates the structures of 17 $\beta$ -estradiol, the endogenous hormone, DES, and three clinically used antiestrogens – tamoxifen, ICI 182780 (fulvestrant), and raloxifene (Jordan, 2003a,b). It is well known that phytoestrogenic compounds in the diet also constitute a major source of exposure to estrogens. These compounds are present in fruits, nuts, and vegetables and are particularly high in many soya products that are enriched in isoflavonoids (Havsteen, 2002). Figure 75.2 shows the structures of genistein, a major isoflavonoid in soy; equol, a genistein metabolite; and naringenin, a flavonoid that is found in grapefruit. Genistein and equol can be detected in human serum and urine along with the estrogenic lignans enterodiol and enterolactone, and these compounds are used as biomarkers of exposure to dietary phytoestrogenic compounds. Resveratrol is an estrogenic polyphenolic stilbene analog found in grapes and wine.

The list of synthetic estrogenic compounds continues to grow as testing of current and new synthetic industrial chemicals progresses and expands. A major class of xenoestrogens of concern are the alkyl phenols such as nonylphenol, which are widely used in industry as ethoxylates (Soto *et al.*, 1991). These compounds are surfactants and are used in detergents, paints, herbicide/

**FIGURE 75.1** Structures of 17β-estradiol, DES, and the clinically used SERMs tamoxifen, ICI compounds (R = C<sub>14</sub>H<sub>24</sub>F<sub>5</sub>OS, fulvestrant), and raloxifene.

**FIGURE 75.2** Structures of the phytoestrogenic flavonoids (genistein, equol, and daidzein), lignans (enterolactone and enterodiol), and resveratrol.

pesticide formulation, and plastics. Alkyl hydroxybenzoates (parabens) (Figure 75.3), which are used as preservative agents, and cosmetic ultraviolet filters such as 4-methylbenzylidene camphor, which are used in home care products, also exhibit estrogenic activity (Schlumpf *et al.*, 2004; Schreurs *et al.*, 2005). Bisphenol A (BPA) is perhaps one of the most controversial xenoestrogens because it is extensively used in plastic production and plastic lines in which trace levels of BPA have leached directly into food products. This estrogenic compound has also been identified in the environment. Other estrogens of concern include polychlorinated biphenyls (PCBs) and hydroxy-PCBs, which have been identified in the environment and in humans; the pesticide metabolite 1,1-bis(*p*-chlorophenyl)-2,2-dichloroethylene (DDE); and kepone. These compounds are persistent environmental contaminants, and kepone induced estrogenic poisoning in a group of exposed production workers. The

compounds illustrated in [Figure 75.4](#) exhibit relatively weak binding to the ER and induce reporter gene expression in transactivation assays in cell culture systems, and some of these compounds exhibit uterotrophic effects in female rodents. The important toxicological question concerning these chemical estrogens is whether they differ only in potency, which is governed by their intrinsic estrogenicity and bioavailability based on their metabolism and pharmacokinetics. On the other hand, because the estrogenic activity of these compounds is receptor dependent (ER), is the estrogenic activity of structurally diverse xenoestrogens more unique and not necessarily governed by intrinsic ER binding affinities and pharmacodynamic factors?

### Case study: bisphenol A

BPA has been the most widely investigated environmental estrogen, and there has been considerable regulatory, scientific, and public concern regarding the use, exposure, and potential adverse effects of this compound. BPA has been a widely used industrial compound with a major application in the production of resins and polycarbonate-based plastic ([Dekant and Volkel, 2008](#)). BPA was initially identified as an estrogenic material leaching out from plastic material, and subsequent studies have identified BPA in foods, environmental samples, and humans ([Dekant and Volkel, 2008](#)). For example, BPA was identified in laboratory plastic products that resulted in some leaching of BPA ([Krishnan \*et al.\*, 1993](#)), and a major source of human exposure to BPA is due to plastic containers of liners that are in contact with food products. The use of BPA in dental sealants also results in human exposure ([Olea \*et al.\*, 1996](#)), and based on extensive sampling, urinary levels of BPA/conjugates are 1–3  $\mu\text{g}/\text{L}$  with an estimated daily uptake of less than 6  $\mu\text{g}$  (<0.1  $\mu\text{g}/\text{kg}/\text{day}$ ) ([Calafat \*et al.\*, 2008](#); [Dekant and Volkel, 2008](#)).

The initial concerns regarding BPA were linked to its estrogenic activity and the potential adverse effects associated with *in utero* exposure because *in utero* exposure to the potent estrogenic drug DES can lead to serious reproductive tract problems in offspring ([Giusti \*et al.\*, 1995](#)). In contrast to DES, BPA is a relatively weak estrogenic compound in terms of activating nuclear ER $\alpha$ , and concentrations in the micromolar range are required for activity ([Gould \*et al.\*, 1998](#); [Yoon \*et al.\*, 2000, 2001](#)). The effects of BPA in the female rat uterus were also consistent with low estrogenic activity, and it was also reported that BPA acted as a partial antiestrogen ([Gould \*et al.\*, 1998](#)). In contrast to the “weak” estrogenic activity observed for BPA in these studies, several reports show that BPA concentrations in the picomolar range activate nongenomic estrogen-dependent signaling pathways in multiple cell types and the potency of BPA is similar to that observed for E2 ([Quesada \*et al.\*, 2002](#); [Wozniak \*et al.\*, 2005](#); [Wetherill \*et al.\*, 2007](#); [Watson \*et al.\*, 2010](#); [Jeng and Watson, 2011](#)).

A search for the word “BPA” on PubMed gives more than 6000 citations, and many of these deal with a myriad of *in vitro* and *in vivo* studies, indicating diverse tissue-/species- and dose regimen-dependent responses that include modulation of pharmacologic/biochemical responses and a wide spectrum of activities ([Figure 75.5](#)). It is also possible that these responses are both estrogen dependent and independent. A major concern regarding BPA is associated with the effects of *in utero* exposure to low levels of BPA on the development of the male and female reproductive tract ([Vom Saal \*et al.\*, 2007](#); [Chapin \*et al.\*, 2008](#); [Allard and Colaiácovo, 2011](#)). Ryan and co-workers (2010a) compared the effects of *in utero* and lactational exposure of BPA and the potent estrogen ethinylestradiol (EE2) on sexually dimorphic behavior, puberty, fertility, and anatomy of female LE rats. EE2 is an oral contraceptive that has been identified in the environment and may contribute to estrogenization

**FIGURE 75.5** BPA exhibits tissue-specific agonist or antagonist activities for multiple receptors and also induces expression of some receptors.

of male fish in contaminated rivers (Jobling *et al.*, 1998, 2006). *In utero* administration of EE2 (0.05–50 µg/kg/day) induced a wide range of dose-dependent reproductive tract disorders and neurobehavioral deficits in the female rats, with only relatively minor effects in males. In contrast, *in utero* exposure to BPA (2, 20, and 200 µg/kg/day) had minimal to nondetectable effects on female and male offspring (Ryan *et al.*, 2010a), and these results were consistent with those of previous reports (Cagen *et al.*, 1999; Ema *et al.*, 2001; Tinwell *et al.*, 2002; Tyl *et al.*, 2002). Based on the results reported by Ryan and co-workers, it was suggested that future BPA research funding “looks increasingly like an investment with a nil return” (Sharpe, 2010).

Another concern regarding the potential adverse effects of BPA and environmental estrogens is their potential role in the obesity epidemic, particularly in North America, and the increase in multiple diseases associated with obesity (e.g., diabetes) (Newbold *et al.*, 2005, 2007, 2009). The concern about this response is derived, in part, by reports showing that *in utero* exposure to DES results in obesity in adult mice (Newbold *et al.*, 2005, 2007) and by studies showing that early life exposure of rodents to BPA increases body weights in adult offspring (Rubin *et al.*, 2001; Akingbemi *et al.*, 2004; Miyawaki *et al.*, 2007). A review of the data by one panel of scientists suggested that a role for BPA in obesity is unclear (Chapin *et al.*, 2008), whereas another panel of experts expressed a higher level of concern regarding the contribution of BPA to a large number of diseases

(Vom Saal *et al.*, 2007). A study investigated the effects of relevant doses of BPA (0.25 µg/kg/day) and DES (1 µg/kg/day), and the results showed a faster rate of early growth in the BPA-exposed mice compared to controls. However, the authors reported that these differences were no longer apparent when the mice reached adulthood, even when they were tested on a high-fat diet (Ryan *et al.*, 2010b). A commentary on this study concluded that it is unlikely that BPA exposure in early life in humans is a factor in predisposing to metabolic syndrome disorders in adulthood (Sharpe and Drake, 2010). Nevertheless, the controversy regarding the effects of BPA on various laboratory animal models remains a contentious issue among scientists.

Human studies correlating background BPA levels with disease have been limited. Braun and co-workers (2009) estimated *in utero* exposures from maternal urine samples collected at two times (16 and 26 weeks) during gestation, and there was an association between 16-week BPA concentrations and externalizing scores among the 2-year-old offspring. Refinements to this approach and more prolonged observation of the offspring should provide important answers in the future. Two related studies used urinary BPA levels in participants in the National Health and Nutrition and Examination Study (NHANES) to investigate correlations between BPA and diseases (Lang *et al.*, 2008; Braun *et al.*, 2009). Cardiovascular disease, diabetes, and enhanced liver enzymes were associated with increased urinary BPA levels, although the diabetes correlation was variable

at the two sampling time points (2003–2004 and 2005–2006). This type of approach coupled with case–control and prospective studies will also be useful in assessing possible linkages between BPA and human diseases.

## MECHANISMS OF ESTROGEN-INDUCED TRANSACTIVATION

### ER $\alpha$ and ER $\beta$ domain structure

The ER is a member of the nuclear receptor superfamily of transcription factors that exhibit modular structures and similar mechanisms of action. For example, the transactivation function of ER is mediated by two separate but not mutually exclusive transactivation domains, namely ligand-independent activation function (AF)-1 (within the A/B domain) and ligand-dependent AF-2 (within the ligand binding domain (LBD)) (Tora *et al.*, 1989) (Figure 75.6). The A/B domain is the least conserved region between ER $\alpha$  and ER $\beta$ , with only 30% similarity at the amino acid level. The activity of AF-1 in ER $\beta$  is negligible on estrogen-responsive element (ERE) reporter constructs compared to that of the AF-1 of ER $\alpha$  in several different cell lines (Cowley and Parker, 1999).

ER $\alpha$  and ER $\beta$  also exhibit distinctive responses to the synthetic antiestrogens such as tamoxifen and raloxifene, which act as partial ER agonists for ER $\alpha$  and as pure ER antagonists for ER $\beta$  (Barkhem *et al.*, 1998). The functional differences between the respective A/B regions of ER $\alpha$  and ER $\beta$  may explain their differences in ligand-dependent activation (Matthews and Gustafsson, 2003). The AF-1 region of ER $\alpha$  interacts with different transcriptional regulators and co-activators that affect ligand-independent transactivation. The activity of AF-1 is also regulated through kinase-dependent phosphorylation, and the individual pathways involved vary with cell and promoter context (Tzukerman *et al.*, 1994). In most cell lines, both AFs act synergistically to attain maximum transcriptional activity, whereas in other cells only one AF may be activated (Benecke *et al.*, 2000).

The DNA binding domain (DBD; region C) is highly conserved between ER $\alpha$  and ER $\beta$  and exhibits 96% identity. This domain contains two zinc fingers (CI and CII), as observed for other nuclear receptors. The DBDs of both ER $\alpha$  and ER $\beta$  bind with high affinity to EREs. The C-terminal E/F region encompasses the LBD, a co-regulator binding surface, a dimerization domain, another nuclear localization signal, and AF-2 (Nilsson *et al.*, 2001). Significant homology between the two receptors exists in the E/F region, and both proteins display essentially the same binding affinity for E2 and many other estrogenic compounds (Kuiper *et al.*, 1997). However, the

**FIGURE 75.6** Structural domains of human ER $\alpha$  and ER $\beta$ . The percentage identity between the individual domains at the amino acid level is indicated. (Modified from Pearce and Jordan (2004) and Koehler *et al.* (2005).)

two receptors differ in their binding affinities for only a few ligands, including antiestrogens and phytoestrogens. For example, the phytoestrogen genistein binds with approximately a 30-fold higher affinity for ER $\beta$  than for ER $\alpha$  (Barkhem *et al.*, 1998).

## XENOESTROGENS AND PHYTOESTROGENS AS SELECTIVE ER MODULATORS

### Complexity of estrogenic activity

Results of X-ray crystallographic analysis clearly demonstrate that both ER agonists differentially bind the ER and induce compound-specific changes in the bound complex. Although tamoxifen and E2 induce distinct conformations of the ER and exhibit antiestrogenic and estrogenic activity in breast cancer, these compounds both induce ER-dependent activity in the uterus, and prolonged treatment with tamoxifen increases the risk for endometrial cancer (Bernstein, 2002). Tamoxifen is also an ER agonist in the bone and vascular system, and there are tissue- and species-specific ER agonist or antagonist activities in animal models: tamoxifen is an ER antagonist in chicks, a partial ER agonist/antagonist in rats, and an ER agonist in several short-term assays in mice (MacGregor and Jordan, 1998). Studies on tamoxifen and other ER agonists have led to the

**TABLE 75.1** The SERMs tamoxifen, raloxifene, ICI 164384, and E2 differentially activate ER $\alpha$  and also exhibit unique *in vivo* biologies

SERM	ER $\alpha$				ER $\alpha$ -AF-1				ER $\alpha$ -AF-2			In vivo ER activity

<sup>b</sup>Ag and Ant indicate ER agonist and antagonist, respectively; – indicates no agonist activity.

development of the acronym selective ER modulators (SERMs), which exhibit a complex pharmacology and induce tissue-specific ER agonist or antagonist activities. These structure-dependent differences are related to differential activation of estrogen-responsive genes/pathways and due to several factors (Katzenellenbogen *et al.*, 1996; Smith and O'Malley, 2004), including

- the structure of the estrogenic compound;
- tissue-specific expression of ER subtype (ER $\alpha$  and ER $\beta$ ) or variant;
- tissue-specific expression of critical co-activators and other co-regulatory proteins; and
- promoter context and chromatin state, which is dependent on histone methylation or acetylation, promoter methylation, and expression of critical modulating *trans*-acting factors.

## Development of bioassays for clinically relevant SERMs

SERMs were primarily developed for treatment of hormone-dependent diseases or conditions, and they define the increasing complexity of ER action. If xenoestrogens and phytoestrogens are SERMs, then their estrogenic and antiestrogenic activities will also be tissue specific and their role in causation or protection from hormone-dependent problems will depend on the structure of the individual compound, the amount of exposure (assuming a threshold), and the time of exposure where critical modifications of hormone-responsiveness are induced. The structurally diverse SERMs – E2, tamoxifen, raloxifene, and ICI 164,384 – have unique *in vivo* biologies and were used as model compounds to develop an *in vitro* bioassay that distinguishes between these compounds (Tzukerman *et al.*, 1994; McDonnell *et al.*, 1995). This bioassay utilizes the modular structure of ER $\alpha$  and ER $\beta$  in which the various domains (E–F) exhibit both separable and overlapping functions that

govern their interactions with other co-regulatory proteins and promoter DNA. AF-1 and AF-2 are located in the A/B and E domains, respectively, and are particularly important for this assay system. Table 75.1 shows that these four compounds differentially induce transactivation in human hepatoma HepG2 cells transfected with the E2-responsive pC3 construct (human complement C3 promoter linked to the luciferase gene) and expression plasmids for wild-type ER $\alpha$ , ER $\alpha$ -AF-2 in which the AF-1 domain has been deleted, or ER $\alpha$ -AF-1 in which the critical amino acids in AF-2 have been mutated (amino acids D538N, E542Q, and D545N). E2 induces transactivation in HepG2 cells transfected with wild-type/variant ER $\alpha$ ; in contrast, raloxifene activates ER $\alpha$ -AF-1, tamoxifen activates ER $\alpha$  and ER $\alpha$ -AF-1, and ICI 164,384 does not induce or inhibit transactivation.

## Xenoestrogens and phytoestrogens as SERMs

This assay has been used for distinguishing between different structural classes of xenoestrogens and phytoestrogens, including BPA (2',4',6'-trichloro-4-biphenylol (Cl<sub>3</sub>-PCB-OH), 2',3',4',5'-tetrachloro-4-biphenylol (Cl<sub>4</sub>-PCB-OH), *p*-*t*-octylphenol (OP), *o*-nonylphenol (NP), naringenin, kepone, resveratrol, and 2,2-bis(*p*-hydroxyphenyl)-1,1,1-trichloroethane (HPTE). E2, ICI 182,780, and 4-hydroxytamoxifen were used as positive controls (Gould *et al.*, 1998; Yoon *et al.*, 2000, 2001). Results obtained in several cell lines using the E2-responsive complement pC3-luc construct or a construct (pERE<sub>3</sub>) containing three EREs linked to luciferase demonstrate that xenoestrogens/phytoestrogens also differentially induce transactivation.

Table 75.2 compares the maximal induced responses observed for these compounds using human hepatoma HepG2 and human U2 osteogenic cancer cell lines transfected with pERE<sub>3</sub> and ER $\alpha$ , ER $\alpha$ -AF-1, or ER $\alpha$ -AF-2 (Yoon *et al.*, 2001). Even among structurally related compounds such as the hydroxy-PCBs, alkylphenols,

TABLE 75.2 Different structural classes of xenoestrogens, phytoestrogens, E2, and 4-hydroxytamoxifen differentially induce transactivation in HepG2 and U2 cells transfected with pERE<sub>3</sub>, wild-type, and variant forms of ER $\alpha$ 

	ER $\alpha$				ER $\alpha$ -IAF-1				ER $\alpha$ -AF-2		
	A/B	C/D	E	F	A/B	C/D	E***	F	C/D	E	F

BPA	++		++		+		++		++		+++
Kepone	ND		ND		+		ND		+		ND
Naringenin	ND		ND		ND		ND		ND		ND
Resveratrol	ND		ND		ND		ND		ND		ND

From Yoon *et al.* (2001).

<sup>a</sup>E2 induced a maximal response (+++) in all assays. A significant induction response of >40% (+++) or <40% (+) of that observed for E2 and no significant induction (ND) are indicated. ICI 182,780 gave an ND for all responses. The doses used were 10 nM and 1  $\mu$ M for E2 and 4'-hydroxytamoxifen, respectively, 100  $\mu$ M for BPA, and 10  $\mu$ M for the remaining compounds.

and bisphenolics HPTE and BPA, there were some significant differences in their induction of transactivation. Moreover, using a similar approach in HepG2, U2, and MDA-MB-231 cancer cell lines transfected with a pC3-luc construct, similar differences were observed (Yoon *et al.*, 2000). For example, the two bisphenolic compounds HPTE and BPA exhibit a similar pattern of transactivation in many assays, except that in U2 cells BPA but not HPTE induces transactivation in cells transfected with ER $\alpha$ -AF-1. It is also apparent from other *in vivo* and *in vitro* studies that BPA and HPTE exhibit differences in their estrogenic activities. For example, HPTE was a more potent estrogen than BPA in the female rat uterus; however, in combination with E2, lower doses of BPA inhibited E2-induced uterine progesterone receptor binding and peroxidase activity (Gould *et al.*, 1998). HPTE versus BPA also exhibited other differences in HepG2 cells in which both HPTE and BPA are ER $\alpha$  agonists, whereas HPTE is an ER $\beta$  and androgen receptor (AR) antagonist and BPA is an ER $\beta$  agonist and did not affect AR in this cell line (Gaido *et al.*, 1999). These activities can also vary in other cell contexts but clearly demonstrate significant *in vitro* and *in vivo* biological differences between HPTE and BPA, suggesting that structurally diverse estrogenic compounds are SERMs.

Several other *in vitro* studies have demonstrated significant differences among different structural classes of estrogenic compounds and the planar phytoestrogens coumestrol and genistein. For example, an ER $\alpha$  mutant (D351G) is activated by E2 and DES but not by 4'-hydroxytamoxifen or the nonplanar HPTE and related compound (Jordan *et al.*, 2001). It was also reported that the isoflavones daidzein, biochanin, and genistein are

ER $\beta$ -selective, and this is due to their preferential induction of co-activator interactions with AF-2 of ER $\beta$  compared to AF-2 of ER $\alpha$  (An *et al.*, 2001). Other reports also show that activation of gene expression in *in vitro* assays by structurally diverse xenoestrogens/phytoestrogens depends on the promoter context (i.e., different consensus vs. nonconsensus EREs) and on co-activator interactions (Hall *et al.*, 2002; Mueller *et al.*, 2004). Studies have also demonstrated structure-dependent activation of nongenomic kinase pathways by xenoestrogens/phytoestrogens (Li *et al.*, 2006). Moreover, it has also been shown that some estrogenic compounds activate kinases via ER-independent pathways by directly binding to a G protein-coupled receptor (GPR30) (Revankar *et al.*, 2005; Thomas *et al.*, 2005). The structure dependence on this ER-dependent pathway has yet to be determined. These results clearly indicate that xenoestrogens/phytoestrogens are SERMs.

## XENOESTROGENS AND PHYTOESTROGENS AS SERMS AND IMPLICATIONS FOR RISK ASSESSMENT

Xenoestrogens and phytoestrogens differentially activate wild-type and variant ER $\alpha$  *in vitro*, suggesting that these compounds are SERMs. This implies that their estrogenic activity and potency cannot be determined by simple ER binding or gene expression assays. Thus, to fully understand the estrogenic or antiestrogenic activities of phytoestrogens and xenoestrogens, studies

will have to focus on their tissue-specific impacts at various critical periods of exposure. Risk assessment of these compounds will be complex and dependent on all the variables indicated previously. Moreover, because individual SERMs exhibit unique biologies, the overall impact of mixtures of these compounds may not be additive. Another complication associated with the mechanisms of action and risk assessment of many xenoestrogens is due to their multiple tissue/species activities, and this is illustrated by BPA and its interaction with receptors. As indicated previously, BPA activates ER $\alpha$  and ER $\beta$  (Kuiper *et al.*, 1997) and also binds and activates GPR30 (Thomas and Dong, 2006; Dong *et al.*, 2011). BPA also induces CaBP-9k, a progesterin-responsive gene in the mouse uterus (Jung *et al.*, 2005), and induces neuronal PR mRNA levels in rats (Funabashi *et al.*, 2004). BPA also acts as an AR agonist and antagonist in different assays (Lee *et al.*, 2003) and exhibits thyroid hormone receptor antagonist activity (Moriyama *et al.*, 2002; Zoeller *et al.*, 2005). BPA also binds and/or activates estrogen-related receptor  $\gamma$  (EER $\gamma$ ) (Matsushima *et al.*, 2007; Abad *et al.*, 2008) and the steroid and xenobiotic receptor (SXR) and induces NR4A1 (Nur77) in mouse testicular Leydig cells (Song *et al.*, 2002). Moreover, it has been reported that BPA induces the aryl hydrocarbon receptor (AhR), AR, retinoid receptors, and peroxisome proliferator-activated receptor  $\gamma$  (PPAR $\gamma$ ), and this can also result in modulation of receptor-mediated responses (Nishizawa *et al.*, 2005a,b; Kruger *et al.*, 2008; Kwintkiewicz *et al.*, 2010). These factors highlight the challenges faced by scientists and regulators in addressing the health risks and benefits of estrogenic compounds.

## ACKNOWLEDGMENTS

Financial support for the preparation of this chapter was provided by the National Institutes of Health (R01-ES004917 and P30-ES09106) and the Texas Agricultural Experiment Station.

# Phytoestrogens

Michelle Mostrom and Tim J. Evans

## INTRODUCTION

Phytoestrogens are nonsteroidal, natural plant compounds that are structurally or functionally similar to mammalian estrogens, particularly 17 $\beta$ -estradiol (Figure 76.1). Typically, phytoestrogens or their active metabolites exert their estrogenic effect on the central nervous system and on the reproductive system of males and females, inducing estrus and stimulating growth of the genital tract and mammary glands in females. The classic test for estrogenicity of compounds is proliferation of the female reproductive tract. Phytoestrogens may bind to estrogen receptors, mimicking the conformational structure of estradiol (Kuiper *et al.*, 1997, 1998), and act as agonists, partial agonists, or antagonists inducing estrogen-responsive gene products and may exert metabolic effects not related to estrogen receptors. Phytoestrogens are considered endocrine disruptors because these chemicals may interfere with the body's endocrine system and produce adverse developmental, reproductive, and neurological effects in both humans and animals. A large volume of literature has been published on phytoestrogens with regard to their beneficial effects in humans related to reducing atherosclerosis, osteoporosis, angiogenesis, diabetes, and vasomotor effects (hot flushes) at menopause and acting as antioxidants, antineoplastics, anti-inflammatories, and probiotics. Fewer publications discuss adverse effects of phytoestrogens causing infertility in livestock and possible impaired reproductive processes in humans. This chapter focuses on the most extensively studied phytoestrogens found in legumes and beans, such as the isoflavones and coumestans, which may affect reproduction.

## Description

Phytoestrogens are polyphenolic compounds that can be divided into several broad categories (Table 76.1). Many phytoestrogens are grouped into flavonoids and isoflavonoids, including the isoflavone compounds found in soybeans (*Glycine max* L.), red clover (*Trifolium pretense* L.), and white clover (*Trifolium repens* L.). These compounds include daidzein, genistein, formononetin, biochanin A, and glycitein. The normal isoflavone concentration in red clover is between 0.5 and 2.5% of dry matter, which can be 2–10 times greater than the isoflavone concentration found in soybeans. Hops and beer may contain a very potent phytoestrogen, the flavanone 8-prenylnaringenin.  $\beta$ -Sitosterol is one of several plant sterols widely distributed in the plant kingdom, with a chemical structure similar to that of cholesterol. It is

TABLE 76.1 Categories of phytoestrogens and selected compounds

Category	Phytoestrogen examples	Dietary sources	Basic chemical structure
Isoflavones	Daidzein Genistein Fomononetin Biochanin A Glycitein	Clovers (red and white) Soybeans Beans Split peas	 ISOFLAVONE
Flavanones	Naringenin	Hops (8-prenylnaringenin) Apples, red onions	 FLAVANONE
Flavonoids	Apigenin Luteolin	Parsley Capsicum pepper Alfalfa	 FLAVONE
	Quercetin Kaempferol	Tomatoes Broccoli Apples Onions	 FLAVONOL
Plant sterols	B-sitosterol	Corn Soybeans Sugar beet forage Saw palmetto ( <i>Serenoa repens</i> ) Avocados Pistachios and almonds Wood	 BETA-SITOSTEROL
Coumestans	Coumestrol	Legumes (alfalfa, clover) Spinach Split peas, lima beans Soybean sprouts	 COUMESTROL
Stilbenes	<i>Trans</i> -resveratrol ( <i>trans</i> -3,5,4'-trihydroxystilbene)	Grape skin (red wine) Peanuts	 Resveratrol
Lignans	Secoisolariciresinol, matairesinol	Flaxseed (linseed) Squash, pumpkin seeds Tea (black and green) Sunflower seeds Strawberries Cranberries Brans	 Secoisolariciresinol

Adapted from Patisaul and Jefferson (2010).

found in corn, soybeans, sugar beets, avocados, pistachios, pecans, almonds, and saw palmetto. Coumestrol is a potent estrogenic phytoestrogen in the coumestan group. Coumestrol may be found in alfalfa (*Medicago sativa* L.), white clover, spinach, and soybean sprouts. The stilbenes, such as *trans*-resveratrol, are found in red wine (grape skin) and peanuts. Lignans are compounds found in plant cell walls and fiber-rich foods, seeds (flax and sesame seeds), berries, cereals, nuts, and fruits. Typically, a mixture of phytoestrogens can be found in plants and processed food. An excellent database for foods and flavanoid contents can be found online at the U.S. Department of Agriculture ([www.ars.usda.gov](http://www.ars.usda.gov)). In addition to phytoestrogen exposure through plant products, the environmental distribution of phytoestrogens in streams in the United States has been evaluated (Kolpin *et al.*, 2010). Phytoestrogens (particularly formononetin) were commonly detected in several rivers and streams throughout Iowa, but the concentrations were generally less than 50 ng/L and not considered to contribute to an estrogenic effect, although the impact of long-term, low-level exposures of contaminants in streams is unknown.

This chapter does not include the estrogenic *Fusarium* spp. mycotoxins, zearalenone, zearalanols, and zeaxenols, which are resorcylic acid lactones produced as secondary fungal metabolites in plants and grasses. Additional information on phytoestrogens can be found elsewhere with regard to mechanistic effects (Rosselli *et al.*, 2000; Bhavnani *et al.*, 2008), physiology (Kurzer and Xu, 1997; Tham *et al.*, 1998; Benassayag *et al.*, 2002; Patisaul and Jefferson, 2010; Pilšáková *et al.*, 2010), and reproductive functions (Whitten and Patisaul, 2001; Dusza *et al.*, 2006; Cederroth *et al.*, 2009; Baber, 2010).

## HISTORICAL BACKGROUND

More than 50 years ago in Australia, a syndrome of temporary or permanent infertility occurred in female sheep grazing subterranean clover (*Trifolium subterraneum* L.) containing high concentrations of isoflavone phytoestrogens, particularly formononetin (Adams, 1995). Temporary infertility was related to direct effects of phytoestrogen on the ovarian follicle decreasing ovulation and increasing embryo mortality and was associated with abnormalities of ovum transport and uterine function. Prolonged exposure to growing, green subterranean clover caused permanent infertility in ewes that was associated with morphological changes in the cervix, including thick, fused cervical folds and the appearance of cystic tubular glands. Changes in the uterus included development of cystic uterine glands and

mild endometritis. The cervical mucus became watery and lost viscoelasticity, allowing loss of spermatozoa from the cervix and reducing the chances for conception. External genitalia of some ewes underwent masculinization, with fusion of the vulvar lips at the lower commissure and hypertrophy of the clitoris. The permanent changes in cervical structure were analogous to the organizational effects of estrogen reported in mice treated with estrogen neonatally and in women exposed to diethylstilbestrol during fetal development. Unlike sheep, cattle apparently are not permanently affected by phytoestrogens. However, elevated concentrations of phytoestrogens can negatively impact cattle reproduction and induce estrogenic clinical signs. For example, concentrations of coumestrol greater than 25–30 ppm in a ration (on a dry weight basis), or even lower coumestrol concentrations when feedstuffs are fed at high proportions of a ration to dairy cows, can cause ovarian dysfunction, early embryonic death, and repeat breeding in cattle. The potential health benefits and adverse effects of phytoestrogens in humans and animals related to reproduction are described in this chapter.

## PHARMACOKINETICS/ TOXICOKINETICS

### Plant impact

The concentration of phytoestrogens in plant material varies widely. In addition to participating in plant defense, these compounds play a role in attraction of pollinators and seed-dispersing organisms. Phytoestrogens are not translocated within the vascular pathways of a plant but are synthesized and degraded in localized areas that vary with the specific tissue. For example, coumestrol concentrations are found in higher concentrations near the top segment of the alfalfa plant canopy compared to the lower part of the plant (Seguin *et al.*, 2004).

A number of factors affect production of phytoestrogens. Plant fungal infections, animal predation, or insect invasions may increase phytoestrogen production. Growing conditions, particularly temperature and rainfall, can dramatically affect phytoestrogen concentrations in legumes. In cool, wet spring and fall conditions, legumes may contain high concentrations of phytoestrogens (isoflavones and coumestrol). Generally, the concentrations of phytoestrogens decrease with successive cuttings of legumes in a season, with coumestrol at higher concentrations in early and late maturity of the alfalfa crop. Seguin and Zheng (2006) reported that coumestrol concentrations in alfalfa were lower in harvests

**TABLE 76.2** Typical phytoestrogen concentrations in plants used for livestock forage and soy food

Plant	Phytoestrogen	Concentration (mg/kg or ppm dry weight)
Alfalfa	Coumestrol	25–65 <sup>a</sup>
Red clover	Formononetin and biochanin A	3,000–15,000 <sup>b</sup>
	Genistein	300–1,500
	Daidzein	<300
White clover	Isoflavonoids	100–600
	Coumestrol	<10
Soy foods	Daidzein and genistein	~1,000–3,500

From Saloniemi *et al.* (1995) and Franke *et al.* (1995).

<sup>a</sup>Concentrations from 18 to >180 mg/kg coumestrol have been associated with infertility in cattle (Mostrom, 2010).

<sup>b</sup>Concentrations >500 to 750 mg/kg have been associated with infertility in cattle (Mostrom, 2010).

of first-year seeding than in harvests of the postseeding years. The variety of alfalfa cultivar had little impact on coumestrol concentrations. Coumestrol may also be found in alfalfa cubes, extracts, and powders, which can be incorporated into nutraceuticals or livestock and pet feeds.

Fresh herbage tends to have higher concentrations of phytoestrogens than silage or hay (Sivesind and Seguin, 2005). Sivesind and Seguin reported that the red clover cultivar “Start” was consistently lower in detectable isoflavones during multiyear and multisite trials. Lundh (1995) estimated the daily consumption of phytoestrogens by dairy cows on red clover forage to be 50–100 g. Table 76.2 lists typical concentrations of phytoestrogens in legume feeds and soy foods.

In soy foods, boiling, milling, or processing of the commodity does not appear to destroy daidzein or genistein, but roasting soybeans can reduce these isoflavones by 15% (Franke *et al.*, 1995). Three estrogenic isoflavones – daidzein, genistein, and glycitein – were found in soy foods in four chemical forms: aglycone, glucoside, acetylglucoside, and malonylglucoside. Fermentation and processing of soy foods increased the aglycone and glucoside forms of the isoflavone, respectively. Soy processing appears to influence isoflavone bioavailability; the unconjugated isoflavones in fermented soy food may be more bioavailable than glucosides. The total isoflavone content of raw soy beans ranges widely from 18 to greater than 500 mg/100 g.

## Animal biotransformation

Similar to any drug or toxin, the dose or intake of phytoestrogens is not equivalent to the dose at the active site or receptor in tissue. Dietary phytoestrogens undergo

the processes of absorption in the gastrointestinal tract, biotransformation, distribution, and excretion in urine, bile, feces, and milk. Effects of phytoestrogens may vary with the individual phytoestrogen; species exposed; sex; the route, dose, and duration of exposure; and the timing of exposure during reproductive development and cycling. Most phytoestrogens occur in plants as biologically inactive glycoside conjugates with glucose or carbohydrate moieties. Plant glycosides can be hydrolyzed by plant enzymes, or after consumption the glycosides are hydrolyzed and further demethylated in the acidic gut or rumen by microbes and the heterocyclic phenols (aglycones) are free in the gastrointestinal tract. Gut flora may become adapted over a matter of days to the diet and expand their populations for enhanced metabolism. Microbial metabolism of isoflavones can vary greatly between individuals. Isoflavone absorption and bioavailability in humans can vary with intestinal microbial population, gut transit time, fecal digestion rates, and fiber content in the diet (Neilsen and Williamson, 2007).

## Absorption

In ruminants, a majority of the metabolic transformations of phytoestrogens occur in the rumen by microbial action. Complete metabolic pathways have not been defined (Lundh, 1995). Basically, in ruminants, biochanin A is demethylated to genistein and via ring cleavage to *para*-ethyl phenol and organic acids (Figure 76.2). *Para*-ethyl phenol is considered a non-estrogenic compound. Formononetin is primarily demethylated to daidzein and further metabolized via hydrogenation and ring fission to equol (Figure 76.3). Equol contains a chiral center and occurs as two distinct diastereoisomers with R-(+)-equol and S-(–)-equol; intestinal bacteria synthesize exclusively the S-(–)-equol enantiomer that has selective affinity for the estrogen receptor- $\beta$  (Setchell and Clerici, 2010a,b). Formononetin can also undergo reduction to *O*-methyl equol or can be metabolized to *O*-desmethylangolensin. In ruminants, daily consumption of phytoestrogens in the diet can lead to adaption and a larger population of rumen microbes capable of phytoestrogen metabolism. Therefore, estrogenic activity of biochanin A and genistein in ruminants is generally limited to a few initial days of exposure when the unadapted rumen microbes have slower metabolism to non-estrogenic metabolites *para*-ethylphenol and phenolic acid. With the ingestion of formononetin and daidzein, metabolism may lead to compounds with less or greater estrogenic activity (i.e., equol).

Enterodiol and enterolactone are the active, estrogenic mammalian lignans formed by microbes in the intestinal tract from plant lignans matairesinol and secoisolariciresinol and their glycosides (Wang, 2002) (Figure 76.4).

**FIGURE 76.2** Schematic of rumen metabolism of biochanin A to genistein (Cox and Davies, 1988).

Only the unconjugated forms (aglycones) and active metabolites appear to exert estrogen-like activity in animals. Most hydrolyzed phytoestrogens are conjugated by glucuronic acid (a minor fraction is conjugated with sulfate) in the gut epithelium, which is a major mechanism for detoxification of phytoestrogens. A small portion of the free, hydrolyzed compounds are absorbed through the gut or rumen mucosa and reach the blood circulation unconjugated. Absorption of phytoestrogens is fairly rapid. In cattle, formononetin and daidzein (free and conjugated) reached a maximum level in plasma within 1 h after feeding (Lundh, 1995). The unconjugated phytoestrogens reaching the circulation are conjugated by liver (hepatic UDP-glucuronosyltransferases and sulfotransferases) and other tissues, including kidney. Glucuronide conjugated compounds and free phytoestrogens circulate throughout the body. Mammalian lignans and isoflavones can be detected in serum, bile,

and urine following phytoestrogen consumption. Like endogenous estrogens, these conjugated phytoestrogens undergo enterohepatic circulation. The metabolism of coumestrol has not been characterized.

Conjugated equol in the plasma of cattle or sheep is approximately 95–99% of total equol, whereas in pigs approximately 50–70% of total equol is conjugated (Lundh, 1995). The estrogenic effects are related to free compounds and active metabolites, such as equol, which is suggested to have 0.061% of the potency compared to 17 $\beta$ -estradiol (Markiewicz *et al.*, 1993). Equol was considered the primary chemical responsible for infertility in sheep consuming isoflavones in subterranean clover. Ingestion of high concentrations of red clover silage by ruminants can lead to extremely high concentrations of unconjugated equol in plasma and potency 100 times higher than the 17 $\beta$ -estradiol activity during estrus. Following consumption of mixed red clover–grass silage, the concentration of free equol was approximately 10 times greater in bovine plasma compared with ovine plasma, suggesting that the difference in isoflavone sensitivity between cattle and sheep was not caused by differences in metabolism or detoxification of formononetin and daidzein (Lundh *et al.*, 1990).

### Tissue distribution

Data are limited on the tissue distribution of phytoestrogens. Following an intravenous injection of daidzein in rats (40mg/kg body weight), daidzein was detected at high concentrations in plasma, liver, lung, and kidney and at lower concentrations in spleen, heart, and skeletal muscle (Yueh and Chu, 1977). Tissue distribution of isoflavones was determined in two lactating ewes after being fed red clover silage for 1 month (Urpí-Sarda *et al.*, 2008). The fermented silage contained only aglycones and provided a daily intake of approximately 157mg/kg body weight of isoflavones, with an average of 82mg/kg body weight formononetin, 65mg/kg body weight biochanin A, 7mg/kg body weight genistein, and 3mg/kg body weight daidzein. The major compounds recovered in tissues were equol, generally in the largest concentration, and daidzein as glucuronides. The highest concentrations of equol and daidzein were found in kidney – 10-fold higher than in other tissues – and in decreasing order of concentrations in tissues liver, plasma, aorta, suprarenal glands, uterus, thyroid, and mammary gland. Lower isoflavone concentrations were detected in lung, pituitary gland, thymus, heart, muscle, olfactory lobe of brain, cerebellum, and cerebral hemisphere. The penetration into the brain was very limited. Interestingly, isoflavones were found in the thyroid. Red clover silage ingestion has been documented to stimulate thyroid hormone

FIGURE 76.3 Metabolic pathway of formononetin via daidzein to equol in the rumen (Cox and Davies, 1988).

secretion (total and free triiodothyronine) and increase thyroid follicle size and the ER $\alpha$  immune reactivity of thyroid glands in ovariectomized ewes (Madej *et al.*, 2002). The two major isoflavones found in red clover, formononetin and biochanin A, were not recovered in tissues, which is consistent with extensive rumen metabolism of methylated isoflavones.

### Excretion

Conjugated and free metabolites are excreted in urine. A variable amount of phytoestrogens are excreted into bile and feces; for example, a greater fraction of genistein compared with daidzein is eliminated in bile and feces in rats (reviewed by Manach *et al.*, 2005). Phytoestrogens are also excreted into milk, with animal diet playing a major role in detectable concentrations.

Data indicate that animal feeds, such as soy meals, clovers, and grass/alfalfa feedstuffs, may influence milk phytoestrogen content. In a dairy cow ration of mixed red clover-grass silage, formononetin (0.3–0.5%) and biochanin A (0.2%) were the predominant isoflavones. Dairy cows fed a mixed red clover silage produced milk with high concentrations of equol (272 and 364  $\mu\text{g/L}$  or parts per billion (ppb)) and enterolactone (21 and 27  $\mu\text{g/L}$ ), metabolites of formononetin and the plant lignans (secoisolariciresinol and matairesinol), respectively (Steinshamn *et al.*, 2008). Higher equol concentrations were determined in milk from cows fed red clover silage compared with those fed white clover silage. Skimmed milk originating from organically managed Finnish dairy operations contained higher concentrations of isoflavonoids, with equol concentrations of  $411 \pm 65 \mu\text{g/L}$ , compared to that from conventionally managed dairy operations (Hoikkala *et al.*, 2007). The presence of equol

FIGURE 76.4 Schematic diagram of metabolism of plant lignans.

and enterolactone at elevated concentrations in dairy milk, from 14.1 to 293  $\mu\text{g/L}$  and 14.3 to 94  $\mu\text{g/L}$ , respectively, could be considered a health concern in children (Antignac *et al.*, 2004). Trace concentrations of methoxylated formononetin and biochanin A and hydroxylated daidzein and genistein (0.1–5.0  $\mu\text{g/L}$ ) were detected in bovine milk. Antignac *et al.* found that phytoestrogen concentrations in skimmed and full cream milk were similar, indicating that phytoestrogens are not very lipophilic compounds. For comparison purposes, the total isoflavone content of soy milk has been reported to be 6–10 mg aglucone equivalents/100 g wet weight (Chan *et al.*, 2009).

## MECHANISM OF ACTION

Reproduction is under hormonal regulation. Abnormalities in the dynamics of hormone production, metabolism, target molecule binding, and elimination can lead to alterations in the structure and/or function of the reproductive system. Estrogens influence cell growth and differentiation of both female and male reproductive tissue. They regulate the ovaries and testes, uterus, vagina, mammary glands, epididymis, and prostate gland. Phytoestrogens have been reported to affect physiological responses related to reproduction through

**TABLE 76.3** Several proposed mechanisms of phytoestrogen actions on reproduction and development

---

Genomic effects through binding to estrogen receptors $\alpha$ and $\beta$ causing endocrine disruption
Non-genomic effects through binding to steroid membrane receptors
Affects metabolism through inhibition of enzymes in steroidogenesis (3 $\beta$ - and 17 $\beta$ -hydroxysteroid dehydrogenase, aromatase, 5 $\alpha$ -reductase, 17 $\beta$ -hydroxysteroid oxidoreductase type 1)
Stimulation of sex hormone-binding globulin (SHBG)
Inhibition of protein tyrosine kinase involved with signal transduction and cell proliferation
Inhibition of DNA topoisomerases I and II required for DNA replication
Inhibits matrix metalloproteinase 9 (MMP9) involved in cell growth
Down-regulates expression of vascular endothelial growth factor (VEGF) involved with growth factor genes and angiogenesis
Inhibits prostaglandin synthesis via lipoxygenase or cyclooxygenase-2 and exert antioxidant activity

---

numerous mechanisms (Table 76.3). Phytoestrogens are considered weak estrogens, with an activity on the order of  $10^{-2}$  to  $10^{-3}$  of 17 $\beta$ -estradiol, but may be present in the body at concentrations 100-fold higher than those of endogenous estrogens (Adlercreutz and Mazur, 1997). A number of phytoestrogens have been shown to stimulate uterine growth in laboratory and farm animals. However, not all mouse strains were susceptible to isoflavone-induced uterine hypertrophy. The Swiss albino CD-1 mouse and ICR mouse showed no or only a slight response to phytoestrogens, respectively, which may be related to metabolism (reviewed by Kurzer and Xu, 1997). In addition, the isoflavone genistein has been demonstrated to inhibit important pathways for cellular growth and proliferation in multiple tissues.

## Estrogen receptors

Estrogens play an important role in physiological functions via a genomic mechanism. Phytoestrogens can mediate their effects by diffusing through the cell membrane and binding to specific estrogen receptors (ERs) in the target cell. After binding, the phytoestrogens do not act like typical estrogen agonists but, rather, more like selective estrogen receptor modulators (SERMs) that have differential actions as agonists or antagonists in different tissue potentially causing endocrine disruption. The differential action occurs partly from ER ligand conformational changes and the influence of co-regulator proteins (reviewed by Patisaul and Jefferson, 2010). Following phytoestrogen–receptor complex conformation changes, the complex translocates to the nucleus. Within the nucleus, the complex binds to selective regions of the DNA, the estrogen response element (ERE), and stimulates or inhibits specific genes that may result in the production of messenger RNA and subsequently new specific proteins. Numerous studies have focused on the direct effects of phytoestrogen receptor binding *in vitro*. Binding affinities to the ERs, whose subtypes are ER $\alpha$  and ER $\beta$ , vary greatly with

phytoestrogens and the various cell lines used in studies and chosen endpoints of estrogenic potency (Kuiper *et al.*, 1997, 1998). Compared to any phytoestrogen tested, the most potent activator of binding to ERs was the endogenous hormone 17 $\beta$ -estradiol. Daidzein, genistein, coumestrol, equol, and *O*-desmethylangolensin apparently bind to ERs from sheep uterine cytosol, suggesting estrogenic effects. Formononetin at physiological concentrations did not bind to the ER but could be metabolized to daidzein and eventually to equol, both of which have estrogenic properties (Kuiper *et al.*, 1998). Daidzein preferentially activated binding of ER $\beta$ , but with metabolism of daidzein to equol, both ER $\beta$  and ER $\alpha$  can be activated (Kostelac *et al.*, 2003). Phytoestrogens appear to have a predilection for greater affinity to ER $\beta$ . Studies have shown that coumestrol has a 2-fold higher affinity for ER $\beta$  than for ER $\alpha$ , and genistein has a pronounced affinity (30-fold) for ER $\beta$  (Kuiper *et al.*, 1997).

Although coumestrol may bind to both ER $\alpha$  and ER $\beta$ , it is an atypical estrogen because it does not stimulate uterine cellular hyperplasia. Coumestrol significantly increased uterine wet and dry weights in ovariectomized rats, but it did not stimulate cytosolic ER depletion or nuclear ER accumulation (Markaverich *et al.*, 1995). These findings suggest that the estrogenic effects of coumestrol may be mediated by increased sensitivity of the tissue to endogenous estradiol. An antiestrogenic effect of phytoestrogens has been proposed when high concentrations of phytoestrogens compete with endogenous estrogens and bind the ER, which blocks endogenous estrogen actions and reduces cellular growth (Rosselli *et al.*, 2000).

Differential expression of ERs has been reported in tissues, and several physiological roles have been associated with the ER subtypes (Table 76.4). Both subtypes have been found in blood vessels and in breast, uterus, and ovaries of women, but the proportions of  $\alpha$  and  $\beta$  subtypes appear to vary with estrogen target tissues, physiological and pathological status, and age of the individual. Each of these ERs may influence the function of the other, creating a complex process of

TABLE 76.4 Estrogen receptor  $\alpha$  and  $\beta$  proposed actions and distribution<sup>a</sup>

ER $\alpha$ and ER $\beta$ function in:	Normal ovarian follicular development Vascular endothelial cells Myocardial cells Smooth muscle cells Breast cells
ER $\alpha$ associated with:	Bone maturation in males and females Important role maintaining follicle-stimulating hormone and luteinizing hormone in blood More predominant in kidney, adrenal, nonpregnant human myometrium
ER $\beta$ associated with:	Bone maintenance Frontal lobe-mediated memory and learning Coumestrol and genistein bind with higher estrogenic potential Equol has modest affinity for binding More predominant in human brain, thymus, bladder, ovarian granulosa cells, testis Sertoli and germ cells, lung, bone, and pregnant term human myometrium

Based on Kuiper *et al.* (1997, 1998) and Patisaul and Jefferson (2010).  
<sup>a</sup>Distribution of estrogen receptors in tissues can change over a life span and is sexually dimorphic.

estrogenic effects in tissues in which both subtypes are co-expressed (Benassayag *et al.*, 2002). The resulting changes in physiological functions can be difficult to interpret.

Estradiol can bind with high affinity to plasma membrane forms of steroid receptors and may mediate non-genomic actions with a variety of short-term estrogen effects (Pietras and Szego, 1975; Swego, 1984). Estradiol has been shown to induce rapid changes in intracellular calcium concentrations/flux, potassium conductance, and cyclic AMP levels (reviewed by Rosselli *et al.*, 2000). The direct effects of phytoestrogens and membrane ERs have not been fully defined. Resveratrol, a stilbene phytoestrogen found in red wine, apparently binds to and increases the transcriptional activity of ER $\alpha$  and ER $\beta$ . Klinge and co-workers (2005) reported that resveratrol, at nanomolar concentrations achieved by reasonable red wine consumption, can activate membrane-initiated (non-genomic) ER signaling in endothelial cells that activate mitogen-activated protein kinases (MAPKs) involved in signaling pathways and endothelial nitric oxide synthase. Resveratrol increased nitric oxide levels in human umbilical vein endothelial cells after short-term exposure, suggesting a potential cardioprotective effect.

Impact on steroidogenesis

Certain phytoestrogens may alter key steroidal enzymes in tissues, although most studies have used *in vitro* cell

lines or purified microsomal or enzyme preparation (Lacey *et al.*, 2005). Phytoestrogens may interfere with the synthesis or metabolism of steroid hormones, such as cytochrome P450arom (aromatase), an enzyme that can catalyze the conversion of testosterone to 17 $\beta$ -estradiol and  $\Delta$ 4-androstenedial to estrone. The enzyme aromatase has a critical role in the ovary (in premenopausal women) and peripheral tissues, which are sites for estradiol synthesis in postmenopausal women and men. Using an *in vitro* assay with human breast cancer MCF-7 cells, Almstrup and co-workers (2002) reported that phytoestrogens, but not genistein, were aromatase inhibitors at low concentrations (<1 $\mu$ M) but at higher concentrations (>1 $\mu$ M) were estrogenic. The aromatase inhibition at low doses of phytoestrogens may provide antiestrogenic properties that play a role in protection against breast cancer.

Phytoestrogens may decrease endogenous estrogen concentrations through effects on the sex (or serum) hormone-binding globulin (SHBG). This binding protein has specific affinity for estrogens and androgens. Minor changes in the amount or availability of SHBG, caused by phytoestrogens, may change the free fraction of endogenous hormones in circulation either locally or systemically. The phytoestrogen enterolactone (1–10 $\mu$ M) stimulated SHBG *in vitro* with HepG2 cells (Adlercreutz *et al.*, 1992). Equol, genistein, daidzein, enterolactone, and enterodiol appear to exert a dose-dependent inhibitory effect on binding of steroids to SHBG, displacing 17 $\beta$ -estradiol or testosterone (Benassayag *et al.*, 2002). Additional mechanisms of action may affect steroid hormones. Coumestrol and, to a lesser degree, genistein have been shown to inhibit the enzyme 17 $\beta$ -hydroxysteroid oxidoreductase type 1, which converts [<sup>3</sup>H]-estrone to [<sup>3</sup>H]-estradiol in a dose-dependent manner (Mäkelä *et al.*, 1995). *In vitro* studies have reported that phytoestrogens inhibit 17 $\beta$ -hydroxysteroid dehydrogenase, converting androstenedione to testosterone, and 5 $\alpha$ -reductase, converting testosterone to the more potent dihydrotestosterone (reviewed by Whitten and Patisaul, 2001). Biochanin A displayed dose-dependent inhibition of 3 $\beta$ -hydroxysteroid dehydrogenase, an enzyme that catalyzes the conversion of pregnenolone to progesterone and androstenediol to testosterone, in primary cultures of human granulosa luteal cells (Lacey *et al.*, 2005).

Additional impact on cell functions

Angiogenesis is essential for ovarian follicle development and for tumor growth, invasion, and metastasis. Several studies have reported that phytoestrogens inhibited vascular endothelial growth factor (VEGF)-induced endothelial cell functions and signaling pathways. The

flavonoid quercetin at 5 and 50 µg/mL (concentrations higher than physiological range) inhibited VEGF production by porcine granulosa cells *in vitro* (Santini *et al.*, 2009). Santini *et al.* determined that quercetin inhibited steroidogenesis, specifically progesterone production, but not granulosa cell growth.

Genistein has been reported to inhibit ethoxyresorufin-O-deethylase (EROD) activity, part of the enzyme cytochrome P450 family (CYP1A) that is critical in the metabolism of 17β-estradiol to hydroxylated estrogen, in mammalian cell culture lines (Shon *et al.*, 2006). In addition, the activity of ornithine decarboxylase, a critical enzyme in polyamine biosynthesis and normal cell growth and proliferation, was markedly reduced after genistein treatment of MCF-7 breast cancer cells, suggesting that genistein might be of therapeutic value in preventing human breast cancer.

### Altered signal transduction and cell proliferation

Genistein may alter cell growth at several signal transduction pathways, inhibiting protein tyrosine kinase activity and down-regulating epidermal growth factor receptor autophosphorylation, which phosphorylates tyrosyl residues of membrane-bound receptors (Akiyama *et al.*, 1987), and MAPK activity and mitogen proliferation in human aortic smooth muscle cells (Dubey *et al.*, 1999). Inhibition of protein tyrosine kinases and MAPK by isoflavones may play a role in improving heart function. Genistein can inhibit DNA replication enzymes associated with cancer growth, including DNA topoisomerases I and II (required for DNA replication) and matrix metalloproteinase 9 (a matrix enzyme that can degrade a number of structural components) (Kurzer and Xu, 1997). Although inhibition of these pathways may lead to inhibited cell growth and a protective effect, a number of phytoestrogens, including coumestrol, genistein, biochanin A, daidzein, and enterolactone, can stimulate cellular proliferation of the estrogen-dependent MCF-7 human breast cancer cells at concentrations less than 1–10 µM (reviewed by Kurzer and Xu, 1997). The influence of genistein on cells *in vitro* appears to be biphasic in nature, inducing cell growth of MCF-7 cells at low concentrations and inhibiting cell growth at higher concentrations (reviewed by Rosselli *et al.*, 2000). Genistein, which shows a high affinity to ER, has been shown to inhibit growth in both ER-positive and ER-negative cell lines *in vitro*.

The antioxidant activity of phytoestrogens has been reported both *in vitro* and *in vivo*. Isoflavones inhibit lipoxygenase action and prevent sheep erythrocyte hemolysis *in vitro* and inhibit production of hydrogen peroxide in HL60 cells (reviewed by Benassayag *et al.*, 2002). Inhibition of lipoxygenase and possibly

cyclooxygenase may modulate production of prostaglandins and leukotrienes involved in inflammation, carcinogenesis, and reproduction.

## ADVERSE HEALTH EFFECTS

### Developmental effects

The effects of pre- and neonatal exposure to phytoestrogens on development in laboratory animals have been studied, with variable effects observed. Pre- and neonatal treatment of rodents with phytoestrogens has resulted in altered prepubertal or adult morphology and possible function of the uterus, vagina, ovary, breast, pituitary, and hypothalamus (reviewed by Whitten and Patisaul, 2001). *In utero* exposure to several estrogens, including genistein, down-regulated the expression of several testicular genes in the rat and mouse (reviewed by Phillips and Tanphaichitr, 2008). Both male and female rat offspring from dams treated with high levels of genistein (5000 µg) had shorter anogenital distances at birth, and females in this treatment group had a later onset of vaginal opening or puberty (Levy *et al.*, 1995). High levels of dietary coumestrol (100 mg/kg) fed to weanling female rats on days 21–24 or 22–60 caused earlier vaginal opening and irregular vaginal cycles (Whitten and Naftolin, 1992). Coumestrol treatment of neonatal female rats, given a 100 µM dose, resulted in premature uterine gland development and increased uterine weights on postnatal days 1–5, and at later ages the uterine weights and ER levels were reduced; however, if coumestrol was administered on postnatal days 10–14, the uterine gland growth was inhibited (Benassayag *et al.*, 2002).

Female neonatal rats given a subcutaneous injection of 10 µg of genistein showed an increased pituitary response to gonadotropin-releasing hormone, with higher genistein doses causing a decreased luteinizing hormone secretion on postnatal days 1–10 (Faber and Hughes, 1993). The effects of the higher doses were similar to the typical effects of estrogens in masculinizing the brain and decreasing pituitary response. Oral exposure of female CD-1 mice to genistin, the glycosylated form of genistein found in soy-based infant formulas, treated on postnatal days 1–5 caused estrogenic responses, including altered ovarian differentiation (multi-oocyte follicles), delayed vaginal opening, and, subsequently in the adult mouse, abnormal estrous cycles, decreased fertility, and delayed parturition (Jefferson *et al.*, 2009a). Jefferson *et al.* noted that the glucoside forms of isoflavones were quickly hydrolyzed to produce the aglycone forms and subsequently absorbed. The glycosylated form can be passively transported across the intestinal membrane and enter circulation by the sodium-dependent glucose transporter,

unlike passive diffusion by the aglycone form. Major contributions to infertility in genistein-treated neonatal mice were determined to be (1) delay in fertilization by an undetermined mechanism that could lead to altered developmental timing (lack of development between the two- and four-cell stage), (2) adverse oviductal environment because more than half of the embryos were lost in early embryo development, and (3) the reproductive tract (uterus not responsive to hormonal cues) was not capable of sustaining pregnancy (Jefferson *et al.*, 2009b).

Estrogen receptors are located in numerous areas of the brain, and phytoestrogens can have extensive effects. The paraventricular nucleus of the hypothalamus (PVN) is a region coordinating reproductive, social, and stress behaviors that primarily expresses ER $\beta$  (reviewed by Patisaul and Jefferson, 2010). ER $\beta$  is expressed at higher levels than ER $\alpha$  in the basal forebrain, hippocampus, and cerebral cortex (areas important for memory) in the adult. Notably, ER $\alpha$  is primarily expressed in the ventromedial nucleus (VMN) of the brain, which along with the PVN nucleus is important for initiation and regulation of sexual behavior. Patisaul and Jefferson noted that the PVN is the main site for oxytocin production, involved with social behavior and facilitation of sexual behavior. Estrogen binding to ER $\beta$  may stimulate oxytocin production from the PVN, which subsequently binds to the oxytocin receptor in the VMN, a nucleus involved in mediating the lordosis response in females. Up-regulation of oxytocin receptors involves binding to ER $\alpha$ .

The central nervous system–gonadal axis and male sexual behavior of the rat appear to be sensitive to phytoestrogens in the rat (Santti *et al.*, 1998). Altering the isoflavone dietary concentrations significantly affected both the sexually dimorphic nucleus of the preoptic area and the anteroventral periventricular nucleus in the brain of rodents (Lephart *et al.*, 2005).

Phytoestrogens may be incorporated as an alternative protein source for aquatic nutrition and have been found in discharged kraft mill effluent and sewage treatment plant effluent, with low concentrations of genistein detected that could impact fish populations. Phytoestrogens may alter sex differentiation in early development, causing a paradoxical sex reversal with increased male phenotypic sex resulting from the administration of an estrogen mimic in the diet. Increased concentrations of genistein, from 0 to 8 mg/g in the diet, fed chronically to sexually undifferentiated channel catfish (*Ictalurus punctatus*) altered gonadal sex differentiation, with increasing proportions of intersex fish and phenotypically male individuals (Green and Kelly, 2009).

Preliminary evidence indicates that soy infant formulas may exert estrogenic activity in the developing human reproductive tract. Phytoestrogens can cross the placenta and are capable of crossing the blood–brain barrier to a limited extent. The human

myometrium primarily expresses ER $\beta$  in late pregnancy and may be a target for genistein, which preferentially binds to this receptor subtype. A pilot study of female infants fed soy formula, cow milk formula, and breast milk revealed that soy milk-fed infants had re-estrogenization of vaginal cells at 6 months of age (Bernbaum *et al.*, 2008). However, an expert panel report from the National Toxicology Program and the National Institute of Environmental Health Sciences concluded in 2006 that there was insufficient human or experimental animal data to permit determination of the toxicity of soy infant formula on development or reproduction (Rozman *et al.*, 2006).

## Hormones and estrous cycles

Following adult exposures, phytoestrogens may suppress the adult hypothalamic–pituitary–gonadal axis. Data from studies of ovariectomized rodents and of humans suggest that ingestion of isoflavone-rich soy food may suppress circulating estrogen and progesterone concentrations and can attenuate the preovulatory surge of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) (reviewed by Patisaul and Jefferson, 2010). Several studies have reported on the effects of soy isoflavones in premenopausal women. In a limited study during one menstrual cycle in six premenopausal women given 45 mg of isoflavones daily, the follicular phase length was increased and delayed menstruation (Cassidy *et al.*, 1994). Follicular estradiol concentrations were increased and mid-cycle surges of LH and FSH were significantly suppressed. One case report on three women described adverse effects of abnormal uterine bleeding, leiomyomas, and endometriosis related to high intakes of soy products; all of the women improved after withdrawal of soy from their diet (Chandrareddy *et al.*, 2008). A prospective cohort study of almost 20,000 non-Hispanic white women between 35 and 59 years of age, who were enrolled in the National Institute of Environmental Health Sciences Sister Study, evaluated associations of *in utero* and early life exposures and self-reporting of physician-diagnosed fibroids (D'Aloisio *et al.*, 2010). Fibroids are benign smooth muscle tumors (uterine leiomyomata) associated with reproductive problems in women. Increased risk for fibroids in early adulthood was associated with being fed soy formula during infancy, having a mother with prepregnancy diabetes, being born at least 1 month early, and growing up in lower socioeconomic conditions. The authors suggested that exposure of infants to soy formula within the first 2 months of life is a sensitive time period and can result in infant isoflavone levels more than five times higher than typical levels found in adults consuming soy-based foods.

## Infertility

Phytoestrogens have the capability to affect reproduction at many levels, from the hypothalamic–pituitary level to local levels of the ovary and uterus and testis and prostate gland (see Chapter 19, Figure 19.4). In laboratory animals, intravenous infusion of coumestrol, but not genistein, affected control of LH secretion at both pituitary and hypothalamic levels (McGarvey *et al.*, 2001). At the pituitary level, coumestrol inhibited gonadotropin-releasing hormone–LH release *in vivo*, and at the hypothalamic level, coumestrol reduced the frequency of the gonadotropin-releasing hormone pulse generator. The inhibitory effects of coumestrol on LH at the pituitary level occurred via an ER-mediated process. Additional evidence that phytoestrogens immediately affect pituitary responsiveness was found in ewes when genistein was administered directly into the central nervous system (Romanowicz *et al.*, 2004). Lower plasma LH concentrations were detected in ovariectomized ewes infused intracerebroventricularly for 6 h with two different levels of genistein at 1 and 10 µg/100 µL/h. In addition, the plasma prolactin concentrations were significantly higher in treated ewes compared with control ewes. Estrogen has been shown to be a potent stimulator of prolactin release in the pituitary lactotrophs.

Initial cases of temporary and permanent infertility in animals related to phytoestrogens occurred in sheep ingesting subterranean clover in Australia (Adams, 1995). Red clover, a livestock forage supplement, caused adverse effects in reproductive organs of ovariectomized sheep, with increased teat length (a relatively sensitive parameter), mammary gland development, and milky fluid secretions (galactorrhea) from the teats. Nwannenna and co-workers (1995) described clinical effects of edema and mucous discharge from the vulva, fluid accumulation in the uterus, elongated teats, and the presence of milky fluid in the mammary glands in ovariectomized heifers fed 20 kg of 100% red clover silage (daily intake of 35 g phytoestrogens, primarily formononetin and biochanin A) per day for 14 days. The magnitude of the pituitary response to gonadotropin-releasing hormone injections was diminished with lower LH release. The authors noted that the abnormal mounting behavior in one of the heifers was similar to the sexual behavior of cattle treated with estradiol.

Cattle seem to be less sensitive than sheep to clover forage, with temporary estrogenic signs and infertility occurring following ingestion of clover or alfalfa forages, although coumestrol is thought to have a cumulative effect. Concentrations of coumestrol of approximately 25 mg/kg (dry matter) in forage may have adverse effects on reproduction in livestock and reduce fertility (Saloniemi *et al.*, 1995), whereas dietary coumestrol concentrations of 50 mg/kg provided for more than

180 h induced uterine enlargement in rats (Whitten *et al.*, 1992). There is marked variability in the effects of phytoestrogens for different species. High concentrations of daidzein and genistein from soybeans in captive cheetah diets, with an approximate consumption of 50 mg isoflavones/day, may have been a major contributor to the decreased fertility and the veno-occlusive liver disease in the cheetah population (Setchell *et al.*, 1987).

Physiology, particularly the stage of pregnancy or cycling, appears to influence the concentrations of isoflavones (daidzein and genistein) in the plasma of heifers fed 2.5 kg soybeans (Woclawek-Potocka *et al.*, 2008). Pregnancy influenced the kinetics of the isoflavones; plasma concentrations of daidzein and genistein were significantly higher in cycling heifers than in early or late pregnant heifers. In addition, heifers that were 2 months pregnant had higher concentrations of the active metabolite equol compared to heifers that were 8 months pregnant or heifers at the mid-luteal phase of the estrous cycle. Piotrowska and co-workers (2006) found elevated concentrations of equol and *para*-ethylphenol in corpus luteal tissue and plasma of cows fed a soy diet (2.5 kg soybean/animal/day) compared with a standard diet. Metabolites of isoflavone phytoestrogens, such as equol, appear to disturb bovine corpus luteum function *in vitro* by inhibiting LH (needed for a preovulatory surge) and prostaglandin-stimulated progesterone secretion.

Uterine endometrial release of prostaglandin F<sub>2α</sub> is under regulation by oxytocin, progesterone (P<sub>4</sub>) and estradiol (E<sub>2</sub>) in ruminants and causes luteolysis and regression of the corpus luteum. In cattle and sheep, an increase in oxytocin receptors on endometrial epithelial cells is a primary initiator of luteolysis (Goff, 2004). Oxytocin has a functional role in the regulation of ovarian function in ruminants. Mlynarczuk and co-workers (2011a,b) determined that coumestrol, daidzein, and genistein stimulated the expression of several genes that are responsible for synthesis of the oxytocin precursor, neurophysin-I/OT, and post-translation synthesis of oxytocin, peptidyl-glycine- $\alpha$ -amidating monooxygenase or PGA, in granulosa and luteal cells in cattle. These phytoestrogens stimulated the secretion of oxytocin stored in bovine ovarian follicles and corpora lutea, which in cattle may result in premature luteolysis, the formation of persistent corpus lutea, and impair pregnancy maintenance in the cow.

Higher concentrations of active estrogenic metabolites (i.e., equol) in early pregnancy could lead to increased insemination rates (number of breedings) and decreased number of successful pregnancies in cattle fed soybeans at 2.5 kg/head/day (Woclawek-Potocka *et al.*, 2005a,b). The concentrations of a metabolite of prostaglandin PGF<sub>2α</sub> or PGFM were significantly higher in the soybean-fed cattle plasma through the first 21 days after ovulation and artificial insemination; the high

concentrations of PGFM were correlated with isoflavone metabolites in the plasma. Woclawek-Potocka *et al.* concluded that the soy-derived phytoestrogens and their metabolites disrupt reproduction and uterine function by modulating the ratio of  $\text{PGF}_{2\alpha}$  to  $\text{PGE}_2$ , leading to elevated, nonphysiological production of luteolytic  $\text{PGF}_{2\alpha}$  by the bovine endometrium during the estrous cycle and early pregnancy in cattle. In ruminants,  $\text{PF}_{2\alpha}$  is the major luteolytic agent, whereas  $\text{PGE}_2$  is considered luteoprotective with anti-luteolytic properties; the ratio of  $\text{PGF}_{2\alpha}$  to  $\text{PGE}_2$  is important for the development and maintenance of the corpus luteum and establishment of pregnancy.

### Male infertility

There are a limited number of reports of adverse effect of phytoestrogens on male reproductive function. In a review on soy and male reproductive function, Cederroth *et al.* (2009) stated that overall there are some indications that phytoestrogens may alter reproductive hormones, spermatogenesis, sperm capacitation, and fertility; however, there is lack of consistency in human and animal studies examining these effects. Adult male mice fed a soy-rich diet from conception to adulthood exhibited normal male behavior and were fertile but had a 25% reduction in epididymal sperm counts and a 21% reduction in litter size (Cederroth *et al.*, 2010). Irrigated red clover, containing higher estrogenic activity than non-irrigated clover, was fed with non-irrigated red clover in diets to Japanese quail chicks for 2 weeks (Rochester *et al.*, 2009). Both irrigated and non-irrigated red clover reduced chick growth compared with that of control chicks, but irrigated red clover reduced both absolute and relative testes and ovary weights and increased the relative oviduct weights, suggesting isoflavones affect avian reproductive development. Bilgoraj ganders were fed diets containing high concentrations of phytoestrogens ( $\sim 140 \mu\text{g/g}$  of diet) from soy and alfalfa meal during growth, photorefractoriness, and laying periods (reviewed by Dusza *et al.*, 2006). Semen samples analyzed from phytoestrogen-fed ganders had decreased volume of ejaculates and increased number of abnormal spermatozoa, but fertility of eggs and the percentage of normal hatching were not different in males and females fed the control and phytoestrogen diets during the breeding season.

Male goat kids fed a conventional diet supplement with red clover isoflavones (60% biochanin A), at approximately 3 or 4 mg/kg/day for 3 months, exhibited a rise in plasma-free and total triiodothyronine ( $\text{T}_3$ ) followed by a significant increase in plasma testosterone concentrations during puberty compared with those of control goats (Gunnarsson *et al.*, 2009). The increased concentration of  $\text{T}_3$  had a direct effect on pubertal Leydig cell steroidogenesis leading to increased testosterone. In

an *in vitro* experiment with pubertal rat Leydig cells, Maran and co-workers (2000) reported that  $\text{T}_3$  modulated LH-mediated secretion of testosterone and estradiol in a dose-dependent manner. Additional phytoestrogen studies have not found an effect on thyroid hormones.

Phytoestrogens have been evaluated with normal sperm to determine altered cell signaling through inhibition of tyrosine kinase. Protein tyrosine kinase is believed to have a major role in sperm function in humans and other animals through phosphorylation of tyrosine proteins on the spermatozoa and subsequent capacitation, followed by the zona pellucida-induced acrosomal reaction and penetration of zona pellucida-intact oocytes (Pukazhenthil *et al.*, 1998). Utilizing *in vitro* genistein exposure and cat spermatozoa, no effect was detected in sperm motility, but genistein inhibited the zona pellucida-induced acrosome reaction and reduced sperm penetration into the inner zona pellucida. Menzel and co-workers (2007) reported similar findings in cryopreserved bovine spermatozoa incubated with a range of genistein concentrations, from 0.74 to  $7.4 \mu\text{mol/L}$ . Genistein did not affect tyrosine phosphorylation in cryopreserved spermatozoa, but it inhibited the progesterone and ZP3-6 peptide-induced acrosomal exocytotic event or reaction and decreased sperm-zona pellucida binding, probably by a process independent of protein tyrosine kinase inhibition.

Data from castrated rats treated with  $5\alpha$ -dihydrotestosterone (DHT) and equol showed that equol bound and sequestered DHT from the androgen receptor, resulting in increased plasma concentrations of DHT (Lund *et al.*, 2004). Lund *et al.* reported that equol administration to intact male rats somewhat blocked the negative feedback effects of DHT on pituitary LH regulation, increasing circulating LH levels and reducing ventral prostate and epididymal weights, acting as an anti-androgen. Tan and co-workers (2006) used seven marmoset monkey twins to evaluate potential adverse effects of feeding human male infants soy milk formula. Male co-twin marmoset monkeys were fed soy milk formula from age 4 or 5 days for approximately 5 or 6 weeks, which resulted in normal body weights, penis length, and fertility. However, the soy-fed monkeys had significantly increased testis weights and Sertoli and Leydig cell numbers per testis. Additional studies are needed on the influence of phytoestrogens on male development and subsequent adult male reproductive and endocrine functions.

## RISK ASSESSMENT

Phytoestrogens may result in marked adverse effects on reproduction in livestock. This risk has been recognized for years in livestock, particularly in sheep and cattle

production. With regard to sheep grazing subterranean clover in Australia, temporary and permanent fertility are recognized reproductive conditions. The occurrence of adverse reproductive effects from clover or alfalfa forage consumption in livestock cannot be reliably predicted, nor can most of the factors affecting enhanced phytoestrogen concentration be controlled (e.g., weather and insect or fungal invasion). Elevated phytoestrogen concentrations in soybeans and forages can be analyzed in rations. Producers can mitigate most of the adverse effects by diluting or eliminating the forage from the ration.

In subchronic and chronic studies of oral genistein dosing in beagle dogs, the no-observed-adverse-effect level (NOAEL) was considered to be greater than 500mg/kg/day for the 4-week and 52-week studies (McClain *et al.*, 2005). The primary effects reported were in reproductive organs and included (1) increased uterine weights in female dogs in the 4-week study, (2) atrophy of the testes and prostate gland and absent spermatozoa in the epididymis in males in the 52-week study, and (3) small decreases in ovarian weights in female dogs in the 52-week study. The no-observed-effect level (NOEL) was considered to be 150mg/kg/day for the 4-week study and 50mg/kg/day for the 52-week study. A 4-week recovery period, after the 52-week study at 500mg/kg/day of genistein, resulted in no observed changes in the dogs. To assess teratogenic and fetal toxic potential of genistein in rats, McClain and co-workers (2007) conducted several *in vivo* embryo–fetal developmental safety studies using genistein by gavage, with dosages of 0–1000mg/kg/day from days 6 to 20 of gestation, and dietary admix, with dosages of 0–500mg/kg/day from days 5 to 21 of gestation, and an *in vitro* rat whole embryo culture assay (preliminary screen) using 1–100µg/mL genistein. *In vitro* genistein exposure in the embryo culture at 10µg/mL or greater resulted in anomalies that were not predictive of *in vivo* findings. A slight maternal toxicity was reported at 1000mg genistein/kg/day by gavage doses and included decreased maternal body weights and food consumption, with adverse effects in pups reported as increased pup mortality and reduced pup body weights and milk uptake. No external malformations were noted in pups, with minor visceral and skeletal variations observed at the high dose. At the high dietary admix dose of 500mg/kg/day, maternal body weight and feed consumption were reduced, and the incidence of fetal resorptions increased with a corresponding decrease in the number of live fetuses per dam. Fetal body weights were reduced, but no treatment-related teratogenic effects were detected during external, visceral, and skeletal examinations of fetuses or in body weight normalized anogenital distance. The authors concluded that on the basis of the definitive prenatal developmental safety study (oral dietary admix exposure), the NOAEL

for maternal toxicity and adverse effects on embryonic development was 100mg genistein/kg/day when given orally by dietary admix.

## TREATMENT

The focus of phytoestrogens is on both beneficial and adverse effects. Regarding the adverse impact of phytoestrogens on livestock fertility, the current recommendation is to either delete or dilute the estrogenic component of the diet. Typically, problems with fertility (irregular cycling) or mammary gland hypertrophy in cattle or horses are related to using specific cuttings of alfalfa or clover forages. Forages and soybeans can be analyzed for isoflavones and coumestrol concentrations, and nondetectable or low phytoestrogen feeds can be substituted into rations. A washout period of several weeks (4 to 6 or more weeks) will usually result in a return to normal reproductive cycling. The current phytoestrogen data for humans do not substantiate any treatment recommendations for humans.

## CONCLUDING REMARKS AND FUTURE DIRECTIONS

Because of the variability in multiple parameters of exposure (dose, timing, and duration of exposure) of numerous phytoestrogens to experimental animals and humans, there are not adequate data to determine the developmental and reproductive toxicity in animals. Laboratory and livestock research should focus on the dose–response relationship of phytoestrogens (particularly isoflavones and coumestrol) on ovarian follicular development, ovarian follicle counts, and ovarian failure. The dose–response relationship for isoflavones and coumestrol in forages and potential for adverse effects of ovarian dysfunction and early embryonic death in livestock, particularly in dairy, need to be determined. Further research on the mechanisms that underlie the impact – detrimental or beneficial – of phytoestrogens on reproductive processes in humans and farm animals is necessary.

## Poisonous plants of the United States

K.E. Panter, K.D. Welch, D.R. Gardner, S.T. Lee, B.T. Green, J.A. Pfister, D. Cook, T.Z. Davis and B.L. Stegelmeier

### INTRODUCTION

Poisonous plants and the secondary compounds they produce cause major economic losses to the livestock industries throughout the world. Based on 1989 data, it was determined that poisonous plants cause losses of more than \$340 million annually to the livestock industry in the 17 western states of the United States (Nielsen *et al.*, 1988; Nielsen and James, 1992). This cost only considered death losses and specific reproductive losses in cattle and sheep, and only the 17 western states were included. Less obvious costs such as lost grazing opportunities, additional feed costs, increased health care costs, management changes, increased culling costs, lost weight gains, delayed or failed reproduction, and the emotional stress accompanying many poisonous plant cases were not included in the Nielsen and James analysis. When one considers these other costs, inflation, and current animal values, and when all pastures and ranges in the United States are factored in, the economic cost of poisonous plants to the livestock industry is very high. In addition, an often ignored cost is the lost biodiversity frequently resulting from invasive species, many of which are poisonous. These invasive and poisonous species are often aggressive invaders and reduce optimum utilization of private, federal, and state managed forest, range, and pasture lands. This aspect alone has far-reaching implications, not only for livestock producers but also for many other segments of society.

A frequently asked question is why do animals consume plants that may harm them or their offspring? In some cases, it is a matter of survival. For example, in the arid livestock-producing regions of the world, such

as the western United States, regions of South Africa, Australia, China, and others, browsing or grazing animals may have limited access to high-quality forage at certain times of the year and are forced to survive by grazing some poisonous species. In other instances, hay or forages harvested in areas where poisonous plants are abundant may be contaminated with a high percentage of poisonous plants, and when animals are fed contaminated hay, they may be poisoned. Poisonous plant problems are often exacerbated during periods of below normal rainfall when the abundance of grasses is reduced. Frequently, the animal's diet shifts during the season as grasses and palatable forbs mature and senesce; for example, the consumption of some poisonous plants such as lupines, locoweeds, or larkspurs, which stay green longer into the season, may increase as the season progresses. In other instances, poisoning occurs early in the season before grasses begin to grow but poisonous plants have emerged and are usually very toxic. Poisoning by plants only occurs when animals eat too much too fast or graze it over a prolonged period of time. Therefore, management strategies to control these factors can minimize losses from poisonous plants.

At the Poisonous Plant Research Laboratory in Logan, Utah, poisonous plant problems are dealt with using a multidisciplinary approach. Veterinary medicine, chemistry, toxicology, pathology, animal and plant physiology, and range management are all key in the approach to reduce losses to the livestock industry. The plants discussed in this chapter are some of the most important poisonous plants in the United States, and considerable research has been conducted to reduce their incidence of poisoning.

This chapter is not intended to be all-inclusive but focuses on some of the most economically important and geographically widespread poisonous plants to livestock producers in the United States. There are excellent comprehensive texts available with a more general and broad coverage of specific poisonous plants (Burrows and Tyrl, 2001; Knight and Walter, 2001; Keeler *et al.*, 1978 (ISOPP1); Seawright *et al.*, 1985 (ISOPP2); James *et al.*, 1992 (ISOPP3); Colegate and Dorling, 1994 (ISOPP4); Garland and Barr, 1998 (ISOPP5); Acamovic *et al.*, 2004 (ISOPP6); Panter *et al.*, 2007 (ISOPP7); Riet-Correa *et al.*, 2011 (ISOPP8)). The ISOPP series, 1–8, 1978–2011 (Proceedings of the International Symposium on Poisonous Plants), provides a worldwide view of poisonous plant research. In 2013, the ninth international symposium (ISOPP 9) will be held in Ho Hot, Inner Mongolia, China. In addition, current research information on poisonous plants from throughout the world is available in the online peer-reviewed journal, the *International Journal of Poisonous Plant Research*, by the Poisonous Plant Research Laboratory, U.S. Department of Agriculture – Agricultural Research Service. International research, both basic and applied, as well as case reports of plant poisonings and short communications are published in a spring and a fall issue each year.

## ASTRAGALUS AND OXYTROPIS SPECIES (LOCOWEEDS, NITRO SPP., AND SELENIUM SPP.)

### Locoweeds

Of all the poisonous plants in the United States, the *Astragalus* and *Oxytropis* genera cause the most losses to the livestock industry in the western states (Graham *et al.*, 2009; Cook *et al.*, 2009c). The locoweeds are those species of the *Astragalus* and *Oxytropis* genera that contain the “loco” toxin (swainsonine) and induce the classic neurological and pathological signs of “locoism.” Swainsonine is also present in other *Astragalus* species not usually considered locoweeds, such as some selenium and nitro-containing *Astragalus*. There are three toxic syndromes associated with these species: (1) locoism, caused by the indolizidine alkaloid swainsonine (1) (24 species); (2) nitrotoxins (356 taxa); and (3) species that accumulate selenium at high levels (22 species).

### Description

These species are members of the Fabaceae (Leguminosae) or pea family. This family is distinguished by its papilionaceous flower (butterfly-like) having a single large banner petal, two side petals or wings,

**FIGURE 77.1** Comparison of *Astragalus* and *Oxytropis*. *Astragalus mollissimus* (purple loco) is on the left, and *Oxytropis lambertii* is on the right.

and two lower petals fused together to form a keel. Flowers are leguminous (pea-like), few or many, in axillary racemes, and they may be blue, purple, yellow, or white in color; fruit is a legume pod of various shapes, sizes, and surfaces among the species containing one or more kidney-shaped seeds. The distinguishing feature in *Oxytropis* is the porrect beak on the keel petal, whereas the *Astragalus* have a blunt keel petal (Figure 77.1). Some *Astragalus* species have extensions of the keel forming points, but they are not turned upward as in *Oxytropis*. In addition, *Oxytropis* species are acaulescent (without a stem, all leaves basal) with leafless flowering stalks originating from the crown, whereas leaflets of *Astragalus* species grow from the multibranched stems with the flowering head on top (Figure 77.1). Leaflets are opposite and pinnately compound. Pod shape, size, and chambers are very diverse and are a principal means of distinguishing between species (Figure 77.1).

*Astragalus* is a very large and complex genus, with 354 species and 198 varieties of *Astragalus* (552 taxa) in the United States and Canada (Welsh *et al.*, 2007). *Oxytropis* is much smaller, with 22 species and 35 varieties (57 taxa). Barneby (1964) earlier described and classified 368 species and 184 varieties of *Astragalus* and 35 species of *Oxytropis* in North America. Regardless, the *Astragalus* genus is the largest of the Leguminosae family. Species and variety identification are difficult even for trained botanists. Because of obvious similarities between *Oxytropis* and *Astragalus*, some botanists treat them together as *Astragalus*. Certainly, from a toxicology perspective, both can contain swainsonine and induce the same condition in livestock; therefore, both genera are treated the same in this discussion.

### Distribution and ecology

The *Astragalus* and *Oxytropis* are worldwide in their distribution and toxic effects on livestock. Table 77.1 lists those species in the western United States suspected

TABLE 77.1 Locoweed (*Astragalus* and *Oxytropis*) species, habitat, and distribution and *Astragalus* species containing nitro-toxins or accumulating selenium<sup>a</sup>

Species	Common name	Habitat	Distribution
<i>A. allochrous</i>	Rattleweed	Desert grassland	AZ, NM
<i>A. asymmertricus</i>	Horse loco	Annual grasslands	CA
<i>A. bisulcatus</i> <sup>b</sup>	Two-grooved milkvetch	Limestone, shale, high in Se	MT, ND, WY, CO, NM, UT
<i>A. didymocarpus</i>		Creosote deserts	CA, AZ, NV
<i>A. drummondii</i> <sup>b</sup>	Drummond milkvetch	Prairies, sage, oak, P/J	MT, WY, CO, NM, UT
<i>A. emoryanus</i> <sup>c</sup>	Red stem peavine	Creosote, mesquite, P/J	NM, TX
<i>A. humistratus</i>	Ground cover milkvetch	P/J woodlands	AZ, NM
<i>A. lentiginosus</i>	Spotted locoweed	Salt-desert shrub, sage, P/J	AZ, UT, NV, ID
<i>A. lonchocarpus</i>	Great rushy milkvetch	P/J woodlands	CO, UT, AZ, NV
<i>A. missouriensis</i>	Missouri milkvetch	Shortgrass prairies	Canada to TX
<i>A. mollissimus</i>	Woolly loco	Shortgrass prairies	CO, KA, OK, TX, NM
<i>A. nothoxys</i>	Beaked milkvetch	Oakbrush, P/J woodlands	AZ
<i>A. oxyphysus</i>	Diablo loco	Desert grasslands	CA
<i>A. praelongus</i> <sup>b</sup>	Stinking milkvetch	Sandstone, shale high in Se	UT, NM, AZ
<i>A. pubentissimus</i>	Green river milkvetch	Salt-desert shrub	CO, WY, UT
<i>A. purshii</i>	Pursh loco	Sagebrush, P/J woodlands	WY, MT, ID, NV
<i>A. pycnostachyus</i>	Brine milkvetch	Salt marshes and beaches	CA
<i>A. tephrodes</i>	Ashen milkvetch	Oakbrush, P/J woodlands	AZ, NM
<i>A. thurberi</i>	Thurber milkvetch	Creosote, oak, P/J woodlands	AZ, NM
<i>A. wootoni</i>	Garbancillo	Creosote desert	AZ, NM, TX
<i>O. besseyi</i>	Red loco	Gravelly hill tops	MT, WY
<i>O. campestris</i>	Yellow loco	Prairies, mountain meadows	MT, Canada
<i>O. lambertii</i>	Lambert locoweed	Short- and mid-grass prairies	MT, ND, SD, WY, CO, NM
<i>O. sericea</i>	White locoweed	Rocky soils, foothills, and mountains	MT, SD, WY, CO, NM, UT
<b>Nitro-toxins</b>			
<i>A. atropubescens</i>	Kelsey milkvetch	Gravelly benches	ID, MT
<i>A. Canadensis</i>	Canada milkvetch	Introduced	Throughout U.S.
<i>A. convallarius</i>	Rushy milkvetch	Sagebrush	ID, NV, UT, WY
<i>A. emoryanus</i>	Red-stem peavine	Shortgrass prairies	AZ, NM, TX
<i>A. falcatus</i>		Introduced	
<i>A. miser</i>	Timber milkvetch		
var. <i>serotinus</i>	Columbia milkvetch	Rough fescue grasslands	BC Canada
var. <i>hylophilas</i>	Yellowstone milkvetch	Sagebrush/timber	WY, MT
var. <i>oblongifolius</i>	Wasatch milkvetch	Mountains, sagebrush	UT, CO
<i>A. pterocarpus</i>	Winged milkvetch	Sagebrush	CA, NV
<i>A. tetrapterus</i>	Four-winged milkvetch	Sagebrush	CA, NV
<i>A. toanus</i> <sup>d</sup>	Toano milkvetch	Salt-desert shrub	Great Basin
<i>A. whitneyi</i>		Sierra Mountains	CA, NV
<b>Selenium accumulators</b>			
<i>A. albulus</i> <sup>d</sup>	Cibola milkvetch	Salt-desert shrub	Northwestern NM, AZ
<i>A. beathii</i> <sup>c</sup>	Beath's milkvetch	Badlands	AZ, NV, UT
<i>A. bisulcatus</i>	Two-grooved milkvetch	Sagebrush	MT, WY, ND, SD, CO, UT, NM
<i>A. crotalariae</i> <sup>d</sup>	Rattle box milkvetch	Desert	AZ, CA
<i>A. cutleri</i> <sup>d</sup>			
<i>A. debequaeus</i> <sup>d</sup>			
<i>A. eastwoodiae</i> <sup>d</sup>	Eastwood's milkvetch	Badlands	Four Corners
<i>A. flavus</i>	Yellow milkvetch	Alkaline soils	Colorado Plateau
<i>A. grayii</i> <sup>d</sup>	Gray's milkvetch	Badlands	WY, MT
<i>A. moencoppensis</i>	Moenkopi milkvetch	Badlands	UT, AZ
<i>A. nelsonianus</i> <sup>d</sup>		Alkaline flats	WY
<i>A. oocalycis</i> <sup>d</sup>		Sagebrush	CO, NM
<i>A. osterhouti</i>	Osterhout milkvetch	Clay hills	Grand Co., CO
<i>A. pattersoni</i>	Patterson milkvetch	Oakbrush	Rocky Mountains
<i>A. pectinatus</i>	Tine-leaved milkvetch	Northern prairies	MT, ND, WY, CO, KA
<i>A. praelongus</i>	Stinking milkvetch	Badlands	Four Corners
<i>A. racemosus</i>	Alkali milkvetch	Badlands	Plains states
<i>A. sabolus</i>	Cisco milkvetch	Badlands	Eastern UT
<i>A. saurinus</i> <sup>d</sup>	Dinosaur milkvetch	Badlands	Eastern UT
<i>A. sophoroides</i> <sup>d</sup>	Painted desert milkvetch		AZ
<i>A. toanus</i> <sup>d</sup>	Toano milkvetch	Salt-desert shrub	Great Basin

P/J, pinyon-juniper.

From Ralphs *et al.* (2003) and Welsh *et al.* (2007).<sup>a</sup>Many varieties, especially of *A. lentiginosus*, *A. mollissimus*, and *O. sericea*, have been referred to as separate species in the past.<sup>b</sup>Also contains selenium.<sup>c</sup>Also contains nitro-toxins.<sup>d</sup>Minor species.

of field cases of poisoning or that have been shown by chemical analysis to contain swainsonine (Molyneux *et al.*, 1991).

Species of *Astragalus* and *Oxytropis* occur in every major plant community. However, livestock poisoning is erratic due to the cyclic nature of the locoweed populations. Locoweeds have different survival strategies that allow perpetuation of the species through long-term climatic cycles and short-term weather conditions (Ralphs *et al.*, 2003). Climate controls the establishment and growth of these plants by the amount and timing of precipitation. The following are the three main survival strategies:

- 1 Annual plants avoid drought by seed dormancy through dry cycles and germinate in years when sufficient moisture is available (winter annuals such as *A. wootonii* and *A. emoryanus*).
- 2 Biennial or short-lived perennial plants exhibit opportunistic survival strategies by relying on both timely and adequate moisture for germination, growth, flowering, and seed set. Seeds germinate in fall following autumn rains, persist over winter, and flower in spring. If sufficient moisture is available, they will remain for 2 or 3 years until the next drought occurs (*A. mollissimus*, *A. lentiginosus*, and *A. pubentissimus*).
- 3 Long-lived perennial plants exhibit a stress-tolerant survival strategy. They have deep taproots that can access deep stored water. They grow where moisture is more abundant and more regularly available. The plants flower and produce seed for many years following initial establishment, although they too may die out during extended droughts (*O. sericea* and *O. lambertii*).

The seed bank in the soil supports these cycles. The seeds have hard coats and remain viable for many years, thus providing an ecological advantage to exploit environmental conditions and maintain the “boom and bust” population cycles (Ralphs *et al.*, 2003). Livestock poisonings follow these cycles, often in catastrophic proportions.

### Toxicology

Locoweed poisoning was one of the first poisonous plant problems recognized by stockmen and reported as early as 1873. Extensive stock losses in the western United States eventually led to the establishment of a field station in Hugo, Colorado, in 1905 to study the problem. Research from 1905 to 1907 determined that certain species of the *Astragalus* and *Oxytropis* genera were responsible, and this research was published in 1909 as a U.S. Department of Agriculture bulletin titled “The Locoweed Disease of the Plains” by C.D. Marsh.

There are numerous effects of locoweed on animals, but the classic syndrome from which the term “locoism” derived is one of neurological dysfunction. The disease is a chronic one developing after weeks of ingesting locoweeds and beginning with depression, dull-appearing eyes, incoordination progressing to aberrant behavior including aggression, staggering, solitary behavior, and emaciation and ending in death if continued consumption is allowed. Other problems associated with locoweed ingestion include reproductive failure, abortion, birth defects, weight loss, and enhanced susceptibility to brisket disease at high elevations (Panter *et al.*, 1999b).

Locoweed poisoning affects all animals, but because of the transient nature of the poisoning, animals removed from the locoweed early in the toxicosis will recover most of their function and may be productive animals. In the final stages of locoism, central nervous system tissue shows swelling of axonal hillocks (meganeurites) and growth of new dendrites and synapses. This altered synaptic formation in nervous tissue in severely affected animals is permanent and may be the cause of some irreversible neurological signs. Because of neurological dysfunction and apparent permanence of some lesions in the nervous system, horses are believed to be unpredictable and therefore unsafe to use for riding, but they may remain reproductively sound once they have recovered from the poisoning.

### Toxin

The toxin in locoweeds is the indolizidine alkaloid swainsonine (**1**). First isolated from the Australian plant *Swainsona canescens* (Colegate *et al.*, 1979), swainsonine and its N-oxide were isolated and identified soon thereafter from the locoweeds (Molyneux and James, 1982). Remarkably, in 1909, C.D. Marsh made the connection between the clinical and pathological syndrome of locoweed poisoning and a similar condition reported in Australian livestock called “peastruck.” Confirmation feeding trials in New South Wales with Darling pea (*Swainsona* spp.) were reported a few years before Marsh reported the details of locoweed poisoning. Ironically, the toxin (swainsonine) was isolated and characterized from *S. canescens* and reported in Australia in 1979 (Colegate *et al.*, 1979) and subsequently identified and

isolated from locoweeds (*Astragalus* and *Oxytropis*) in the United States and reported in 1982 (Molyneux and James, 1982).

The isolation and characterization of swainsonine from *S. canescens* resulted from investigations by a multi-disciplinary research team in Australia whose members were experienced in various aspects of lysosomal storage diseases in domestic animals (Dorling *et al.*, 1989). This investigation concentrated on the details of the pathogenesis of the toxicosis enabling the research team to elucidate the mechanism of action, which provided the bioassay method for toxin isolation and identification. A review of the historical aspects can be found in Dorling *et al.* (1989). In essence, the locoism syndrome is a lysosomal storage disease in which  $\alpha$ -mannosidase is inhibited, resulting in prevention of hydrolysis of mannose-rich oligosaccharides in cells and accumulation of these oligosaccharides resulting in cellular dysfunction. Swainsonine has also been identified with mixtures of other glycosidase-inhibiting polyhydroxy alkaloids in toxic species of *Ipomoea*, *Sida*, *Solanum*, *Physalis*, and *Convolvulus* (Asano *et al.*, 1995; Haraguchi *et al.*, 2003). Most organ systems are affected, but some are more susceptible, such as glandular and neurological tissues. Comparative pathology of the glycosidase inhibitors swainsonine, castanospermine, and calystegines A3, B2, and C1 in mice was reported (Stegelmeier *et al.*, 2008). Although there were similar vacuolar changes, there were differences in the organ systems involved and minor changes in protein glycosylation, and it was determined that in mice calystegines and castanospermine are less toxic than swainsonine.

It has been discovered that swainsonine in *Astragalus* and *Oxytropis* species is produced by a fungal endophyte, *Undifilum oxytropis* (formerly called *Embellesia oxytropis*). A positive correlation was shown to exist between swainsonine concentrations found in the plant and concentrations of swainsonine produced by the endophytic fungus cultured from the same plant (Pryor *et al.*, 2009; Cook *et al.*, 2009a). This same correlation was demonstrated for *Oxytropis glabra*, an important poisonous plant in Inner Mongolia steppe (Ping *et al.*, 2009). Major locoweeds were screened for the presence of endophyte and swainsonine content using both culture methods and polymerase chain reaction (PCR; Ralphs *et al.*, 2008). PCR was demonstrated to be the most sensitive method of detecting the endophyte because the endophyte in plants with very low levels of swainsonine (<0.01%) was not detected by culture methods, only PCR. Oldrup *et al.* (2010) demonstrated that *U. oxytropis* is transferred by seed and the endophyte resides in the parenchyma layers of the seeds. Seedlings of *Astragalus lentiginosus* produced in embryo culture without seed coats did not contain swainsonine or the fungus. Plants produced from whole seed contained *Undifilum* in

both foliage and root tissues. Simulated environmental stresses, including high temperature, low and high pH media, nutrient-deficient media, and polyethylene glycol-amended media, impacted both dry mass and swainsonine levels.

Research results have shown that inhibition of  $\alpha$ -mannosidase is relatively transient and quickly reversible once animals stop eating locoweed (Stegelmeier *et al.*, 1994). Blood serum clearance of swainsonine is rapid (half-life of 20h); thus, the effects of locoweed should be reversible if tissue damage has not become extensive and permanent. This suggests that intermittent grazing of locoweed should be an effective means of reducing locoweed poisoning. There is also an apparent threshold dosage where severity of cell damage is more time dependent than dosage dependent. Once the threshold dosage is reached, which appears to be relatively low (0.35mg/kg in the rat), eating more locoweed does not accelerate the toxicosis. Therefore, increasing animal numbers on loco pastures and reducing time of grazing is also a logical method to reduce adverse effects.

Many locoweeds are biennials or perennials that flourish periodically under optimum environmental conditions. Historically, losses are regional and sporadic, with large regional economic impact. Individual cases of significant losses are frequent and reported in James and Nielsen (1988). In a single case, 25% of more than 500 mother cows of a university foundation herd either aborted or apparently resorbed their fetuses after grazing pastures with *O. sericea*. Necropsy of aborted fetuses showed pathological lesions characteristic of locoweed poisoning, and 50 calves born alive showed outward signs of toxicity (James, personal communication, 1994). Follow-up communication indicated that locoed calves were immunologically compromised, and 3 or 4% of these calves died after weaning. The remainder of the loco calves remained approximately 200 pounds less than calves not exposed to locoweed even though after the first 28 days in the feedlot, the rate of gain was approximately the same.

### Conditions of grazing

The early literature suggested that locoweeds were distasteful and animals were forced to start eating them because of hunger. However, once started, animals seemed to become addicted to locoweeds. Recent research showed that locoweeds are not addicting but, rather, are relatively more palatable than associated forages during various seasons of the year.

Preference for locoweed is relative to what other forage is available. Many locoweeds are cool-season species that green up and start growth early in the spring, flower, set seed and go dormant in summer, and then resume growth in fall. Livestock generally prefer the

green, growing locoweeds to dormant grass. Sheep preferred the regrowth foliage of Green River milkvetch to dormant grasses during late fall and early winter on desert range in eastern Utah. Horses selected green spotted locoweed instead of dormant grasses in spring in Arizona (Pfister *et al.*, 2003). Cattle readily grazed Wahweap milkvetch in proportion to its availability on desert winter range in southeastern Utah. In a series of grazing studies in northeast New Mexico, cattle readily grazed white locoweed in March–May but stopped grazing it in June as warm-season grasses became abundant and white locoweed matured and became coarse and rank. Stocker cattle grazed white locoweed on short-grass prairies in May and early June, but the weight loss continued throughout the summer, even though they were not eating locoweed. On mixed-grass prairies on the eastern foothills of the Rocky Mountains in northern Colorado, cattle ceased grazing white locoweed when it matured following flowering in mid-June and became rank and unpalatable. However, they continued to graze it throughout the subsequent summer when abundant summer precipitation caused locoweed leaves to remain succulent (Ralphs *et al.*, 2001).

#### ***Prevention of poisoning and management recommendations***

Prevention of poisoning remains a matter of management strategy adapted to individual grazing programs to minimize grazing of locoweed plants (Graham *et al.*, 2009). Currently, no broad management schemes or methods of treatment are known to generally prevent locoweed poisoning. Management strategies for individual operations have been developed once the grazing practices and options are identified, allowing utilization of the particular range and yet minimizing losses. It was determined that cattle generally rejected woolly loco even under extreme grazing conditions, but once they were forced to start eating it, they continued to graze it and became intoxicated. Ranchers should watch for these “loco eaters” and remove them to clean pastures. Shortage of feed with high grazing pressure, social facilitation (loco eaters teaching non-loco eaters to eat loco), or supplementing with alfalfa hay or cubes may compel cattle to start grazing woolly locoweed. White locoweed is more palatable than woolly locoweed and is green before spring grasses begin to grow in northeastern New Mexico. Therefore, cattle readily graze white loco in early spring while grasses are dormant, and once green grass starts to grow, cattle switch off of loco. Recommendations include creating loco-free pastures through spraying, fencing, or selection of low loco-infested pastures for early spring grazing and also to provide a place to move the identified loco-eaters. This practice appears to reduce the impact of locoweed on these ranges.

Many minerals, feed additives, and clay minerals have been investigated to prevent poisoning, but none have been effective. The poisonous plant literature is filled with statements that native livestock are less likely to be poisoned than new, inexperienced livestock. Locoweed poisoning does not follow this general trend. Cattle that are familiar with locoweed will likely select it first. Early observations by C.D. Marsh as early as 1909 suggested that black cattle and black-faced sheep were more inclined to be poisoned by locoweed than were white-faced cattle and sheep. In a grazing study comparing breeds, Brangus steers consumed more locoweed than did Hereford and Charolais steers. The gregarious nature of Brangus cattle may have facilitated the social acceptance of locoweed among the steers.

Livestock should be denied access to locoweeds during critical periods when they are relatively more palatable than associated forages. On short-grass prairies of northeastern New Mexico, stocker cattle should not be turned onto locoweed-infested rangelands until warm season grasses start growth in late May or early June. Cattle on rangeland year-round should be removed from locoweed-infested areas in the spring when it is green and growing and warm-season grasses remain dormant. They can be returned to locoweed-infested pastures in summer when warm-season grasses are abundant.

Most locoweed species are endemic, growing only in certain habitats or on specific soils. Fences could be constructed on soil or vegetation boundaries to provide seasonal control of grazing. Reserving locoweed-free pastures for grazing during critical periods in spring and fall can prevent locoweed poisoning.

Locoweed-free areas can be created by strategic herbicide use. White locoweed is most susceptible to Clopyralid, but Picloram and Escort are also effective. However, natural population cycles should be considered to determine the practicality of spraying large areas and the potential lifetime of control. With the abundant seed bank in the soil, locoweeds are sure to germinate and reestablish when environmental conditions are favorable.

Animals that start eating locoweed may influence others to start. Social facilitation or peer pressure is a very strong influence inducing others to start eating locoweed (Ralphs *et al.*, 1994). Graham developed the “eat and pull” management strategy, whereby livestock should be watched closely and removed if they start eating locoweed to prevent poisoning and prevent them from influencing others to start.

Grazing pressure can also force cattle to begin grazing locoweed when they run short of desirable forage (Ralphs *et al.*, 1994). Ranchers should not overstock locoweed-infested ranges but, rather, should ensure adequate forage is always available. Improper use of

some grazing systems can cause livestock to graze locoweed. Rest-rotation grazing systems are designed to force livestock to uniformly graze all forage in a pasture. This caused cattle and horses to start grazing spotted locoweed in western Utah. Changing to a three-herd, four-pasture deferred rotation grazing system stopped locoweed poisoning by reducing the grazing pressure and allowing the cattle to select alternative forages in preference to white locoweed. The heavy grazing pressure associated with short-duration grazing systems may also induce poisoning problems.

Conditioned food aversion can be used as a management tool to train animals to avoid grazing locoweed. In the conditioning protocol, animals are brought into a pen and fed fresh-picked locoweed, and then lithium chloride (an emetic that causes gastrointestinal distress) is administered by stomach tube. The animals associate the induced illness with the taste of the plant and subsequently avoid eating it. Naive animals that are unfamiliar with the target plant form strong and lasting (>3 years) aversions following a single dose. Averted animals must be kept separate from nonaverted animals on locoweed areas to prevent social facilitation from extinguishing the aversions. Aversion conditioning may be feasible where losses are heavy and persist year after year.

### Summary

Locoweed is the most widespread poisonous plant problem in the western United States. Knowledge of sites where locoweeds grow and environmental conditions when they cause problems is necessary to manage livestock and prevent poisoning. Locoweeds are relatively palatable, and many locoweeds are the first plants to start growing in the spring and they may also regrow in the fall. Livestock generally prefer the green-growing locoweeds to other forage that is dormant in the fall, winter, and spring. The most effective management strategy is to deny livestock access to locoweeds during critical periods when they are more palatable than associated forage. Reserving locoweed-free pastures or controlling existing locoweed populations with herbicides can provide "safe" pastures for critical periods. Watching animals closely and removing those that begin eating locoweed can prevent further intoxication and prevent them from influencing others to start. Finally, conditioned food aversion is an effective practice to train animals to avoid eating locoweeds, and it may be economical where losses are large and persistent. Good range management and wise grazing strategies can provide adequate forage for livestock and avoid critical periods of the year when locoweed is relatively more palatable than associated forages.

## Nitro-containing *Astragalus* (milkvetches)

There are more than 260 species and varieties (356 taxa) of nitro-containing *Astragalus* in North America (Barneby, 1964; Welsh *et al.*, 2007). They are frequently referred to as milkvetches, as are some of the other *Astragalus* species. Nitro-toxins are therefore the most common toxin in the *Astragalus*, followed by swainsonine (loco) and selenium. Major livestock losses occur in many regions of the western United States. These plants are very diverse and concentrated on the deserts, foothills, and mountains of the west.

### Description

The description of these plants is the same as that of the locoweeds. The milkvetches emerge from late April to June depending on elevation and snow cover. After seed dispersal in July or August, the stems and leaves become dry and less dangerous as toxicity and palatability are reduced.

### Distribution

The aliphatic nitro-containing *Astragalus* are distributed throughout North America, with substantial livestock losses occurring in the 17 western states where cattle or sheep are concentrated in areas of milkvetch infestation (Table 77.1). There are examples of a number of *Astragalus* spp. such as *A. cicer* that are good forages and apparently contain low levels of the toxins discussed. Because of the extent of this group of *Astragalus*, only a few of those implicated in poisonings are mentioned here. For a more comprehensive review of the nitro-containing *Astragalus*, the reader is referred to Williams and Barneby (1977). Examples of these include *A. emoryanus* (emory milkvetch) in New Mexico, Texas, and Arizona (*A. emoryanus* also contains swainsonine); *A. tetrapteris* (four-winged milkvetch) in Oregon, Utah, Nevada, and Arizona; *A. pterocarpus* (winged milkvetch) in Nevada; and *A. miser* var. *serotinus*, *A. miser* var. *oblongifolius*, and *A. miser* var. *hylophylus* (collectively referred to as timber milkvetch) in western Canada, Montana, Idaho, Utah, Colorado, and Wyoming.

### Toxicology

The nitro-containing *Astragalus* species cause an acute and chronic type of poisoning in sheep and cattle. The acute form results in weakness, increased heart rate, respiratory distress, coma, and death. Although blood methemoglobin is high (induced from nitro-toxin metabolism to nitrites) and a contributing factor to the respiratory difficulties, administration of methylene blue in cattle does not prevent death. Therefore, the methemoglobinemia is apparently not the primary cause of death. The chronic form is the most frequent form of poisoning

observed and follows a course of general weakness, incoordination, central nervous system involvement resulting in knuckling of the fetlocks, goose stepping, clicking of the hooves, "cracker heels" progressing to paralysis, and death. A respiratory syndrome is also present in the chronic and acute forms, with emphysema-like signs causing the animals to force respiration: "roaring disease." Sheep manifest the respiratory syndrome more than the central nervous syndrome and are more resistant to poisoning compared to cattle.

The toxic principles are  $\beta$ -D-glycosides of 3-nitro-1-propanol (NPOH) or 3-nitropropionic acid (NPA). The glycoside conversion occurs more readily in the ruminant because of the microflora and is apparently the reason for increased toxicity in ruminants. The glycoside (miserotoxin) is metabolized to the highly toxic NPOH in the gastrointestinal (GI) tract of ruminants (Williams *et al.*, 1970). Thus, NPOH is absorbed in the gut and apparently converted to NPA by the liver. Further metabolism yields inorganic nitrite and an unidentified metabolite that may be involved in toxicity. It appears that NPOH is more rapidly absorbed from the gut than is NPA; therefore, forage containing the alcohol form is the most toxic.

#### Prevention and treatment

There is no preferred treatment for milkvetch poisoning, although treatment with methylene blue appears to reverse the methemoglobinemia but does not prevent death in cattle. Oxidation of NPOH to NPA was prevented if alcohol dehydrogenase was saturated with ethanol or inhibited with 4-methylpyrazole before NPOH was given. This suggests that NPOH is a good substrate for the enzyme alcohol dehydrogenase. This information could be useful in acute cases; however, its value in treatment of poisoning in the field is unknown.

Livestock losses can be reduced by decreasing the density of the *Astragalus* species with herbicides or avoiding grazing livestock on infested areas when the plant is most poisonous. Wasatch milkvetch contains the highest concentration of miserotoxin from bloom to immature pod stage of growth. Nitro compounds are found in all parts of the plant, but the leaves contain the highest concentration. Once the leaves begin to dry and lose their green color, the nitro levels drop very rapidly and the plant is relatively nontoxic. However, the toxins in plants pressed green and preserved in herbaria appear to remain stable for years (Williams and Barneby, 1977). Herbicide treatment decreases the density of plants and also decreases the toxicity of the plants once they start to dry; therefore, spraying milkvetch appears to be the best method to reduce losses and still utilize infested ranges.

### Seleniferous *Astragalus*

Approximately 22–24 species of *Astragalus* known to accumulate selenium (Se) have been identified (Rosenfeld and Beath, 1964; Welsh *et al.*, 2007). These are less numerous and more geographically restricted than the nitro-containing species. Many of these species are referred to as Se-indicator plants because they only grow on soils high in bioavailable selenium; therefore, they are helpful in locating and identifying areas or soils high in selenium. The *Astragalus* are generally deep rooted plants and may bring selenium from deeper soil profiles unavailable to other plants so that it is available and can subsequently be taken up by grasses and other forbs. It is these facultative accumulators that create most of the subacute or chronic toxicity problems for livestock.

#### Description

The selenium-containing *Astragalus* species appear similar to those of locoweed and nitro-containing species as discussed previously. One identifying feature of the selenium-containing *Astragalus* species is an unpleasant garlic-like odor of the volatile selenium compound dimethyl diselenide, especially if picked and allowed to sit in a warm car or window. The Se-indicator plants are generally considered to be unpalatable to livestock because of their high selenium content. Some *Astragalus* species have been shown to accumulate selenium at concentrations of up to 10 mg Se/g (dry weight) while growing on soils containing 2–10  $\mu$ g Se/g. The majority of selenium in accumulator plants is found as organic methylselenocysteine and selenocystathionine or as inorganic selenate. Many selenium-containing *Astragalus* may also contain other toxins; for example, *A. praelongus* and *A. bisulcatus* contain swainsonine (the loco toxin), and *A. toanus* contains nitro-toxins and swainsonine in addition to selenium.

#### Distribution

The selenium-containing *Astragalus* species are limited in their distribution to geographical locations and soil sites of high selenium (Table 77.1), of which most are alkaline in nature, causing selenium to be oxidized and making it soluble and available to plants. Major seleniferous areas of the west are in North and South Dakota, Montana, Wyoming, Colorado, and Utah, with minor isolated pockets of seleniferous soils in most of the other western states.

The *Astragalus* species most associated with selenium poisoning include *A. bisulcatus* (two-grooved milkvetch), *A. praelongus* (stinking milkvetch), *A. pattersonii* (Patterson milkvetch), *A. pectinatus* (tiny-leaved milkvetch), and *A. racemosus* (alkali milkvetch).

### Toxicity

With selenium poisonings, one may observe acute, sub-acute, or chronic selenosis depending on the daily dose and duration of exposure. Acute cases of selenium poisoning are rare and usually involve animals that have been exposed by one of three methods. First, livestock graze forages that have accumulated selenium from seleniferous soils. Second, selenium toxicosis occurs from environmental contamination from agricultural drain water, reclaimed soils from phosphate or ore mining, or from fly ash. Third, acute selenosis can be caused by accidental overdosing with organic selenium or Bo-Se in the treatment of white muscle disease or by misformulated feed mixes. The signs of acute selenium poisoning include diarrhea, unusual postures, increased temperature and heart rate, dyspnea, tachypnea, respiratory distress, prostration, and death (Tiwary *et al.*, 2006). Gross pathological findings are usually limited to pulmonary congestion and hemorrhage and pulmonary edema. Histologically, multifocal myocardial necrosis and pulmonary alveolar vasculitis are common (Tiwary *et al.*, 2006).

Chronic selenium poisoning is common and referred to as alkali disease because most areas with high concentrations of available selenium are alkaline in nature. Chronic selenosis occurs from prolonged ingestion of seleniferous forages containing 5–40 ppm Se. Clinical signs include rough coat, hair or wool loss, poor growth, emaciation, abnormal hoof growth and lameness, dermatitis, and depressed reproduction (Rosenfeld and Beath, 1964; Raisbeck, 2000). In swine, a condition of paralysis (poliomyelomalacia or polioencephalomalacia) often occurs with cervical or lumbar involvement (Panter *et al.*, 1996b). The description of a second chronic syndrome in cattle called “blind staggers” has been redefined and is now believed to be polioencephalomalacia induced by high sulfate water or high sulfate forage sources.

Selenium is found in plants in both inorganic and organic forms. The organic forms are more bioavailable than the inorganic forms, resulting in higher tissue concentrations when administered at equivalent doses (Tiwary *et al.*, 2006; Davis *et al.* 2011). Although a dramatic difference in tissue selenium uptake between organic (selenomethionine) and plant (*A. bisulcatus*) forms and inorganic (sodium selenate) forms occurs, the clinical and pathological syndromes are similar – that is, poliomyelomalacia in pigs (Panter *et al.*, 1996b) and pulmonary edema and hemorrhage in sheep (Tiwary *et al.*, 2006; Davis *et al.* 2011).

### Prevention of poisoning

There is no treatment for selenium poisoning except removal of the source, allowing spontaneous recovery

in chronic cases. Monitoring soils in a particular area and understanding the plant communities can provide the management information to avoid poisoning. In areas where selenium is a problem, many ranchers have switched to grazing steers because of decreased reproductive efficiency in cows. Sheep appear to be more resistant to chronic selenosis compared to cattle and are better adapted for some of these ranges. However, sheep are sensitive to acute selenium poisoning, as was observed when a large number of sheep died within days after grazing on mine reclamation sites that contained very high soil and plant selenium concentrations (Panter, personal communications, 2004). Monitoring for selenium concentrations and forms in soil, vegetation, as well as animal tissues and hair can help avoid poisoning incidences. Likewise, deficiency problems can be rapidly resolved with frequent monitoring and supplementation.

## LARKSPURS (*DELPHINIUM* SPP.)

There are more than 80 wild species of larkspurs in North America, and there are a larger number of domestic horticultural varieties. Wild larkspurs are classified into three general categories based primarily on mature plant height and distribution: low, tall, and plains larkspurs (Figure 77.2). The dominant larkspur species in the western United States are shown in Table 77.2. The larkspurs are a major cause of cattle losses on western ranges. As early as 1913, C.D. Marsh reported that

FIGURE 77.2 Low larkspur (*Delphinium bicolor*) is on the left and tall larkspur (*D. barbeyi*) is on the right.

TABLE 77.2 Characteristics of the dominant larkspur species in western North America

Class/species	Height at maturity (cm)	Elevation (m)	Associated plant communities	Toxicity ranking <sup>a</sup>	Typical risk of losses <sup>b</sup>
<b>Tall larkspurs</b>					
<i>D. glaucum</i> <sup>c</sup>	90–200	>2000	Aspen, conifers, alpine meadows	1	Low
<i>D. barbeyi</i>	90–180	>2200	Aspen, conifers, alpine meadows, mountain brush, alpine tundra	2	Moderate to severe
<i>D. glaucescens</i>	76–90	>2000	Mountain meadows, sagebrush	3	Low to moderate
<i>D. occidentale</i>	90–180	>2000	Mountain brush, sagebrush, conifer, aspen	4	Low to severe
<b>Low larkspurs</b>					
<i>D. nuttallianum</i>	20–60	>1200	Mountain brush, sagebrush, aspen, conifer, mountain and foothill meadows	2	–
<i>D. bicolor</i>	20–40	>800	Mountain brush, sagebrush	–	–
<i>D. andersonii</i>	10–60	>1200	Desert shrub, mountain brush, sagebrush, pinyon–juniper	1	–
<b>Plains larkspur</b>					
<i>D. geyeri</i>	40–80	>1500	Desert shrub, mountain brush, sagebrush, short-grass prairie	–	–

<sup>a</sup>Tall larkspur and low larkspur species are each ranked according to the concentration of toxic alkaloids, from greatest (1) to least (4).

<sup>b</sup>The risk of losing cattle to tall larkspur species is a subjective evaluation based on plant toxicity, numbers of grazing cattle threatened during the growing season, and the geographical distribution of the larkspur species. *Delphinium glaucescens* is relatively more toxic late in the growing season compared to mature plants of the other tall larkspur species. Spatial and temporal variability in plant density and toxicity preclude making such a risk assessment ranking for low larkspurs and plains larkspur.

<sup>c</sup>*D. glaucum* = *D. brownii* in Canada; livestock losses to *D. brownii* in Canada may greatly exceed those of *D. glaucum* in the United States.

more cattle deaths on western ranges are caused by *Delphinium* spp. than by any other poisonous plant except locoweed.

## Description

Most of the wild larkspurs have flowers of blue or purple, bilaterally symmetrical, in erect terminal racemes or panicles: five sepals, the upper prolonged backwards in a prominent spur; petals smaller and variable among species, usually four and sometimes two, with the upper pair projecting back inside the spur; and carpals one to five, sometimes fused, ripening into many-seeded follicles.

The tall larkspurs (Figure 77.2) are 1 or 2 m tall or more, flower in summer, and set seed in late summer, subsequently senescing in the fall. In the west, the tall larkspurs typically inhabit higher mountain elevations in the more open moist areas of canyons, draws, and meadows. *Delphiniums* are frequently confused with *Aconitum*, but certain features distinguish them. As implied by the common names, *Delphiniums* have a distinct spur (hence larkspur), whereas *Aconitum* has no spur but a hood (hence monkshood). Tall larkspurs have hollow stems, and their leaves are relatively long petioled, whereas monkshood has stems that are solid and pithy and leaves are short petioled.

Low larkspurs (Figure 77.2) appear similar to tall larkspurs except they grow in different habitats and

locations – that is, lower elevations in drier habitats, on foothills and flats. They appear first as a rosette-like clump in early spring, soon producing an erect flowering stem, usually not more than 1 m in height, and then die back in early summer.

Plains larkspur falls between the low and tall larkspur classifications. Plants range from 0.3 to 2 m tall. It grows on the short-grass plains of Wyoming into Nebraska and in the sagebrush and juniper woodlands of the Colorado Plateau.

## Distribution and habitat

### Low larkspur

*D. nelsonii* – Idaho, South Dakota, Wyoming, Colorado, and Utah

*D. bicolor* – North Dakota, Montana, Wyoming, Oregon, and Washington

*D. andersonii* – Oregon, California, Nevada, Utah, and Idaho

*D. tricornis* – Nebraska and Oklahoma eastward

*D. virescens* – Great Plains, east of the Rockies

### Intermediate larkspur

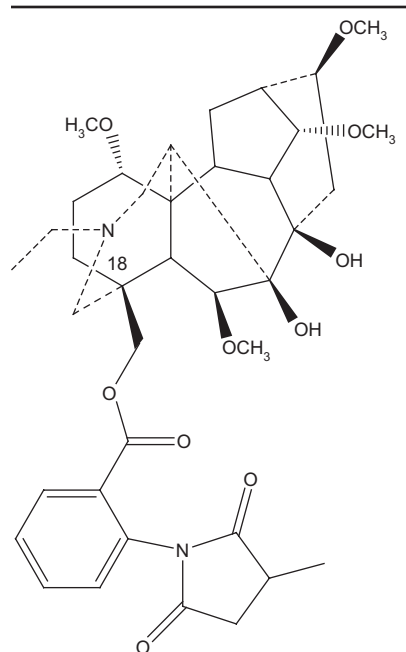

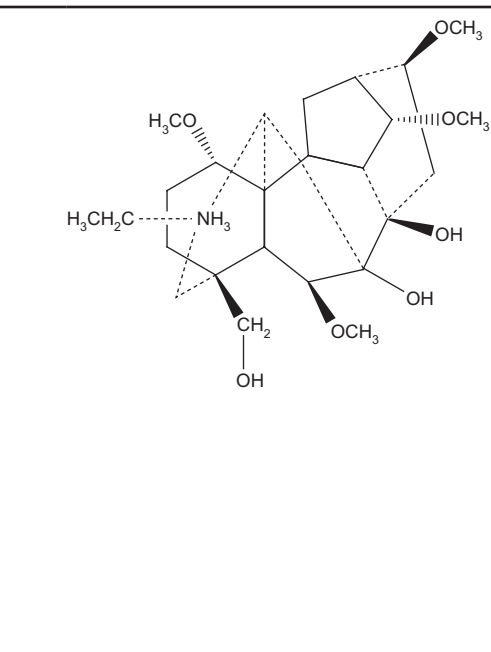

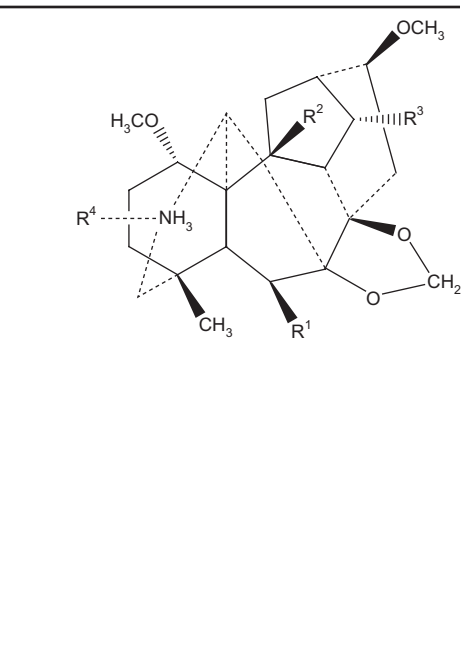

*D. geyeri* – Colorado, Wyoming, Nebraska, and Utah

### Tall larkspur

*D. barbeyi* – Utah, Wyoming, Colorado, and New Mexico

*D. occidentale* – Washington, Idaho, Wyoming, Nevada, Utah, and Colorado

## Toxicology

Larkspurs (*Delphinium* spp.) are a serious toxic problem for cattle on foothill and mountain rangelands in western North America. The toxicity of larkspur plants is due to norditerpenoid alkaloids, which occur as one of two chemical structural types – the 7,8-methylenedioxylycoctonine (MDL) type and the *N*-(methylsuccinimido) anthranoyllycoctonine (MSAL) type. Although the MSAL-type alkaloids are much more toxic (typically >20×) (Panter *et al.*, 2002), the MDL-type alkaloids are generally more abundant in *D. barbeyi* and *D. occidentale* populations (Gardner *et al.*, 2002). Three MSAL-type alkaloids that are of primary concern are methyllycaconitine (MLA (2)), 14-deacetylnudicauline (DAN), and nudicauline (NUD). MLA and DAN occur

to some extent in all classes of larkspurs, whereas NUD occurs only in low and plains larkspurs. The LD<sub>50</sub> for NUD, MLA, and DAN in mice is 2.7, 4.8, and 4.0 mg/kg intravenously (i.v.), respectively (Table 77.3; Panter *et al.*, 2002). The toxic alkaloid concentration of the tall larkspur (*D. barbeyi*) dosed to cattle in a lethality study was not determined. However, data from a pen study in which Hereford cattle were dosed via oral gavage with ground plant material indicate that a lethal dose of *D. glaucum* is approximately 2.5 g dried plant material/kg body weight (BW) (unpublished observations). The lethal dose in a grazing situation, however, may be quite different due to the fact that tall larkspur is often ingested repeatedly over 2–4 days.

There are two primary structural features necessary for toxicity: (1) an *N*-ethyl bicyclo tertiary alkaloid nitrogen atom and (2) a C-18 anthranilic acid ester. Other studies have also shown that MLA's aromatic ester function is a significant haptophore and that the succinimide group imparts significant toxicity to alkaloids. Two other structural features also enhance toxicity: (1) functionality at the anthranilic acid amine nitrogen and (2) functionality at C-14 (Panter *et al.*, 2002).

Tall larkspur species vary substantially in toxicity, with a relative ranking (most to least toxic, based on the MSAL alkaloid content) of *D. glaucum* (*D. brownii* in Canada), *D. barbeyi*, *D. glaucescens*, and *D. occidentale*. Generally in tall larkspurs, the concentration of MLA and DAN is highest in immature plant tissue. MLA concentrations in immature tall larkspurs may exceed 20 mg/g. Before shattering, tall larkspur pods are relatively high in toxicity (MLA + DAN = 7–12 mg/g). Toxicity declines rapidly in tall larkspurs once pods begin to shatter. Measuring plant toxicity early in the growing season may allow prediction of season-long toxicity and risk (Ralphs *et al.*, 2002).

Due to the fact that the MSAL-type alkaloids are much more toxic than the MDL-type alkaloids, management recommendations for grazing cattle on larkspur-containing ranges are based primarily on the concentration of MSAL-type alkaloids in larkspur (Pfister *et al.*, 2002; Ralphs *et al.*, 2002). However, in many species of tall larkspur, the MDL-type alkaloids are generally more abundant (Pfister *et al.*, 1999; Gardner *et al.*, 2002). Research using a mouse model suggested that MDL-type alkaloids enhance the overall acute toxicity of MLA in an additive manner (Welch *et al.*, 2008). In subsequent studies with cattle, the MSAL-type alkaloids such as MLA were the primary factors responsible for the toxicity of larkspur plants (Welch *et al.*, 2010). However, populations of larkspur plants that contained large amounts of MDL-type alkaloids, in addition to high MSAL-type alkaloid content, were found to be more dangerous to cattle than plants with only high MSAL-type alkaloids.

Consequently, for a larkspur plant to be toxic to livestock, a sufficient quantity of MSAL-type alkaloids is required. However, MDL-type alkaloids appear to potentiate the overall toxicity of the MSAL-type alkaloids and should be considered when predicting potential toxicity of larkspur populations. Therefore, when chemical analyses are performed on larkspur plants to assess their toxic potential, the concentration of both the MSAL-type and the total alkaloids should be determined, with more weight given to the MSAL-type alkaloids.

MLA and NUD are the dominant toxic alkaloids in low larkspurs, with concentration ranges of 0.8–4.5 and 1–4 mg/g, respectively, for MLA and NUD in low larkspur populations (*D. nuttallianum* and *D. andersonii*) in Utah, Colorado, and Arizona (Gardner, unpublished data). Reports of very high concentrations of MLA (up to 8.7 mg/g) in vegetative low larkspur (*D. nuttallianum*) from Canada were contrasted with a concentration of 2 mg/g in flowering plants (Bai *et al.*, 1994). Unlike tall larkspurs, concentrations of toxic alkaloids in low larkspurs do not decline precipitously after senescence (Gardner, unpublished data). MLA is the major toxic alkaloid in plains larkspur (*D. geyeri*), with concentrations ranging from 1 to 4 mg/g in Wyoming and Colorado. We emphasize that NUD is more toxic than MLA, and both alkaloids are frequently found together in low larkspurs (Gardner, unpublished data). Thus, the potential lethality of low larkspurs can be highly variable depending on alkaloid concentrations and plant density.

The primary result of larkspur toxicosis is neuromuscular paralysis from blockage at the postsynaptic neuromuscular junction (Benn and Jacyno, 1983). MLA also elicits central effects in mice and rats (Stegelmeier *et al.*, 1998). Larkspur alkaloids compete as postsynaptic inhibitors of acetylcholine particularly at  $\alpha_1$  nicotinic sites (Dobelis *et al.*, 1999). MLA strongly competes with  $\alpha$ -bungarotoxin at nicotinic acetylcholine receptors (nAChRs). Larkspur alkaloid binding to nAChRs appears to be correlated with toxicity in various tissues and may explain sheep tolerance to larkspur if larkspur toxins bind less avidly to nAChRs in sheep (Stegelmeier *et al.*, 1998).

Clinical signs of intoxication include muscular weakness and trembling, straddled stance, periodic collapse into sternal recumbency, respiratory difficulty, and death while in lateral recumbency. An effective dose of larkspur causes labored breathing, rapid and irregular heartbeat, and collapse but not death. The effective i.v. dose for purified MLA is 2 mg/kg BW in calves versus 10 mg/kg in sheep given a single injection (Panter, unpublished data). Nation *et al.* (1982) reported that an effective dose of MLA in cattle receiving two i.v.

injections was 1.1 mg/kg. Conversely, the effective i.v. dose for deltaline in both calves and sheep is 50 mg/kg (Panter, unpublished data). Cattle typically show clinical signs (i.e., tremors and periodic collapse) when given an MLA + DAN dose (i.e., via ground plant) of  $20 \pm 3$  mg/kg BW (Pfister *et al.*, 1994). Stress and/or exertion will reduce the effective dose. Assuming an MLA + DAN concentration of 5 mg/g (dry wt), a 450-kg cow may show clinical signs after rapidly eating 1.8 kg (dry wt) of tall larkspur ( $\approx 7.2$  kg wet wt).

Key factors in larkspur intoxication are the amount eaten and the rate of ingestion. Studies utilizing direct observations of grazing animals have provided a number of insights into the amount and timing of tall larkspur ingestion. More than 10 such studies have been conducted since 1986 and have led to two major conclusions: (1) cattle eat little or no tall larkspur before the plant has elongated flowering racemes, and (2) weather patterns are very important determinants of larkspur consumption (Pfister *et al.*, 1999). Cattle often eat more tall larkspur during summer storms and reduce larkspur consumption during drought for reasons that are not clear. Another variable that may play a role in the susceptibility of cattle to larkspur toxicosis is breed differences. Anecdotal observations of differences in the susceptibility of different breeds of cattle to larkspur toxicosis have been supported using a rodent model in which different strains of mice had up to a twofold difference in LD<sub>50</sub> to MLA (Welch *et al.*, 2009a).

Cattle generally begin consuming tall larkspur after flowering racemes are elongated, and consumption increases as larkspur matures. Consumption usually peaks during the pod stage of growth in late summer, when cattle may eat large quantities (25–30% of diet as herd average; >60% on some days by individual animals). Because larkspur toxicity generally declines throughout the growing season and cattle tend to eat more larkspur after flowering, the period of greatest danger has been termed a “toxic window” (Pfister *et al.*, 2002). This toxic window extends from the flower stage into the pod stage, or approximately 5 weeks depending on temperature and elevation (Figure 77.3). Many ranchers typically defer grazing on tall larkspur-infested ranges until the flower stage to avoid death losses. This approach wastes much valuable forage and often places cattle into larkspur-infested pastures when risk of losses is high. An additional 4–6 weeks of grazing may be obtained by grazing these ranges early, before larkspur elongates flowering racemes. The risk of losing cattle is low when grazing before flowering, even though larkspur is very toxic, because larkspur consumption is typically very low. Once pods are mature and begin to shatter, larkspur ranges can usually be grazed with impunity because pod toxicity declines rapidly, and leaf

**FIGURE 77.3** Relationship between toxicity and palatability in tall larkspurs. Most cattle deaths are predicted to occur during the toxic window when the concentration of toxic alkaloids is relatively high and consumption by cattle begins to increase after flowering racemes elongate. There is a low-risk grazing window early in the season before flowering when larkspur is generally very toxic but risk is low because cattle typically eat little tall larkspur during this phenological stage. There is also a low-risk grazing window in late summer after pods shatter.

toxicity is low. Based on limited study, cattle increase consumption of low larkspur after flowering, and increases in grazing pressure increase amounts of low larkspur eaten by cattle. No consistent consumption patterns of plains larkspur (*D. geyeri*) by cattle were found; thus, management recommendations need to be tailored to each specific year and location (Pfister *et al.*, 2002).

Studies have been performed to characterize the kinetic profile of larkspur alkaloids in cattle (Green *et al.*, 2009b, 2011). In these studies, the elimination half-life of MLA from cattle dosed once with dried and finely ground larkspur via oral gavage was approximately 20 h. In addition, the  $T_{max}$ , or time to maximal toxin concentration, was approximately 10 h. These data suggest that cattle that have consumed larkspur will be most susceptible to poisoning 10 h after consumption, and that after the cattle have stopped consuming larkspur, greater than 99% of the toxins will be eliminated after 6 days.

## Prevention and management of poisoning

### Grazing management

A simple and low-risk grazing management scheme can often be used based simply on tall larkspur growth and phenology: (1) graze during early summer when sufficient forage is available until larkspur elongates flowering racemes (4–6 weeks depending on elevation and

weather); (2) remove livestock, or contend with potentially high risk from flowering to early pod stages of growth (4 or 5 weeks); and (3) graze with low risk during the late season when larkspur pods begin to shatter (4–6 weeks). This scheme can be refined substantially if livestock producers periodically obtain an estimate of the toxicity of tall larkspur, and if ranchers spend time periodically observing and documenting larkspur consumption by grazing cattle.

Management to reduce losses to low larkspur begins with recognition of the plant during spring. Vegetative low larkspur plants will typically begin growth before the major forage grasses. Low larkspur populations fluctuate with environmental conditions (Pfister, unpublished data). Risk of losing cattle is much higher during years with dense populations. During those years, recognizing the plant, and finding alternative pasture or waiting to graze infested pastures for 4–6 weeks until the low larkspur has dried up, will reduce losses. In addition, it is recommended that animals not be watered or provided mineral supplementation in areas that have high densities of larkspurs.

#### *Graze sheep before cattle*

Sheep can be herded into or bedded on the patches to reduce larkspur availability or acceptability to cattle on tall larkspur-infested ranges where larkspur grows as discrete patches. In those areas in which larkspur is uniformly spaced over a pasture, sheep must eat immature larkspur and leave sufficient feed for subsequent grazing by cattle. This can be problematic because early growth tall larkspur may not be palatable to sheep. Our observations (Pfister, unpublished data) indicate that sheep eat little low larkspur (*D. nuttallianum*) unless a high stock density is used.

#### *Drug intervention*

A variety of remedies have been applied in the field when ranchers find intoxicated animals (e.g., bleeding by cutting the tail), but most are without a solid scientific rationale. Any imagined success with these treatments was probably related to the dose. If less than a lethal dose were ingested, the animal would likely recover despite any treatment, unless bloat or aspiration pneumonia occurred during recumbency. Treatment for overt poisoning is usually symptomatic, and recovery is often spontaneous if animals are not stressed further by driving. Once the animal is observed showing muscular tremors, it should be allowed to drop back and proceed at its own pace. Poisoned animals should never be forced to continue moving because this will exacerbate the clinical effects and can result in death. Drugs that increase acetylcholine effectiveness at the neuromuscular

junction have potential for reversing larkspur toxicosis or reducing susceptibility. The cholinergic drug physostigmine (0.08 mg/kg i.v.) has been successfully used under field and pen conditions to reverse clinical larkspur intoxication (Nation *et al.*, 1982; Pfister *et al.*, 1994). Similarly, i.v. administration of neostigmine (0.04 mg/kg) significantly reduced clinical signs in cattle (Green *et al.*, 2009a), and neostigmine administered intramuscularly at 0.02 mg/kg can be used as a rescue treatment for cattle in recumbency. This reversal lasts approximately 2 h, and repeated injections of physostigmine are sometimes required. Under field conditions, physostigmine temporarily abates clinical signs and animals quickly (~15 min) become ambulatory. Depending on the larkspur dose, the intoxication may recur. The use of physostigmine-based treatments may aggravate losses in the absence of further treatment if suddenly ambulatory animals later develop increased muscular fatigue, dyspnea, and death.

#### *Herbicidal control*

Larkspur losses can be greatly reduced if dense larkspur populations are reduced by herbicides. Picloram, metsulfuron, and glyphosate have proven to be effective in killing tall larkspurs when applied at specific growth stages (Ralphs *et al.*, 1991). These herbicides do not reduce toxic alkaloid concentrations in treated larkspur plants, and metsulfuron may increase toxicity. Therefore, sprayed areas should not be grazed until the following growing season.

## LUPINES (*LUPINUS* SPP.)

The *Lupinus* genus contains more than 150 species of annual, perennial, or soft woody shrub lupines. More than 95 species occur in California alone. The lupines are rich in alkaloids, responsible for most of the toxic and teratogenic properties. There are domestic lupines that through plant breeding are low in alkaloid content and have been selected for ornamental purposes or for animal and human food. Only those range lupines known to cause poisoning or birth defects are discussed here.

Stockmen have long recognized the toxicity of lupines when livestock, particularly sheep, were poisoned in the fall by the pods and seeds of lupine. Major losses in sheep were reported in the 1950s, and individual flock losses of hundreds and even thousands were reported. Lupines are also poisonous to other livestock, and field cases of poisoning in cattle, horses, and goats have been reported. However, the most recognized condition of lupine ingestion is the “crooked calf syndrome,” a congenital condition in calves resulting in skeletal contracture-type malformations and cleft palate after their

FIGURE 77.4 *Lupinus leucophyllus*.

mothers have grazed lupines during sensitive periods of pregnancy (Panter *et al.*, 1999a,b). The condition was first reported in 1959 and experimentally confirmed after large outbreaks in Oregon and Montana in 1967.

## Description

Lupines belong to the Leguminosae family, with alternate palmately compound leaves with 5–17 oblong to lanceolate leaflets (Figure 77.4). Flowers are terminal legume-like and can be blue, purple, white, yellow, or reddish. The seeds are flattened in legume-like pods. Range lupines are generally low, perennial or annual forbs, and species and varieties are taxonomically difficult because extensive hybridization occurs and the literature may be somewhat confusing in this regard.

The plant grows early in spring, flowering in early to mid-summer, and forms pods in late summer or early fall. Seedlings may germinate in fall if temperature and moisture are conducive for seed germination. Some lupines are annuals and others are woody and shrub-like; however, neither the annual nor the woody species have been reported in livestock poisoning.

Chemical profiles (chemo-taxonomy) can support or contradict taxonomic identification, and this is a valuable resource if included in a voucher specimen, especially if the identified species is implicated in toxicoses or teratogenicity and is identified by geographical location. Cook *et al.* (2009b) demonstrated this variability in a single species, *Lupinus sulphureus*, which is yellow lupine species, selected from herbaria or collected from different geographical regions of Oregon, Washington, and British Columbia. A total of seven distinct alkaloid

profiles were reported, and each alkaloid profile was unique in its geographical distribution and its potential risk to livestock. A collection near Pendleton, Oregon, came from a population that was responsible for a significant outbreak of crooked calf syndrome in a herd of cattle (56% loss) and the alkaloid profile showed high levels of the teratogen anagyrene (Panter *et al.*, 1997). Therefore, taxonomic classification without chemical support is of little value in predicting risk of crooked calf syndrome.

## Distribution

Most species of lupines grow in states and provinces from the Rocky Mountains westward. They are classified as increaser species; that is, they increase in abundance following disturbance from overgrazing or fire, to the point that they may dominate the plant community at times. Their populations also cycle, increasing in wet years and dying back during drought. Table 77.4 lists species involved in toxicity and their common names, habitats, and geographical distribution.

## Toxicology

Most lupine species contain quinolizidine alkaloids, a few contain piperidine alkaloids, and some contain both. The specific alkaloids responsible for crooked calf syndrome are anagyrene (3), ammodendrine (4), and

TABLE 77.4 Lupine species known to be toxic or teratogenic

Scientific name	Common name	Habitat	Distribution
<i>L. alpestris</i>	Mountain silvery lupine	Dry rocky soils	CA to MT, CO and AZ
<i>L. arcticus</i>			AK, British Columbia
<i>L. andersonii</i>	Anderson's lupine	Mountain meadows and clearings	Sierra Nevada, CA to 2900 m elevation
<i>L. arbustus</i>	Spur lupine	Dry open hillsides	NV, CA to CO, western MT
<i>L. argenteus</i>	Silvery lupine	1200–1500 m elevation; dry flats, slopes, woods, open hillsides	CA to MT, NM, OR, ID, UT, NV
<i>L. caudatus</i>	Tail cup lupine		CA, OR, ID to UT, NV
<i>L. cyaneus</i>			MT
<i>L. formosus</i>	Lunara lupine	Dry flats	CA
<i>L. greenei</i>		Plains and hills	WY, NV, CO, AZ
<i>L. latifolius</i>	Broad-leaved lupine	Mountain meadows, stream banks	Pacific states
<i>L. laxiflorus</i>	Spurred lupine	Hillsides, dry soils	WA, OR, ID
<i>L. leucophyllus</i>	White-leaved lupine, poison lupine	Dry soils	WA, MT, UT, CA
<i>L. nootkatensis</i>	Nootka lupine		AK
<i>L. onustus</i>	Plumes lupine	Open pine wood	CA
<i>L. polyphyllus</i> (five varieties)	Meadow lupine	Mountain meadows, banks	WA, British Columbia
<i>L. pusillus</i>	Rusty lupine, small lupine	Dry plains	British Columbia to KS, NM, AZ
<i>L. sericeus</i>	Silky lupine	Dry hills, valleys	UT, WY to MT, British Columbia
<i>L. sulphureus</i>	Yellow lupine	Open hillsides	OR

N-methyl ammodendrine. Hence, risk is based on chemical profile and the presence and concentration of these teratogenic alkaloids. It is known that chemical profile and concentration differ, resulting in changing levels of toxicity within and between species and populations. The chemical phenology has been studied in *L. caudatus* and *L. leucophyllus* (Lee *et al.*, 2007b). Total alkaloid concentration is high in the new early growth but diluted as the plant biomass increases. Pools of total alkaloids increase during the phenological growth stages and peak at the pod stage, concentrating in the pods. The teratogenic alkaloid anagryne appears to be an end product in the biosynthetic pathway and accumulates in the floral parts and is stored in the seed. Following seed shatter, both concentration and pools of all alkaloids decline precipitously, leaving the senescent plant relatively nontoxic.

Stockmen recognize the toxicity of lupines in the fall when the pods and seeds are ripe. Historically, lupines were responsible for more sheep deaths than any other single plant in Montana, Idaho, and Utah. Most losses occurred from hungry sheep grazing seed pods. Poisoning occurred following trucking or trailing bands in late summer or fall or after getting caught in early snowstorms that covered herbaceous vegetation. Hungry sheep nonselectively grazed lupine pods, which are highest in alkaloids, and were poisoned. Large losses have also occurred when lupine hay harvested in the seed pod stage was fed in winter. Seeds alone

can be toxic to sheep at 0.25–1.5% of their body weight depending on alkaloid composition. A few cases of poisoning occurred on young plants. Losses of 80–100 sheep in multiple bands have been reported during the past 5 years in Idaho and Wyoming (Panter, personal communication, 2005).

Poisoning by lupine plants should not be confused with lupinosis reported in Australia. This condition is entirely different and is a mycotoxicosis of livestock caused by toxins produced by the fungus *Phomopsis leptostromiformis*, which colonizes domestic lupine stubble. It affects livestock that graze lupine stubble and limits the use of this animal feed in Australia.

The lupine-induced crooked calf syndrome was first reported in 1959 and 1960 and experimentally confirmed in 1967 (Panter *et al.*, 1999a). Crooked calf disease includes various skeletal contracture-type birth defects and occasionally cleft palate. The skeletal defects

are similar to an inherited genetic condition reported in Charolais cattle. Based on epidemiologic evidence and chemical comparison of teratogenic and nonteratogenic lupines, the quinolizidine alkaloid anagryne was determined to be the teratogen (Keeler, 1973). A second teratogen, a piperidine alkaloid called ammodendrine found in *Lupinus formosus*, was also demonstrated to cause the condition (Keeler and Panter, 1989). Further research determined that the anagryne-containing lupines only caused birth defects in cattle and did not affect sheep or goats; however, the piperidine-containing lupine *L. formosus* induced similar birth defects in cattle and goats (Keeler and Panter, 1989). This led to interesting speculation about possible metabolism or absorption differences between cattle and small ruminants. Keeler and Panter (1989) hypothesized that perhaps the cow was metabolizing the anagryne to a complex piperidine, meeting the structural characteristics determined for a teratogenic piperidine. This was supported by feeding trials with other piperidine-containing plants, extracts, and pure compounds. Coniine (5), a simple piperidine from poison hemlock, and anabasine (6), a simple piperidine from tree tobacco (*Nicotiana glauca*), induced the same defects in cattle, sheep, and goats. Although comparative studies support the hypothesis that the cow may metabolize the quinolizidine anagryne to a complex piperidine, evidence regarding the absorption and elimination patterns of many of the quinolizidine alkaloids, including anagryne, in cattle, sheep, and goats does not support the metabolism theory (Gardner and Panter, 1993). This research is currently ongoing at the Poisonous Plant Research Laboratory. A review of lupine-induced cases of crooked calf syndrome reported to the Poisonous Plant Research Lab during the past 20 years can be found in Lee *et al.* (2007a).

Different lupines produce varying toxic syndromes in a given species of livestock, apparently because the alkaloid profile varies remarkably among species. Season and environment influence alkaloid concentration in a given species of lupine. Generally, alkaloid content is highest in young plants and in mature seeds. Alkaloids are not lost upon drying, so wild hay may be highly toxic if young lupine plants or especially seed pods are present. For many lupines, the time and degree of seeding vary from year to year. Most losses occur under conditions in which animals consume large amounts of pods in a brief period, such as when they are being driven through an area of heavy lupine growth, unloaded into such an area, trailed through an area where the grass is covered by snow but the lupine is not, or when feeding lupine hay when lupine is in the pod stage, which apparently is palatable. Most serious poisonings may occur in the late summer or early fall because lupine remains green after other forage has dried and seed pods are present. Once the poisonings were understood, the

**FIGURE 77.5** The relationship between the concentration of the teratogen anagryne in the plant and the amount of lupine in the diets of cattle during breeding and susceptible gestational stages.

practice of harvesting lupine hay for winter sheep feed was discontinued.

#### Cattle grazing

Lupine is not very palatable to cattle, although it has been considered fair to good quality feed on some ranges that are heavily utilized. Its palatability or acceptability depends on availability and maturity of other forage. In a grazing study of velvet lupine (*L. leucophyllus*) on annual cheatgrass ranges in eastern Washington (Ralphs *et al.*, 2006), cows selected lupine in July and August after cheatgrass dried and other forbs were depleted or matured and became rank. The deep-rooted lupine remained green and succulent longer into the summer than the other forage. Lupine was higher in crude protein and lower in fiber (NDF) than the other forages throughout the season (the crude protein level in foliage was 15%, and in seeds it was 36%). However, the thick, velvety pubescence was believed to be partially responsible for its lack of palatability. The high alkaloid concentration in the floral parts and seed pods may also have contributed to its lack of palatability. Once the seeds shattered in early July, the alkaloid concentration declined, and the cows began selecting lupine. Figure 77.5 shows the overlap of lupine consumption with the susceptible period of gestation, in relation to the anagryne concentration in the lupine plants. Cattle selected velvet lupine in July after cheatgrass and other forbs matured.

The abundance of lupine is another factor influencing the amount of lupine consumed. Lupine population cycles are influenced by weather patterns. Catastrophic losses from lupine-induced crooked calves occurred in the Channel Scabland region of eastern Washington in 1997. Annual precipitation from 1995 to 1997 was 33% above average, initiating an outbreak of lupine throughout the region. The density of velvet lupine plants has

declined since then (Ralphs, unpublished data), and the incidence of crooked calves has returned to what has become an acceptable tolerance of 1–5% incidence.

Clinical signs of poisoning are those of muscular weakness (neuromuscular blockade) beginning with nervousness, frequent urination and defecation, depression, frothing at the mouth, relaxation of the nictitating membrane, ataxia, muscular fasciculations, weakness, lethargy, collapse, sternal recumbency followed by lateral recumbency, respiratory failure, and death. Signs may appear within 15 min to 1 h after ingestion or as late as 24 h depending on the amount and rate of ingestion. Death usually results from respiratory paralysis.

The incidence of crooked calves is variable geographically and from year to year within a given herd. Up to 100% of a given calf crop may be affected, and individuals may be more severely affected than others. Affected calves are generally born alive at full term. Dystocia may occur when calves are severely deformed and assistance is required, often by cesarean section.

Arthrogryposis is the most common malformation observed and is often accompanied by one or more of the following: scoliosis, torticollis, kyphosis, or cleft palate. Elbow joints are often immobile because of malalignment of the ulna with the articular surfaces of the distal extremity of the humerus. The part of the limb distal to the elbow joint is often rotated laterally. In crooked calf disease, the osseous changes observed are permanent and generally become progressively worse as the calf grows and its limbs are subjected to greater load-bearing stress. Frequently, minor contractions such as “buck knees” often attributed to lupine will resolve on their own and the calf will appear relatively normal.

No breed predilection or genetic susceptibility to the lupine-induced condition has been determined. Likewise, lactation or age did not influence the propensity for cattle to graze lupine (Pfister *et al.*, 2008a). However, body condition was shown to affect the absorption and elimination half-life of anagryne in sheep (Lopez-Ortiz *et al.*, 2004). Research on cattle has demonstrated that body condition impacts absorption, distribution, and elimination of the alkaloids and therefore could impact the risk of toxicity or teratogenic outcome of lupines (Lee *et al.*, 2008d). This difference in toxicokinetics was significant for two teratogenic alkaloids – anagryne and ammodendrine. The disposition of teratogenic alkaloids in the fetal compartment is unknown and will require further research.

The sensitive gestational period in the pregnant cow for exposure is 40–70 days with suspicious periods extending to day 100 (Panter *et al.*, 1997). The condition has been experimentally induced with dried ground lupine at 1 g/kg BW and with semi-purified preparations of anagryne (the apparent teratogen) at 30 mg anagryne/kg BW fed daily from 30 to 70 days of

gestation. The dose range of anagryne to cause crooked calves is 6.5–11.9 mg/kg BW/day for 3 or 4 weeks during gestation days 40–70. Crooked calf disease has also been induced by feeding the piperidine alkaloid-containing lupine, *L. formosus* (Keeler and Panter, 1989). The teratogenic piperidines, ammodendrine, *N*-acetylhystrine, and *N*-methyl ammodendrine, are absorbed quickly after ingestion and can be detected in blood plasma by 0.5 h, with peak levels maintained for more than 24 h (Gardner and Panter, 1993). The mechanism of action has been determined to be an alkaloid-induced reduction in fetal movement by a neuromuscular blocking effect during the critical stages of gestation (Panter *et al.*, 1990a). This inhibition of fetal movement is due to stimulation followed by desensitization of skeletal muscle-type nAChR (Lee *et al.*, 2006). This mechanism is a common factor for multiple alkaloids found in many species of lupines, poison hemlock (*Conium*), and wild tree tobacco (*N. glauca*), and research using TE-671 cells that express human fetal muscle-type nAChR and SH-SY5Y cells that express human autonomic-type nAChR supports this mechanism (Green *et al.*, 2010). Interestingly, many of these teratogenic alkaloids are produced in the plants as enantiomeric pairs and exhibit differences in activity using these specialized cells and when compared using a mouse bioassay (Lee *et al.*, 2006, 2008a–c). This inhibited fetal activity is responsible for the skeletal contracture malformations and cleft palates (Panter *et al.*, 1990a), and a goat model developed in the 1990s using anabesine as the teratogen and ultrasound imaging to evaluate fetotoxicity has been utilized for biomedical research to improve treatments and potential fetal intervention for cleft palate in children (Panter and Keeler, 1992; Weinzwieg *et al.*, 1999, 2008).

## Prevention, management, and treatment

Keeler *et al.* (1977) proposed a simple management solution to prevent crooked calves: stagger grazing of lupine-infested pastures so that the susceptible period of gestation (40–70 days) does not overlap the flower and pod stage of growth when anagryne is highest. Ralphs *et al.* (2006) refined Keeler’s recommendations to restrict access during the susceptible period of gestation, when anagryne concentration is still high in the flower and pod stage, only when cattle are likely to eat lupine, and in years when it is abundant. Panter (unpublished data) suggested that intermittent grazing between lupine pastures and clean pastures would allow the fetus to regain normal movement for a few days during the sensitive stage of gestation. It has been hypothesized that inhibited fetal movement over a prolonged period of time is required for severe malformations to occur (Panter *et al.*, 1999a).

Lupines are easily controlled with 2,4-D-type broad-leaf herbicides (Ralphs *et al.*, 1991); however, herbicide treatment alone rarely provides long-term solutions to poisonous plant problems. Seed reserves in the soil will rapidly reestablish the stands if grazing management practices are not implemented.

Death losses in sheep can be reduced by recognizing the variability in lupine toxicity with stage of growth and the conditions under which animals graze the plant. Providing a choice of other quality forages usually prevents excess lupine grazing. The dangerous period of plant growth for sheep exists mainly with plants in the pod stage. The hazard increases if sheep are hungry, as is often the case with crowding, hauling, driving, or overgrazed conditions. The hazard is reduced or eliminated when lupine is in post-seed stage.

Treatment for overt poisoning is usually symptomatic, and recovery is often spontaneous if animals are not stressed further by driving. Once the animal is observed showing muscular tremors, it should be allowed to drop back and proceed at its own pace. Poisoned animals should never be forced to continue moving because this will exacerbate the clinical effects and can result in death. The elimination of the toxic alkaloids in the urine is quite rapid ( $t_{1/2} = 6.32 - 6.88\text{h}$ ) and begins within hours of ingestion (Lopez-Ortiz *et al.*, 2004). Therefore, allowing the animal to rest and move slowly will often result in full recovery within 24h. There is no treatment for the malformations, and euthanasia is recommended for the serious skeletal defects and cleft palate. However, less severe contracture defects, particularly of the front legs (buck knees), will often resolve if the knee joint can be locked within 1 week after birth. If not, the defect generally becomes worse with growth and size, and although the animal will continue to grow, the front legs will break down and the animal will not be adequate for the feedlot.

## Summary

A reduction in incidence can be expected and has been achieved by using one or more of the following: (1) coordinating grazing periods according to plant growth stage, (2) changing time of breeding by either advancing or delaying or changing from spring to fall calving, (3) reducing lupine populations through herbicide treatment, and (4) intermittent grazing between clean pastures and lupine pastures to break the cycle of lupine ingestion.

## POISON HEMLOCK (*CONIUM MACULATUM*)

Poison hemlock was introduced into the United States as an ornamental herb and grows throughout the country.

**FIGURE 77.6** The hemlocks – poison hemlock (*Conium maculatum*) on the left and water hemlock (*Cicuta douglassii*) on the right. Note the tubers and partitioned stalk on water hemlock versus the single taproot on poison hemlock. Leaf structure is different, and poison hemlock has purple spots on the stems.

Generally, poison hemlock grows in waste areas where adequate moisture will sustain the biennial stands. Four species are recognized worldwide, but only one (*Conium maculatum*) is found in the United States. Historically, poison hemlock has been associated with human poisoning more than livestock and is believed to be the tea used to execute Socrates.

## Description

Unlike the lupines, locoweeds, etc., multiple *Conium* species are few worldwide, and only one species, *C. maculatum*, is described in the United States. *Conium maculatum* is a biennial plant 1–2.5m tall (Figure 77.6). The stems are stout, rigid, smooth, and hollow except at the nodes. A distinguishing characteristic of the plant is the purple spots found up and down the main stem and a single carrot-like taproot. The leaves are large, triangular, fern-like, and alternate on the erect stem. The stem grows the second year from a rosette and taproot established from seed. Frequently, seeds will germinate in the fall before winter and then complete their reproductive cycle the following year. The flowers are small, white or cream colored, and in umbellate clusters. The fruits are grayish brown with conspicuous wavy, knotted ridges. The plant has a fleshy, usually unbranched, white taproot that

looks like parsnips. Roots have been mistaken for parsnip, seeds for anise, and leaves for parsley.

The geographical distribution of poison hemlock is throughout the United States, restricted only by cultivation and adequate moisture to sustain stands of the plant from year to year. The plant usually grows in waste places where moisture may accumulate and protected from cultivation.

## Toxicology

Eight piperidine alkaloids are known in poison hemlock, five of which are commonly discussed in the literature. Two alkaloids (coniine (5) and  $\gamma$ -coniceine (7)) are prevalent and likely responsible for toxicity and teratogenicity of the plant.  $\gamma$ -Coniceine is the predominant alkaloid in the early vegetative stage of plant growth and is a biochemical precursor to the other *Conium* alkaloids (Panter and Keeler, 1989). Coniine predominates in late growth and is found mainly in the seeds.  $\gamma$ -Coniceine is seven or eight times more toxic than coniine in mice. This makes the early growth plant most dangerous in the early spring and the seedlings and regrowth again in the fall. This is also the time when green feed is limited to livestock and may impact their propensity to graze this plant. Seeds, which are very toxic, can contaminate poultry and swine cereal grains (Panter and Keeler, 1989). Plants often lose their toxicity upon drying, but seeds remain toxic as long as the seed coat is intact.

An analysis of a single plant of *Conium*, second-year rosette, revealed  $\gamma$ -coniceine levels of 387, 326, 198, 176, and 850 mg/g fresh plant for whole plant, root crown, stem, leaf, and green seed, respectively. Coniine was only detected in the leaf at 12 mg/g fresh plant (Panter and Gardner, unpublished data, 1994).

The clinical signs of toxicity are the same in all species and include initial stimulation (nervousness) resulting in frequent urination and defecation (no diarrhea), rapid pulse, temporarily impaired vision from the nictitating membrane covering the eyes, muscular weakness, muscle fasciculations, ataxia, incoordination followed by depression, recumbency, collapse, and death from respiratory failure (Panter *et al.*, 1988).

*Conium* plant and seed are teratogenic, causing contracture-type skeletal defects and cleft palate like those of lupine. Field cases of teratogenesis have been reported

in cattle and swine and experimentally induced in cattle, swine, sheep, and goats (Panter *et al.*, 1999a). Birth defects include arthrogryposis (twisting of front legs), scoliosis (deviation of spine), torticollis (twisted neck), and cleft palate. Field cases of skeletal defects and cleft palate in swine and cattle have been confirmed experimentally.

In cattle, the susceptible period for *Conium*-induced terata is the same as that described for lupine and is between day 40 and day 70 of gestation. The defects, susceptible period of pregnancy, and probable mechanism of action are the same as those of crooked calf disease induced by lupines (Panter *et al.*, 1999a). In brief, these alkaloids and their enantiomers in poison hemlock, lupines, and *N. glauca* were more effective in depolarizing the specialized cells TE-671, which express human fetal muscle-type nAChR, relative to SH-SY5Y, which predominantly express autonomic nAChRs, in a structure-activity relationship (Panter *et al.*, 1990a; Lee *et al.*, 2006, 2008b; Green *et al.*, 2010). In swine, sheep, and goats, the susceptible period of gestation is 30–60 days. Cleft palate has been induced in goats only when plant or toxins were fed from 35 to 41 days of gestation (Panter and Keeler, 1992).

Field cases of poisoning have been reported in cattle, swine, horses, goats, elk, turkeys, quail, chickens, and Canadian geese (Panter *et al.*, 1999a). Poisoning in wild geese eating small seedlings in early spring was most recently reported (Panter, personal communication). Human cases of poisoning are frequently reported in the literature, and a case of a child and his father mistakenly ingesting the plant has been reported. Field cases of teratogenesis have been reported in cattle and swine and experimentally induced in cattle, sheep, goats, and swine (Panter *et al.*, 1990a). Pigs become habituated to poison hemlock, and if access to the plant is not limited, they will eat lethal amounts within a short time.

There are no diagnostic lesions in poisoned animals, and diagnosis is based on clinical history of exposure and/or alkaloid detection in liver, urine, or blood. At necropsy, the presence of plant in the stomach and a characteristic pungent odor in the contents with chemical confirmation of the alkaloids may be diagnostic.

## Prevention and treatment

Prevention of poisoning is based on recognizing the plant and its toxicity and avoidance of livestock exposure when hungry. If a lethal dose has not been ingested, the clinical signs will pass spontaneously, and a full recovery can be expected. Avoidance of stressing animals poisoned on *Conium* is recommended. However, if lethal doses have been ingested, supporting respiration,

gastric lavage, and activated charcoal are recommended. Control of plants is easily accomplished using broadleaf herbicides; however, persistent control measures are recommended because seed reserves in the soil will quickly reestablish a population.

The mechanism of action of the *Conium* alkaloids is twofold. The most serious effect occurs at the neuromuscular junction, where they act as nondepolarizing blockers like curare. Systemically, the toxins cause biphasic nicotinic effects, including salivation, mydriasis, and tachycardia, followed by bradycardia as a result of their action at the autonomic ganglia. The teratogenic effects are undoubtedly related to the neuromuscular effects on the fetus and have been shown to be related to reduction in fetal movement (Panter *et al.*, 1990a). Likewise, cleft palate is caused by the tongue interfering in palate closure during the reduced fetal movement and occurs during days 30–40 of gestation in swine, 32–41 days in goats, and 40–50 days in cattle (Panter and Keeler, 1992).

## WATER HEMLOCK (*CICUTA* SPP.)

Water hemlock (*Cicuta* spp.) is among the most violently poisonous plants known to humans. It is often confused with poison hemlock because of its name, growth patterns, and appearance. There are distinct differences in appearance, as shown in Figure 77.6.

### Distribution

There are approximately 20 species of *Cicuta* throughout the world, and all are poisonous. Most of these species are found in North America; nine are common in the United States, and seven are found in the western United States (Table 77.5).

### Description

Water hemlock is often confused with poison hemlock; in fact, there are similar plant characteristics and both belong to the Umbelliferae family (Figure 77.6). However, their toxic effects are dramatically different,

and when toxicoses occur, differentiation between the two genera is important.

Water hemlock (*Cicuta*) is a biennial, 1 or 2 m tall, with thickened tubers possessing long, slender parsnip-like roots radiating out from the main tuber. Water hemlock frequently grows directly in streambeds or water sources and is limited to wet habitats. The tubers are bulbous and exhibit several chambers or cavities separated by cross-partitions as seen in a vertical cut through the tuber at the base of the stem. The cut surface of the stem or tuber exudes a yellowish, thick, oily liquid believed to be predominantly cicutoxin (8). This oily substance has a parsnip-like odor. The chambered tuber is a distinguishing feature of this plant (Figure 77.6). The roots extending from the tuber may be solid, white, and fleshy, closely resembling a parsnip. The stems are hollow except at the nodes, hairless, and occasionally have purple stripes up the stem. Leaf stalks alternate up the stem and leaves two or three pinnately divided may be 30–60 cm long. Flowers are small, white or cream colored, and in terminal umbrella-shaped clusters. The fruits are small, with prominent ribs, and encased in a hard brownish shell very similar to those of poison hemlock. The primary distinguishing feature separating water and poison hemlock is the tuberous roots with the very distinct partitions in water hemlock (Figure 77.6). Poison hemlock lacks the large tubers, although occasionally there are very small partitions observed in the area where the root and stem connect if the plant is cut vertically. The parsnip-like root is a single taproot in poison hemlock, whereas there are often multiple white parsnip-like roots radiating off the main tubers in water hemlock (Figure 77.6).

TABLE 77.5 Water hemlock species and geographical distribution

Species	Geographical distribution
<i>C. bulbifera</i>	Northern U.S., southern Canada
<i>C. bolanderi</i>	Central to western CA
<i>C. californica</i>	Central to western CA
<i>C. douglasii</i>	Throughout U.S.
<i>C. machenziana</i>	Southeastern AK north to the Brooks Range
<i>C. occidentalis</i>	Rocky Mountains, Black Hills, WA; south into NV and NM
<i>C. vagans</i>	Pacific Northwest U.S. and Canada

## Toxicology

The toxic principle in water hemlock is a long-chain, highly unsaturated alcohol called cicutoxin. Water hemlock acts on the central nervous system as a stimulant, inducing violent grand mal seizures and death from respiratory failure.

Tubers are the most toxic part of the plant, especially in early spring. The parsnip-like roots extending from the tuber are two to four times less toxic, and as the vegetative parts of the plant grow and mature, they become less toxic. Preliminary studies suggest that mature leaves and stems are much less toxic and after drying are non-toxic (Panter *et al.*, 1988). Historically, water hemlock was believed to be most dangerous in early spring, and poisoning usually occurred when animals milled around in streambeds or sloughs and exposed tubers, which were then ingested. Although this is true, a recent case of poisoning and death in cattle after ingesting flower and green seed heads implicates this phenological stage as dangerous also (Panter *et al.*, 2011). Chemical comparison of green seed and tubers and mouse bioassay studies showed that green seed was equally as toxic as tubers. Like tubers, the more mature vegetation, including leaves, flowers, and green seed heads, was very palatable. Free choice exposure of hamsters to the white parsnip-like roots suggests that they are quite palatable and are less toxic than the tuber. Observations of cattle grazing early in spring suggest that the young shoots of water hemlock are very palatable because young plants growing in streambeds were frequently and extensively grazed (Panter, personal observation).

Clinical signs of poisoning appear within 10–15 min after ingestion and progress from nervousness, frothing, ataxia, dyspnea, muscular tremors, and weakness to involuntary, spastic head and neck movements accompanied by rapid eye blinking and partial occlusion of the eyes from the nictitating membranes. This is quickly followed by collapse and intermittent grand mal seizures lasting 1 or 2 min each followed by relaxation periods of 8–10 min. Depending on the dosage, recovery may occur or seizures continue until death from exhaustion or respiratory failure. There appears to be a threshold response in which very small increases in dosage will induce an apparently normal animal into grand mal seizures (Panter *et al.*, 1996a).

Upon necropsy, gross lesions are confined to pale areas in heart muscle and skeletal muscles, particularly the long digital extensor muscle groups (Panter *et al.*, 1996a). Microscopic lesions include multifocal, subacute to chronic myocardial degeneration characterized by granular degeneration of myofiber cytoplasm necrosis and replacement fibrosis in the heart. These areas correspond to the pale areas observed grossly. There is bilateral symmetrical, subacute to chronic myofiber

degeneration and necrosis of the long digital extensor muscle groups. Clinical serum chemistry changes of elevated lactic dehydrogenase, aspartate aminotransferase, and creatine kinase occur in relation to severity of seizures. The extent of gross and microscopic lesions and clinical chemistries are a result of the severity of the seizures. Experimentally, barbiturates prevented seizures, death, and lesions in sheep, and a 3× lethal dose of water hemlock could be reversed with pentobarbital and no death occurred (Panter *et al.*, 1996a). In animals in which seizures were prevented by barbiturates, there were no lesions observed even though doses of two and three times the lethal dose were administered.

## Prevention and treatment

Prevention of poisoning is accomplished by recognizing the plant and avoiding exposing animals to it early in the spring or when in flower/seed stage. Water hemlock is easily controlled with herbicides (2,4-D per manufacturer's specification); however, herbicide use is often restricted near natural water sources. If few plants are present, hand pulling may be accomplished using caution to discard tubers away from possible exposure to animals or humans.

Successful treatment with barbiturates or perhaps tranquilizers prevents death and the lesions and serum chemistry changes; however, treatment must be prompt (Panter *et al.*, 1996a). This treatment has been successful in humans, but in animals it has never been demonstrated in the field and would require a veterinarian to be on sight soon after the ingestion of this plant.

## PONDEROSA PINE NEEDLES (PINUS SPP.)

The needles of ponderosa pine have been known for years to induce abortion in pregnant cows when grazed, particularly during the last trimester of pregnancy (Gardner *et al.*, 1999). Occasional toxicosis in pregnant cows occurs; however, cases of toxicosis in nonpregnant cows, steers, or bulls are not reported.

## Description

Ponderosa pine (*Pinus ponderosa*) is one of the most prevalent species of *Pinus* in the western United States. Under ideal conditions, it grows to heights of more than 60 m and 1.5–2.5 m in diameter. It is extensively harvested for lumber. During early growth, the bark is dark brown to

black, hence the name “black jack” pine. Older trees have a bark of cinnamon brown to yellow, hence the name “yellow” pine. Ponderosa pine is a three-needled pine, although groups of two and three can be found on the same tree. The needles are approximately 8–20 cm long growing in clusters. They are soft and quite palatable, especially in the winter, when green feed is limited. The cones are brown, 7–15 cm long, and frequently grow in clusters. Two varieties of ponderosa pine have been identified, var. *ponderosa* and var. *scopulorum*, along with a separate five-needled species *Pinus arizonica*.

## Distribution

Ponderosa pine grows in every state west of the Great Plains and western Canada. It has a total stand greater than any native tree in the western United States except Douglas fir. It grows at elevations between 1500 and 2500 m, although populations in California do extend almost to sea level. Ponderosa pine is drought resistant and is extensively harvested for lumber. Gardner and James (1999) surveyed numerous other *Pinus*, *Juniperus*, *Abies* species, etc. for isocupressic acid content, and Table 77.6 lists common name,

location, and isocupressic acid concentration of many species of trees or shrubs. The bark from both Utah juniper and western juniper trees has also been found to be abortifacient to cattle (Gardner *et al.*, 2010; Welch *et al.*, 2011a).

*Pinus ponderosa* var. *ponderosa* (western variety) extends from the mountains of southern California northward on the western and eastern sides of the Sierra

Nevada–Cascade crest to Canada. The eastern variety *P. ponderosa* var. *scopulorum* meets the western variety near the Continental Divide in west-central Montana and extends southward throughout mountains, plains, and basins to scattered stands in the Sierra Madre Occidental and Sierra Madre Oriental of northern Mexico. *Pinus arizonica* (once considered a third variety) has scattered populations in southern Arizona and New Mexico.

## Toxicology

The toxin in ponderosa pine that induces abortion in cattle is the labdane resin acid isocupressic acid (9) (ICA; Gardner *et al.*, 1994). Two related derivatives (succinyl ICA and acetyl ICA) also contribute to the induction of abortion after hydrolytic conversion to ICA in the rumen (Gardner *et al.*, 1996). Other related labdane acids (agathic acid, imbricatoloic acid, and dihydroagathic acid) that are found in ponderosa pine needles at low levels may also contain abortifacient properties based on their similar chemical structure to ICA. Other genera and species have also been implicated in abortions, such as Monterey cypress (Parton *et al.*, 1996), Korean pine (Kim *et al.*, 2003), and California juniper and lodgepole pine (Panter, personal communications). Table 77.6 summarizes current information on plant species analyzed for ICA and/or ICA derivatives believed to contribute to abortions. Current research indicates that the concentration of ICA in ponderosa pine needles is not uniform throughout the same tree, the concentration of ICA in ponderosa pine needles can vary from location to location, and there is evidence for seasonal fluctuations as well (Cook *et al.*, 2010).

The primary toxicological effects of ponderosa pine needles in cattle are abortion and complications associated with abortion, such as retained fetal membranes, metritis, and occasional overt toxicosis and death (Gardner *et al.*, 1999). The abortions generally occur in the last trimester of pregnancy in the late fall, winter, or early spring. Abortions have been induced as early as 3 months of gestation and have been reported by ranchers to occur any time; however, the closer to the time of normal parturition that ingestion of pine needles occurs, the higher the risk of abortion. Abortions may occur following a single exposure to the needles, but results from controlled experiments indicate the highest incidence of abortion is in cows eating the needles over a period of days. Abortions have been associated with grazing of green needles from trees, slash from the lumber industry, and dead, dry needles from the ground.

Abortions are generally characterized by weak uterine contractions, uterine bleeding, incomplete cervical

dilation, dystocia, birth of weak but viable calves, agalactia, and retained fetal membranes (Gardner *et al.*, 1999). Two syndromes seem to occur depending on the amount of pine needles eaten. In the first syndrome, abortion occurs relatively quickly (3–6 days) with no signs of pending abortion, such as udder filling, vulvar swelling, or pelvic relaxation, but a small weak calf is quickly delivered. In the second syndrome, abortion occurs after 6–14 days, and all the previously mentioned signs occur before the calf is born. Unless complications occur, most calves are born alive, and the closer to normal parturition, the higher the survival rate. Calves born after 255 days of gestation will often survive with extra care but need to be supplemented with colostrum and milk from other sources until the dam begins to lactate. Cows with retained fetal membranes may need antibiotic therapy to avoid uterine infections.

Pine needles will induce abortion in buffalo, but sheep, elk, and goats do not abort. Pine needles, pine bark, and new growth tips of branches are all abortifacient and new growth tips are also toxic (Panter *et al.*, 1990b).

A separate toxic syndrome has been described in addition to abortion in which the abietane-type diterpene resin acids cause depression, feed refusal, weakness, neurological problems, and, eventually, death. Specific compounds include abietic acid, dehydroabietic acid, and other related compounds (Stegelmeier *et al.*, 1996). At 15–30% of the diet, pine needles have been shown to alter rumen microflora and affect the rumen fermentation (Pfister *et al.*, 1992). Rumen stasis is part of the toxic syndrome (Stegelmeier *et al.*, 1996).

Pine needle-induced abortion appears to mimic normal parturition except premature. The mechanism of action appears to be a reduction in blood flow to the caruncular vascular bed stimulating the fetal parturition mechanism (Ford *et al.*, 1992). ICA has not been found to be directly vasoactive, and it is unclear if ICA metabolites are vasoactive or if the vasoconstriction is a secondary response to ICA or ICA metabolites. Further research is needed to determine the cellular or biochemical mechanism and whether metabolic alteration of the ICA occurs.

Extensive vasoconstriction of the caruncular vascular bed with accompanying necrosis and hemorrhage are the only reported pathological changes in maternal tissues. These findings are supported by Ford *et al.* (1992), who reported that serum from pregnant cows fed pine needles showed vaso (vasoconstriction) activity *in vitro*.

## Prevention and treatment

The only recommendation to prevent pine needle abortion is to avoid grazing pregnant cows around pine trees, especially in the third trimester. There is no known

treatment for cattle once ingestion of pine needles has occurred. Open cows, steers, or bulls are apparently unaffected by pine needles; likewise, sheep, goats (pregnant or not), and horses can graze pine needles with impunity and experience no adverse effects. Supportive therapy (antibiotic treatment or uterine infusion for retained fetal membranes) is recommended for cows that have aborted, and intensive care of the calf may save its life. Grazing of pine needles intensifies during cold inclement weather and if other forage is in short supply. In spring, before green grass is available, cows will leave feeding grounds in search of new green grass and frequently graze old, dry needles from surrounding trees where the snow has melted. These cows are at risk and should be kept away from the pines. Research has also determined that low body conditioned cows are more likely to eat pine needles than cattle in adequate body condition (Pfister *et al.*, 2008b). Consequently, it is recommended that pregnant cattle grazing in ponderosa pine areas be maintained in good body condition (Pfister *et al.*, 2008b). Anecdotal information suggests that pregnant llamas may be at risk from pine needles, but no experimental support has been presented (Panter, personal communications).

## BROOM SNAKEWEED (*GUTIERREZIA* SPP.)

Broom snakeweed causes significant losses to cattle, sheep, and goat producers in Texas and New Mexico from abortions and toxicoses. There are some similarities with ponderosa pine needles, except pine needles apparently affect only cattle.

### Description and distribution

There are two major species of broom snakeweed, *Gutierrezia sarothrae* (perennial snakeweed or turpentine weed) and *G. microcephala* (threadleaf broomweed). Snakeweeds are short-lived perennial half shrubs ranging from 15 to 60 cm tall (Ralphs and McDaniel, 2011). Many unbranched erect stems originate from a woody base and die back when the plant enters dormancy. They have a suffrutescent growth form, with new stems originating from the crown each year without becoming woody. The stems originate from the crown and are unbranched, giving rise to the common name of broom snakeweed, with the stems resembling the straight straws of a broom. Leaves are narrow and linear and alternately arranged on stems. These species are of the Composite family; thus, they have two types of flowers.

Disc flowers are tightly clustered in the center of the head, whereas long yellow petal ray flowers radiate out from the head (Lane, 1985).

### *Broom snakeweed (Gutierrezia sarothrae (Pursh) Britt. & Rusby)*

Broom snakeweed has more than three florets (usually seven) per involucre or flowering cluster. Broom snakeweed is one of the most ubiquitous range plants and widely distributed throughout North America, ranging from the cold temperate climate of Canada to subtropical areas of Mexico and from the subhumid Great Plains to the montane Rocky Mountains and Sierras and the arid Great Basin. It ranges in elevation from 50 to 2900 m, rainfall from 20 to 50 cm, and temperatures from 4 to 21°C. It is a principal component of the following plant communities: desert creosote, desert grassland, short-grass prairie, salt-desert shrub, sagebrush, pinyon-juniper, and mountain brush. Its wide tolerance limits allow it to inhabit a broad range of environments, and it can dominate and cause significant problems as both a noxious and a poisonous weed in the short-grass prairies and sagebrush plant communities.

### *Threadleaf snakeweed (G. microcephala (DC) Gray)*

Threadleaf snakeweed has one floret per flowering cluster. Threadleaf snakeweed is restricted to the Mojave, Sonoran, and Chihuahuan deserts of the southwestern United States and northern Mexico. It grows in dry, desert habitat and favors sandy soils, and it has a greater tolerance for arid climates than does broom snakeweed.

### Ecology

Broom snakeweed is a native range shrub found throughout semiarid rangelands of the western United States. Although a minor component of pristine plant communities, it can predominate on rocky ridges, gravely slopes, and immature infertile soils. Ralphs and McDaniel (2011) provide an up-to-date review of broom snakeweed ecology, including seed ecology, population cycles, toxicology, and management. Broom snakeweed increases and may dominate rangelands following disturbances such as overgrazing, fire, and drought (Ralphs and Banks, 2009). Broom snakeweed will increase where it is established and will invade deeper soils and more productive habitats. It is very competitive with desirable grasses and greatly suppresses forage production.

A two-tier root system allows the deep taproot to extract deep-stored water, and the extensive adventitious roots near the surface take advantage of the light sporadic rain showers. It has little leaf stomatal control; thus, it is a luxuriant water user for maximum growth.

It grows early in the spring and depletes moisture from the entire soil profile before warm-season grasses break dormancy. Broom snakeweed is one of the most undesirable plants in the various regions of the west. On many localized rangelands of the southwest, it is the most significant problem limiting forage and livestock production.

Broom snakeweed is short-lived and experiences dramatic population cycles, which appear to be related to climatic patterns. Although it is very competitive for soil moisture, it is not particularly drought tolerant. Broom snakeweed populations die off in drought and from insect depredation, but it is one of the first plants to germinate and establish when rains resume, forming widespread monospecific stands (Ralphs and Sanders, 2002).

## Toxicology

The snakeweeds are toxic and abortifacient to cattle, sheep, and goats. Abortions and retained fetal membranes in cattle are among the most serious problems in livestock. In 1985, McGinty estimated losses in excess of \$15 million annually to the cattle industry in Texas alone and more than \$30 million when losses in New Mexico and Arizona were included. This does not account for indirect losses, such as loss of usable forage, management changes, increased calving intervals, or added veterinary care.

Snakeweed contains toxic and abortifacient compounds. Extracts of a saponin fraction from threadleaf snakeweed caused abortions in rabbits, goats, and cattle at low doses and caused death at high doses. Molyneux *et al.* (1980) identified some major monoterpenes and sesquiterpenes in the essential oil fraction of snake-weed, including  $\alpha$ -pinene, myrcene, linalool, *cis*-verbenol, *trans*-verbenol, verbenone, geraniol, caryophyllene, and  $\gamma$ -humulene. Several furanoditerpene acids and flavones from the resinous exudate in trichomes on leaves of broom snakeweed have been identified. These diterpene acids were structurally similar to ICA, the abortifacient compound in ponderosa pine (*P. ponderosa* Laws) needles. Gardner *et al.* (1999) speculated that some of the furanoditerpene acids may be abortifacient, whereas others may be toxic, and the relative concentrations determine whether animals are poisoned or abort. The crude resin content of broom snakeweed, which includes the diterpene acids along with other monoterpenes, increased from 5% in early growth up to 13% at flowering in August (Ralphs *et al.*, 2007).

Snakeweeds are both abortifacient and toxic. In west Texas in the 1930s, 10–60% of cattle ranches experienced abortions, and cows retained placentas, which led to infection and death of the cows. Many calves were born small and weak. Threadleaf snakeweed was fed to cattle, sheep, and goats, causing damage to the liver and

kidneys, but no abortions were produced. Dollahite and Anthony (1957) and others found that threadleaf snakeweed did cause abortions, retained placenta, and weak calves, and it was more toxic on sandy soils. Low levels of snakeweed cause abortions and high levels are toxic. Clinical signs of poisoning include anorexia, mucopurulent nasal discharge, loss of appetite and listlessness, diarrhea, and then constipation and rumen stasis, which may lead to death.

There appears to be a relationship between nutrition and fertility problems caused by broom snakeweed. Smith *et al.* (1991) summarized research in rats at New Mexico State University and concluded that increasing amounts of snakeweed in rat diets reduced intake, which led to malnutrition and contributed to diminished fertility and increased fetal mortality. Edrington *et al.* (1993) confirmed that increasing amounts of snakeweed in rat diets reduced intake and contributed to problems of malnutrition and toxicity. However, they determined that the overriding factor in reducing fertility and reproduction was the impaired hormone balance and disruption of blood flow to the uterus and developing embryos. Ewes on a high-quality alfalfa diet (18% crude protein) consumed snakeweed for up to 25% of the ration with no adverse effects on estrus; whereas ewes fed blue grama hay (11% crude protein) would not consume rations containing more than 10% snakeweed, and 43% of these ewes did not show estrus and did not breed. In heifers fed snakeweed as 15% of a balanced diet before breeding and during early gestation, there was no effect on progesterone levels or conception rates. During the last trimester of gestation, snakeweed added up to 30% of this same diet did not cause abortion or lower calf birth weight. In a grazing trial on snakeweed-infested crested wheatgrass, cows in the last trimester of gestation were forced to graze snakeweed as a biological control. Snakeweed consumption averaged 10% of bites over the day and peaked at 20% of bites in the evening grazing periods. There were no signs of toxicity or abortions, even though their feed intake was severely restricted (Ralphs *et al.*, 2007).

## Management and treatment

Broom snakeweed is usually not palatable to most large ungulates; cattle will not graze snakeweed unless all other vegetation is depleted (Ralphs *et al.*, 2007). Thus, the management strategy to prevent grazing of broom snakeweed and prevent toxicosis is simple: ensure adequate feed is available. This can be accomplished by maintaining range in good condition and moving animals when proper utilization is reached. Although this sounds relatively simple, there are thousands of acres of rangeland on which broom snakeweed is dominant;

thus, how can these ranges be restored or utilized by livestock or wildlife?

Thacker *et al.* (2008) studied the invasion of broom snakeweed in two plant communities during a 5-year period following disturbance and evaluated vegetation change in a state-and-transition model. In a sagebrush/bunchgrass community that burned, bluebunch wheatgrass became the dominant species, and in the sagebrush-only dominated community that burned, broom snakeweed quickly established and dominated the community. Snakeweed cover increased from 2 to 31% during the 5-year period.

Broom snakeweed can be controlled by the common rangeland herbicides: Tordon (0.25–0.5lb/ac) is most consistent, Escort (3–6oz./ac) is a promising herbicide, and 2,4-D (1–2lb/ac) can be applied for two successive years when soil moisture is not limiting growth (Whitson and Freeburn, 1990). Better control is obtained in fall after flowering, when the carbohydrate stream is going down and carries the herbicide to the roots.

Ralphs and Banks (2009) used intense short-duration grazing pressure and high stocking rates to force cattle to graze snakeweed in an attempt to reduce snakeweed dominance. This intense targeted grazing pressure actually reduced snakeweed plants, but this method of snakeweed control has yet to be recommended, especially considering the health of the animals and the potential for reestablishment of snakeweed. Although the long-term success of targeted grazing to control snakeweed is yet to be determined, one should strongly consider seeding with cool-season grasses following episodes of overgrazing or targeted grazing such as reported by Ralphs and Banks. Defoliation studies to mimic grazing suggested that spring treatments put snakeweed at a disadvantage compared to fall clipping (Ralphs, 2009). Although there was little difference in the effect of clipping cool-season grasses in the spring versus the fall, there was a distinct effect on snakeweed.

Snakeweed is readily killed by fire, and prescribed burning is an effective control in the early stages of the population cycle while there is sufficient grass to carry a fire and respond to the released resources. In the latter part of the population cycle, grasses will be crowded out, and spraying with herbicides may be the only alternative. In this case, spraying must be followed by seeding to ensure a weed-resistant plant community is established that will resist reinvasion of snakeweed. Cool-season grasses such as crested, pubescent, and bluebunch wheatgrass will compete with snakeweed seedlings. Following drought, wildfires, or herbicide control, it was recommended that cool-season grasses should be seeded in an attempt to establish a solid stand that will prevent snakeweed establishment and subsequent domination in the plant community. If this approach is not successful, downy brome will likely fill

in, which will also often suppress the establishment of broom snakeweed.

Insects may play a role in snakeweed population die-off. Many insects are associated with snakeweed: defoliators (leaf tyers, grasshoppers, and weevils), sap suckers (scale insects and mealybugs), and root-boring weevils and gall formers. Individually and collectively, they contribute to the demise of mature snakeweed populations. However, it is unlikely that they will contribute to preventing a population buildup because of the time lag of their populations in relation to that of snakeweed.

Treatment of sick animals is only symptomatic, providing supplementation to weak calves and antibiotic therapy to cows with retained fetal membranes to avoid infection.

## RAYLESS GOLDENROD (*HAPLOPAPPUS HETEROPHYLLUS*)

Rayless goldenrod (*Haplopappus heterophyllus*) is a toxic range plant of the southwestern United States. The disease associated with toxicity has been referred to as “alkali disease” because originally it was associated with drinking of alkali water. Currently, it is referred to as “milk sickness” or “trembles” (the same as white snake-root in the Midwest) because the toxin tremetone (10) is excreted in the milk and subsequently results in poisoning of humans and nursing offspring. *Haplopappus acradenius* was implicated in poisoning in cattle in southern California (Galey *et al.*, 1991).

### Description

Rayless goldenrod is an erect, bushy, unbranched perennial shrub that grows 0.5–1.5m tall. The base is woody, and leaves alternate linearly up the stem. Heads are numerous, small, and clustered at the top of the stem, with 7–15 yellow flowers on each head.

### Distribution

Rayless goldenrod grows in the desert rangelands of the southwestern United States from southern Colorado into

Texas, New Mexico, Arizona, and California into Mexico. The plant grows abundantly on alkaline and gypsic soils in western Texas and the Pecos River Valley.

## Toxicology

The toxic constituents of rayless goldenrod are similar to those found in white snakeroot, and the original term, tremetol, is a mixture of ketones and alcohols. Tremetone (5-acetyl-2,3-dihydro-2-isopropenyl-benzofuran) was thought to be the principle toxic factor; however, 11 different compounds have now been isolated and identified (Lee *et al.*, 2010). This elucidation of different chemotypes of white snakeroot partially explains the sporadic and unpredictable toxicoses reported in livestock throughout the midwestern United States.

The toxicity of rayless goldenrod mimics that of white snakeroot. Clinical signs of poisoning may occur after ingestion of 1–15% BW during a 1- to 3-week period. Signs begin with depression or inactivity, followed by noticeable trembling of the fine muscles of the nose and legs. Most cases of poisoning reported constipation, nausea, vomiting, rapid labored respiration, progressive muscular weakness, stiff gait, standing in a humped-up position, dribbling urine, inability to stand, coma, and death. Signs are similar in cattle, sheep, and goats. The disease is often more acute and severe in horses than in cattle, and horses may die of heart failure after subacute ingestion of white snakeroot and presumably rayless goldenrod. Cattle have also been poisoned on a related plant (*Haplopappus acradenius*) in southern California (Galey *et al.*, 1991). In this case, 21 of 60 cattle died and 15 of 60 were affected but recovered. Creatine phosphokinase and ketones were elevated, and severe myonecrosis was described in the dead animals.

## Prevention and treatment

Rayless goldenrod is not readily palatable, and toxicity results from animals being forced to graze the plant due to lack of good quality forage. Avoiding overgrazing will usually minimize poisoning in livestock.

Control of rayless goldenrod can be accomplished with herbicide applications. Late summer and early fall application of picloram or 2,4-D ester is successful in reducing plant populations.

Treatment is generally symptomatic and supportive, providing dry bedding, good shelter, and fresh feed and water. Activated charcoal and saline cathartic may be beneficial. Treatment may include fluids, B vitamins, ketosis therapy, and tube feeding. Hay and water should be placed within reach if the animal is recumbent. In lactating cows, frequent milking may facilitate a more

rapid elimination of the toxins. In horses, monitoring of cardiac arrhythmias and electrocardiogram will provide information concerning heart damage and associated circulatory dysfunction. Treatment is the same for rayless goldenrod and white snakeroot because the toxins are the same.

## HALOGETON (*HALOGETON GLOMERATUS*)

Halogeton is an alien, invasive, noxious, and poisonous weed introduced from central Asia in the early 20th century. It was first collected along a railroad spur near Wells, Nevada, in 1934 and rapidly invaded 11.2 million acres of the cold deserts of the western United States (Young, 1999). There has been no appreciable spread since the 1980s because halogeton has filled all the suitable niches within its tolerance limits. It currently infests disturbed areas within the salt-desert shrub and sagebrush plant communities in the Great Basin, Colorado Plateau, and Wyoming's Red Desert physiographic provinces, which have 3–15 in. of annual precipitation.

Halogeton's infamy began in the 1940s and 1950s by causing large, catastrophic sheep losses. There were many instances of large dramatic losses; sometimes entire bands of sheep died overnight from halogeton poisoning. *Life* magazine ran a cover story titled "Stock Killing Weed" that focused national attention on halogeton. Congress passed the Halogeton Act in 1952 with the intent to

- detect the presence of halogeton;
- determine its effects on livestock; and
- control, suppress, and eradicate this stock-killing weed.

Federal research was reallocated from the Forest Service Experiment Stations to the Bureau of Plant Industries, creating the Range Research unit devoted specifically to "solving" the halogeton problem. It was realized that halogeton was not the problem but a symptom of a larger problem – that of degradation of desert rangelands (Young, 1999). It invaded disturbed sites where sheep congregated – around railroad loading sites, trail heads, stock drive ways, and water holes. When hungry sheep were turned loose to graze, halogeton was the only feed available, and they consumed too much, too rapidly, and were poisoned.

## Description and ecology

Halogeton is an annual plant germinating from seed each year. Its stems are branched from the base and

tinged with red and purple. Its leaves are fleshy and “hot dog” shaped, with the distinguishing feature of a single spine on its tip. It can be distinguished from Russian thistle and pigweed (with which it grows) by the tubular, spine-tipped leaf. It does not have flowers but, rather, bracteoles formed in the axils of leaves from which seed clusters develop. These seed clusters occur throughout the length of its stems. A robust plant may have 1500 linear inches of stem, with 75 seeds/in., producing 200–400lb seed/acre. The seeds are winged and are spread by wind and rodents.

Its seeds are dimorphic, which is key to its successful survival strategy. The majority of its seeds are black and readily germinate anytime; temperature and soil moisture are favorable. However, the black seeds are viable for less than 1 year. A small percentage of the seeds are hard and brown with low germination rates, but they survive for long periods in the soil and germinate when favorable conditions return. The dimorphic seed provided abundant seed for germination each year but also a reserve if drought killed its populations over successive years.

Although halogeton will germinate whenever conditions are favorable, it remains as a seedling until May, at which time lateral branches develop and ascend. It reaches its reproductive stage by mid-summer, or when soil moisture becomes limiting. When mature, the winged fruits are blown by wind or carried and deposited by rodents.

Halogeton is not competitive with perennial shrubs and grasses. It will not invade healthy desert plant communities. When a site is disturbed, halogeton will invade and establish, and its allelopathic properties provide an added advantage to its invasive nature. It takes up sodium and potassium from saline soils, forming the respective oxalates. These oxalates provide an important metabolic function to maintain high cell sap osmotic potential to allow the plant to take up saline water. Oxalates accumulate during the growing season, reaching peak concentration in the fall (20–36% of plant dry weight). Soluble oxalates leach out of the senescent foliage during the winter and accumulate on the soil surface, increasing its salinity. Thus, halogeton modifies its environment, making it more saline to meet its requirements, while exceeding the tolerance limits of associated species.

## Toxicology

The toxins are sodium and potassium oxalates, and plants are high in these oxalates in the fall and early winter when sheep enter the desert winter ranges. Poisoning occurs when sheep consume more oxalates than the body can detoxify (James, 1999). Rumen microbes can

detoxify the oxalates, and their populations can be induced to accommodate increasing levels of oxalates. Furthermore, calcium in the native plants or Ca supplements will rapidly combine with the oxalates in the rumen to form Ca oxalates that cannot be absorbed and are excreted in feces. If the Na oxalates are absorbed, they can be flushed out in urine. If they reach the bloodstream, they precipitate the Ca from the blood, creating Ca oxalate crystals, causing hypocalcemia resulting in shock and death. The Ca oxalate crystals physically damage the tubules of the kidney. The Na oxalates interfere with two key enzymes (succinic dehydrogenase and lactic dehydrogenase) in the Krebs cycle, disrupting energy metabolism. Combined, they cause rapid and acute death.

Clinical signs of poisoning include depression, anorexia, weakness, incoordination, recumbency, blood-tinged nasal discharge, coma, and rapid death. Gross pathologic changes include hemorrhage and edema of the rumen wall, hyperemia of the abomasal wall, and intestinal mucosa and ascites. Morphologic changes include hemorrhage and calcium oxalate crystal formation in the rumen wall and oxalate crystals with accompanying cellular damage in the renal tubules of the kidney.

## Treatment of poisoned animals

Animals can be drenched with water to flush oxalates out in the urine, or including dicalcium phosphate in the drench provides Ca that will combine with oxalates in the rumen and can be excreted. Intravenous injection of calcium gluconate can maintain blood Ca levels, but the forming Ca oxalate crystals will continue to damage kidneys (James, 1999). However, it is generally impractical to treat a severely poisoned animal. Prevention is the key to avoid poisoning. Only hungry sheep are poisoned. Research has demonstrated that as little as 1 oz. of soluble oxalates can be lethal to fasted, hungry sheep. Well-fed sheep grazing nutritious forage throughout the day can tolerate more than 4 oz. of soluble oxalate. Sheep grazed in a desert plant community infested with halogeton consumed it from 5 to 25% of their diets without ill effect. If other forage is available, they will likely not get a lethal dose.

## Management to prevent poisoning

Never turn hungry sheep onto dense halogeton-infested sites. Provide good feed following trucking or trailing. Ensure there is good feed available following watering. Introduce sheep gradually to halogeton to allow rumen microbes to adjust. Some sheep producers graze their

sheep on shadscale ranges (which contain low oxalate levels) before going into halogeton areas. Do not overgraze; maintain desert range in good condition. This prevents halogeton invasion as well as provides an alternative food source.

Herbicide control is not recommended because the waxy surface of halogeton's leaves hinders absorption of most herbicides. More important, however, desirable desert shrubs are killed, leaving the site open for further invasion and degradation by halogeton and other invasive weeds.

## OAK POISONING

Toxicoses in cattle from ingestion of oak buds, leaves, and acorns occurs in many areas of the United States and Europe. Poisoning is usually seasonal, with ingestion of buds and leaves in spring and acorns in fall.

All oaks should be considered potentially toxic (Table 77.7). Oaks are perennial trees or woody shrubs. They grow in all areas of the United States, especially in the southwestern states of Texas, Arizona, and Utah, and they also grow in Europe and New Zealand.

### Conditions of poisoning

The most dangerous period for oak poisoning is during March and April when new foliage is sprouting. Poisoning of cattle and, less frequently, sheep and goats occurs on ranges of the southwest and especially during drought years when the forage is limited. Supplemental feeding so that oak ingestion is below 50% of their diet will usually prevent poisoning. Acorn poisoning occurs in the fall, particularly when an acorn crop is heavy. Cattle, sheep, horses, and swine have been involved, and craving for acorns has been observed in which animals appear to seek them out.

Swine seem to be somewhat resistant, and goats apparently utilize oak browse and are used to control oakbrush. Feeding high levels of immature gambel oak to goats did not induce any toxicosis.

The toxins in oak are tannins, particularly tannic acid and the phenolic acid gallic acid, and these are highest in new spring growth. Clinical signs of poisoning begin with depression, nasal discharge, abdominal pain, constipation, thirst, frequent urination, and rapid pulse, progressing over 1–3 days to rumen atony, anorexia, emaciation, weakness, prostration, rough coat, dry muzzle, subnormal temperature, bloody diarrhea, and death. Diagnosis is based on history of ingestion; clinical signs; elevated serum glutamic oxaloacetic transaminase, blood urea nitrogen, creatinine, and serum potassium; and lower urine specific gravity. Death may occur within 24 h of the onset of clinical signs.

Gross and microscopic lesions include gastritis, nephritis, increased peritoneal and pleural fluids, perirenal edema, and hemorrhages with pale swollen kidneys. The proximal convoluted tubules of the kidneys may be damaged, and abundant hyaline or granular casts may be evident. Mucous and blood are common in voided feces.

### Prevention and treatment

The best method of prevention is to provide adequate feed to reduce oak ingestion to less than 50% of the diet. Supplemental high-energy feed at 0.5–1 kg/head/day of a 54% cottonseed or soybean meal with 30% alfalfa meal, 6% vegetable oil, and 10% calcium hydroxide may be beneficial. Treatment includes blood transfusions if anemic, fluid therapy, rumenotomy if warranted, activated charcoal, plenty of fresh water, and avoiding stressing animals as much as possible.

## PYRROLIZIDINE ALKALOID-CONTAINING PLANTS

TABLE 77.7 Oak species believed to contribute to poisoning

Species	Common name
<i>Quercus gambelii</i>	Gambel's oak
<i>Q. harvardii</i>	Shin or shinnery oak
<i>Q. marilandica</i>	Jack oak
<i>Q. stellata</i>	Post oak
<i>Q. breviloba</i> or <i>durandii</i>	
<i>Q. coccinea</i>	Scarlet oak
<i>Q. pedunculata</i> or <i>robur</i>	European oak
<i>Q. prinus</i>	Chestnut oak
<i>Q. xubra</i>	Northern red oak
<i>Q. velutina</i>	Yellow-barked oak

Pyrrolizidine alkaloid (PA)-containing plants are numerous and worldwide in distribution and in toxic significance (Chee and Shull, 1985). Three plant families predominate in PA-producing genera and species: Compositae (*Senecio* spp.), Leguminosae (*Crotalaria* spp.), and Boraginaceae (*Heliotropium*, *Cynoglossum*, *Amsinckia*, *Echium*, and *Symphytum* spp.). All of these do not occur in the western United States. For plant descriptions, readers are referred to those species that cause losses in the western United States, which are listed in Table 77.8 with common names and distribution.

TABLE 77.8 PA-containing plants in the western United States: common names, habitat, and distribution

Scientific name	Common name	Habitat	Distribution
<i>Amsinckia intermedia</i>	Tarweed, fiddleneck	Dry, open cultivated fields	Pacific Coast; CA, WA, OR, ID
<i>Cynoglossum officinale</i>	Houndstongue	Dry, open areas; cultivated fields	Throughout West
<i>Echium vulgare</i>	Vipers bugloss		CA
<i>Symphytum officinale</i>	Comfrey		
<i>Senecio brasiliensis</i>			
<i>Senecio cineraria</i>	Dusty miller		Ornamental
<i>Senecio glabellus</i>	Bitterweed	Wet soils	TX and east
<i>Senecio integerrimus</i>			MT; Rocky Mountains, CA,
<i>Senecio jacobaea</i>	Stinking willy, tansy ragwort	Open fields and woods	Pacific Northwest
<i>Senecio longilobus</i>	Woody or groundleaf groundsel	Deserts	WY to NE, south to AZ and TX
<i>Senecio spartioides</i>	Broom groundsel		CO, UT south to TX, AZ, NM
<i>Senecio riddellii</i>	Riddell groundsel	Deserts	CO, UT south to TX, AZ, NM
<i>Senecio vulgaris</i>	Common groundsel		CA, OR
<i>Crotalaria sagittalis</i>			Pacific Northwest

FIGURE 77.7 Metabolic pathway of pyrrolizidine alkaloids showing the toxic pyrrole pathway and glutathione conjugate pathway for excretion.

Toxicology

More than 150 PAs have been identified and structural characteristics elucidated. The PAs contain the pyrrolizidine nucleus and can be represented by the basic structures of senecionine and heliotrine. The toxic effects of all PAs are somewhat similar, although their potency varies due to their bioactivation in the liver to toxic metabolites called pyrroles (Figure 77.7). These pyrroles are powerful alkylating agents that react with cellular proteins and cross-link DNA, resulting in cellular dysfunction, abnormal mitosis, and tissue necrosis. The primary effect is hepatic damage; however, many alkaloid and species-specific extrahepatic lesions have been described. Small amounts of pyrrole may enter the blood and be transported to other tissues, but there is debate on this issue because most pyrroles are super-reactive and not likely to make it into the circulation

(Stegelmeier *et al.*, 1999). When PA metabolites circulate, they are probably protein adducts that may be recycled. Some alkaloids (monocrotaline) may come off their carrier blood proteins and damage other tissues such as lung. Pigs seem more prone to develop extrahepatic lesions.

Toxicity of *Senecio*, *Heliotropium*, and *Echium* is largely confined to the liver, whereas *Crotalaria* will also cause significant lung damage. Typical histologic lesions are swelling of hepatocytes, hepatocyte necrosis, periportal necrosis, megalocytosis (enlarged parenchymal cells), karyomegaly (enlarged nuclei) fibrosis, bile duct proliferation, and vascular fibrosis and occlusion. Hepatic cells may be 10–30 times normal size, and DNA content may be 200 times normal.

In most species affected by PA poisoning, the liver becomes hard, fibrotic, and smaller. Because of decreased bile secretion, bilirubin levels in the blood rise, causing

jaundice. Common clinical signs include ill thrift, depression, diarrhea, prolapsed rectum, ascites, edema in the GI tract, photosensitization, and aberrant behavior. In horses, "head pressing" or walking in straight lines regardless of obstacles in the path may occur. These neurological signs in horses are due to elevated blood ammonia from reduced liver function. PA poisoning may cause elevated blood ammonia, resulting in spongy degeneration of the central nervous system.

Elevated levels of serum enzymes such as alanine aminotransferase, aspartate aminotransferase,  $\gamma$ -glutamyl transferase, and alkaline phosphatase are reported (Stegelmeier *et al.*, 1999). Use of these tests for diagnosis is supportive but should not be relied on exclusively because they vary with animal species and other conditions. They may also be in the normal range even though liver damage has occurred, and they tend to be transient. Liver function tests such as bilirubin, bile acids, or sulfo-bromophthalein (BSP) clearance may be useful estimates of the extent of liver damage.

There are marked differences in susceptibility of livestock and laboratory animals to PA toxicosis. Cows are most sensitive, followed by horses, goats, and sheep, respectively. In small laboratory animals, rats are most sensitive, followed by rabbits, hamsters, guinea pigs, and gerbils, respectively. Among avian species, chickens and turkeys are highly susceptible, whereas Japanese quail are resistant (Chee and Shull, 1985).

Detoxification mechanisms of PAs generally involve the liver and GI tract. Evidence of ruminal detoxification in sheep suggests this contributes to the reduced toxicity in that species. There are also substantial species-specific differences in the rate of PA metabolism. Both probably contribute to species susceptibility. For example, *Echium* and *Heliotropium* PAs are easily degraded by certain rumen microflora, but there is little evidence of ruminal degradation of *Senecio* PAs. The PAs in *Senecio* are macrocyclic closed esters of retronecine as opposed to the open esters found in heliotridine. Therefore, the reason for the difference in *Senecio* toxicity between sheep and cattle is unlikely to be the rumen detoxification but more likely differences in species-specific enzymatic activation of *Senecio* PAs. For example, in *in vitro* studies, retrorsine metabolism has been shown to be high in those species that are most susceptible and lowest in animals of least susceptibility. In addition, in *in vivo* studies, it was demonstrated that a higher pyrrole production rate occurred in cattle compared to sheep. Simple induction of liver microsomal enzymes by phenobarbitone increased pyrrole production and increased PA toxicity (LD<sub>50</sub> in guinea pigs from >800 to 216 mg/kg). PA toxicity may disrupt other hepatic functions. Abnormal copper metabolism, coagulation, NH<sub>3</sub> metabolism, protein metabolism, etc. may be affected in PA poisoning.

## Prevention and treatment

Because there are no proven effective methods of prevention or treatment, avoidance of the plant and controlling plant populations with herbicides or biological control is essential. Resistance to PA toxicosis in some species suggests that the possibility may exist to increase resistance to PAs. Dietary factors such as increased protein, particularly those high in sulfur amino acids, had minor protective effects in some species. Antioxidants such as BHT and ethoxyquin induced increased detoxifying enzymes such as glutathione S-transferase and epoxide hydrolase. Zinc salts have been shown to provide some protection against hepatotoxicosis from sporidesmin or lupinosis in New Zealand and Australia, and zinc supplementation reduced toxicity in rats from *Senecio* alkaloids (Burrows and Tyrl, 2001; Knight and Walter, 2001).

Many of these plants were introduced either inadvertently or intentionally. Without natural predators to keep populations in check, they experienced explosive growth and distribution followed by epidemic proportions of toxicity. Introduction of biological controls and natural population controls have reduced many of the plant populations and thus toxicoses have declined. Sheep, a resistant species, have been used to graze plants, particularly *S. jacobaea*.

## PHOTOSENSITIZING PLANTS

Numerous plants cause photosensitization resulting in losses to the livestock industry. Photosensitization is the development of abnormally high reactivity to ultraviolet radiation or natural sunlight in the skin or mucous membranes. Primarily induced in livestock by various poisonous plants, the syndrome in livestock has been defined as primary and secondary photosensitization.

## Description and distribution

Photosensitizing plants are too numerous to describe individually, and readers are referred to taxonomic texts for plant description. Photosensitizing plants occur throughout the world and are common in the diets of livestock and people. Their distribution in the western United States, common names, and toxins are listed in Table 77.9.

## Toxicology

### Primary

In primary photosensitization, the photoreactive agent is absorbed directly from the plant and reaches the

TABLE 77.9    Photosensitizing plants of the western United States, listed as primary and secondary photosensitizers

Scientific name	Common name	Distribution	Toxin
<b>Primary photosensitizers</b>			
<i>Hypericum perforatum</i>	St. John's wort, Klamath weed	Pacific Coast states	Hypericin
<i>Fagopyrum sagittatum</i>	Buckwheat	Northwestern U.S.	Fagopyrin
<i>Cymopterus watsoni</i>	Spring parsley	Southwestern U.S.	Furocoumarins
<i>Ammi majus</i>	Bishop's weed	Southwestern U.S.	Furocoumarins
<b>Secondary photosensitizers</b>			
<i>Artemisia</i>	Sagebrush	Western U.S.	
<i>Tetradymia glabrata</i>	Spineless horsebrush	Western U.S.	
<i>Tetradymia canescens</i>	Gray horsebrush	Western U.S.	
<i>Agave lecheguilla</i>	Lechuguilla	Southwest	Saponins
<i>Nolina texana</i>	Sacahuiste	Southwest	Saponins
<i>Tribulus terrestris</i>	Puncture vine	Southwest	Saponins
<i>Trifolium hybridum</i>	Alsike clover	North, Midwest	
<i>Lantana</i> spp.	Lantana	Southwest	Saponins
<i>Panicum</i> spp.	Panic grass, Kleingrass	Western U.S.	
<i>Brassica napus</i>	Rape	Western U.S.	
<i>Senecio</i> spp.	Senecios	Western U.S.	PAs
<i>Cynoglossum officinale</i>	Houndstongue	Western U.S.	PAs
<i>Cooperia pedunculata</i>	Amaryllis family	Southwest U.S.	
<i>Thamnosma texana</i>	Dutchmans breeches	Southwest U.S.	Psoralens
<i>Kochia scoparia</i>	Kochia, burning bush		Saponins
<i>Descurania pinnata</i>	Tansymustard		Unknown

PAs, pyrrolizidine alkaloids.

peripheral circulation and skin, where it reacts with the ultraviolet rays of the sun and results in sunburn, particularly of unprotected areas of the body. Hypericin and fagopyrin are polyphenolic derivatives from St. John's wort and buckwheat, respectively, and are primary photodynamic agents (Cheeke and Shull, 1985). By definition, primary photosensitization does not induce hepatic damage. Most agents are ingested, but some may induce lesions through skin contact. Several of these plants are weedy in nature and can contaminate pastures and feed. Exposure to some plants is increasing as they are becoming widely used as herbal remedies and holistic medicines. In most cases, the photodynamic agent is absorbed from the digestive tract unchanged and reaches the skin in its "native" form (Stegelmeier, 2002).

There are drugs and other toxins known to cause primary photosensitization, and these should be considered in the differential diagnosis. Phenothiazine-induced photosensitization is most common in ruminants because the photodynamic agent is phenothiazine sulfoxide, a rumen metabolite. Clinical signs in addition to photosensitivity include corneal edema and kerato conjunctivitis from the phenothiazine sulfoxide excreted in tears and the aqueous humor. Other toxins associated with primary photosensitivity include thiazides, acriflavins, sulfonamides, tetracyclines, methylene blue, coal-tar derivatives, furosemide, promazine, chlorpromazine, quinindine, and some antimicrobial soaps (Stegelmeier, 2002).

Secondary

In secondary or hepatogenous photosensitization, the photoreactive agent is phylloerythrin, a degradation product of chlorophyll. Phylloerythrin is produced in the stomach of animals, especially ruminants, and absorbed into the bloodstream. In normal animals, the hepatocytes conjugate phylloerythrin and excrete it in the bile. However, if the liver is damaged or bile secretion is impaired, phylloerythrin accumulates in the liver, the blood, and subsequently the skin, causing photosensitivity. This is the most common cause of photosensitization in livestock and horses (Knight and Walter, 2001). Because chlorophyll is almost always present in the diet of livestock, the etiologic agent of secondary photosensitization is the hepatotoxic agent.

The dermatologic signs of photosensitization in livestock are similar regardless of the plant or toxicant involved. Degree or severity varies, depending on the amount of toxin or reactive phylloerythrin in the skin, degree of exposure to sunlight, and amount of normal physical photoprotection (hair and pigmentation). First signs in most animals are restlessness or discomfort from irritated skin, followed by photophobia, squinting, tearing, erythema, itching, and sloughing of skin in exposed areas (i.e., lips, ears, eyelids, udder, external genitalia, or white pigmented areas) (Burrows and Tyrl, 2001). Swelling in the head and ears (edema) of sheep after ingestion of *Tetradymia* has been referred to as big head.

It was determined that sheep grazing black sagebrush (*Artemisia nova*) before *Tetradymia* were three times more likely to develop this photosensitization. Tissue sloughing and serum leakage may occur where tissue damage is extensive. Primary photosensitization rarely results in death. However, in secondary or hepatogenic photosensitization, the severity of liver damage and secondary metabolic and neurologic changes of hepatic failure may ultimately result in death. Recovery may leave sunburned animals debilitated from scar tissue formation and wool or hair loss.

### Prevention and treatment

Prevention of poisoning lies in controlling plants with photosensitizing potential and providing adequate quality forage to animals. Treatment after poisoning involves removing animals from sun exposure, treating areas of necrosis and sunburn, antibiotic therapy, and supplementing young animals when access to sunburned udders is prevented because of nursing discomfort to dams. Identifying chronic hepatic disease is complicated because many of the serum markers for hepatic disease have returned to normal. As normal hepatocytes become replaced with fibrous connective tissue, there are fewer damaged cells to elevate serum enzymes. Percutaneous liver biopsies are invaluable in identifying and diagnosing these cases (Stegelmeier *et al.*, 1999).

Plant-induced hepatopathy generally results in characteristic histologic lesions. For example, pyrrolizidine alkaloids generally cause bridging portal fibrosis with hepatocellular necrosis, biliary proliferation, and megalocytosis. *Panicum* and *Tribulus* species generally produce a crystalline cholangiohepatitis. Liver biopsy also provides prognostic information. The degree of damage is correlated directly with the animal's ability to compensate, recover, and provide useful production. Note that the liver reacts to insult in a limited number of ways, and most histologic changes are not pathognomonic. Hepatic cirrhosis (necrosis, fibrosis, and biliary proliferation) involves nonspecific changes that can be initiated by a variety of toxic and infectious agents (Stegelmeier *et al.*, 1999).

## DEATH CAMAS

All death camas species are assumed to be toxic; however, variation in toxicity exists between species and even within species depending on season, climate, soils, and geographical locations. Poisoning in sheep, cattle, horses, pigs, fowl, and humans has been reported.

**FIGURE 77.8** Foothill death camas with leaf structure, flower head, and bulb.

The largest losses generally occur in sheep. Sheep are primarily affected because of their tendency to select forbs, particularly in early spring when they are turned onto range before grasses have emerged.

Death camas is generally not palatable to livestock but is one of the earliest species to emerge in the spring. Poisoning most frequently occurs in spring when other more palatable forage is not available, or on overgrazed ranges where there is a lack of more desirable forage. Poisonings have resulted due to management errors in which hungry animals were placed in death camas-infested areas (Panter *et al.*, 1987).

### Description, habitat, and geographical distribution

Foothill death camas is typical of the 15–20 species of *Zigadenus* in North America and Asia (Figure 77.8). A list of death camas species and their habitats, distributions, and growth periods is provided in Table 77.10. It is difficult to distinguish between species because they are taxonomically similar. A member of the lily family, death camas is a perennial, glabrous herb with basal V-shaped grass-like leaves growing from an onion-like bulb with a dark-colored outer coat. Stems produced at flowering are single, unbranched, sparingly leafed, and terminated by a terminal raceme of greenish-white, cream-colored, or pink inflorescence. The perianth is six-membered, consisting of three lanceolate or ovate sepals and three petals separate or united below, with one or two glands just above the base; six stamens; and three styles. Floral parts are persistent but winter as the fruits develop. The seed

TABLE 77.10 *Zigadenus* spp.: common name, distribution, habitat, and growth periods

Species	Common name	Distribution	Habitat	Growth period
<i>Z. paniculatus</i> S. Watson	Foothill death camas; sand-corn; panicked death camas	Eastern WA, OR, ID, UT, WY, NV, eastern CA, northern AZ and NM	Foothills and benches	May–July

<i>Z. virescens</i> Kunth.		AZ, NM, and northern Mexico		

is a three-cavited capsule, separating into three members and opening inwardly at maturity. Death camas is easily confused with wild onion, mariposa lily, or common camas particularly before flowering. Wild onions are distinguished by tubular leaves and their onion-like odor. The leaves of mariposa lilies are more U-shaped in cross section, and common camas has a blue flower. Death camas is prevalent in western North America and is native to the open plains and foothills of the United States.

### Toxicity of death camas to livestock

The toxins in death camas are of the cevanine steroidal alkaloid type – that is, zigacine (**11**). Zigacine is a very potent compound with an i.v. LD<sub>50</sub> of 2mg/kg and an oral LD<sub>50</sub> of 130mg/kg in mice (Welch *et al.*, 2011b). Clinical signs of toxicosis are similar in all livestock poisoned by *Zigadenus*, irrespective of the species of plant

involved. Excessive salivation is noted first, with foamy froth around the nose and muzzle that persists, followed by nausea and occasionally vomition in ruminants (Panter *et al.*, 1987). Intestinal peristalsis is dramatically increased, accompanied by frequent defecation and urination. Muscular weakness with accompanying ataxia, muscular fasciculations, prostration, and eventual death may follow. The pulse becomes rapid and weak, and the respiration rate increases but the amplitude is reduced. Some animals become cyanotic, and the spasmodic struggling for breath may be confused with convulsions. The heart fails before respiration, and at necropsy the heart is usually found in diastole. A comatose period may range from a few hours to a few days before death.

Pathological lesions are those of pulmonary congestion. Gross lesions of sheep include severe pulmonary congestion, hemorrhage, edema, and subcutaneous hemorrhage in the thoracic regions. Microscopic lesions include severe pulmonary congestion with infiltration of red blood cells in the alveolar spaces and edema. Diagnosis of poisoning may be established by clinical signs of toxicosis, evidence of death camas being grazed, histopathological analysis of tissues from necropsied animals, and identification of death camas in the rumen or stomach contents (Panter *et al.*, 1987).

Similarity in clinical signs of toxicosis between certain species of these plants suggests that the same alkaloids are present; however, differences in concentrations can explain the differences in relative toxicity of different species (Table 77.11).

## Management and prevention

Conditions conducive to poisoning by death camas include driving animals through death camas-infested ranges; not allowing animals to graze selectively; unloading hungry animals in infested areas; lambing, bedding, watering, or salting livestock in death camas-infested areas; or placing animals on range where little forage is available. Poisoning generally occurs in the early spring when death camas is the first green forage available and the young immature foliage is the most toxic. Single losses of 300–500 sheep have been reported (Panter *et al.*, 1987). In the 1987 case, 80% of the dead sheep were 80- to 90-lb lambs. Three key factors contributed to the losses: (1) ewes with lambs were driven through a heavily infested area of death camas when the sheep were hungry; (2) the sheep were bedded down for the night near the death camas area, providing immediate access to death camas the following morning; and (3) the herder panicked and rapidly forced the sheep out of the area, contributing to the stress and probably exacerbating the toxic effects and increasing the losses.

TABLE 77.11 Relative toxicity in sheep of five *Zigadenus* spp.

<i>Zigadenus</i> species	Average minimum toxic dose <sup>a</sup>	Average minimum lethal dose <sup>a</sup>
<i>Z. gramineus</i>	4	6

## VERATRUM SPP.

*Veratrum* belongs to the Liliaceae (Lily) family and is composed of at least five species in North America. During the mid-20th century, up to 25% of pregnant ewes that grazed on pastures infested with *Veratrum californicum* in the mountains of central Idaho gave birth to lambs with serious craniofacial malformations. These malformations ranged from the gross anomaly of cyclops to less severe deformities of the upper and lower jaws. The Basque shepherds called the cyclopic defect “chatto,” which translated as “monkey faced” lamb disease. Although losses from *Veratrum* have long been reduced or eliminated on these ranges due to the application of research findings and recommended management strategies, biomedical research using the alkaloids, isolated and identified at the Poisonous Plant Research Laboratory, as molecular probes has opened a new frontier for human medical research (James *et al.*, 2004).

## Distribution

*Veratrum californicum* grows primarily in the high mountain ranges of the western United States (Knight and Walter, 2001). *Veratrum viride* is the most widespread species and grows in the northwestern United States north through western Canada into Alaska and is also widespread in the northeastern United States. *Veratrum insolitum* grows in a relatively small region of northwestern California and southwestern Oregon; *V. parviflorum* grows in the central southeastern states; and *V. woodii* grows from Ohio to Missouri, Oklahoma, and Arkansas. Two other species have been reported to cause poisoning in other countries: *V. japonicum* in Korea and *V. album* in Europe. Common names include western false hellebore, hellebore, skunk cabbage, corn lily, Indian poke, and wolfsbane. Caution should be used with common names because they may be used interchangeably within this genera but also in unrelated genera. For example, the name hellebore is also used for the genus *Helleborus* in the buttercup family.

## Habitat and description

Most *Veratrum* spp. are found in similar habitats of moist, open alpine meadows or open woodlands, marshes, along waterways, in swamps or bogs, and along lake edges in high mountain ranges. Most species grow at higher elevations. All species are similar, with coarse, erect plants approximately 1–2.5 m tall with short perennial rootstalks. The leaves are smooth, alternate, parallel veined, broadly oval to lanceolate, up to 30 cm long, 15 cm wide, in three ranks, and sheathed at the base. The inflorescence is panicle flowers; the lower ones often staminate and the upper ones perfect. The flowers of *V. viride* are distinctly green, and the fruit is three-chambered with several seeds.

## Toxicology

More than 50 complex steroidal alkaloids have been identified from the *Veratrum* spp. Five classes of steroidal alkaloids have been characterized: veratrines, cevanines, jervanines, solanidines, and cholestanes. The veratrines and cevanines are of considerable interest in toxicology because they are neurological toxins and hypotensive agents that bind to sodium channels, delaying closure and causing cardiotoxic and respiratory effects. The cevanine alkaloids, such as zigacine, are also found in *Zigadenus* spp., which are also members of the Lily family. The jervanines are most significant for their teratogenic effects; the most notable alkaloids were named cyclopamine (**12**) and jervine, both potent inducers of the congenital cyclopia monkey faced lamb syndrome reported in many flocks of sheep in the late 1950s in central Idaho. This cyclopic defect is induced in the sheep embryo during the blastocyst stage of development when the pregnant mother ingests the plant during the 14th day of gestation. Early embryonic death up to day 19 of gestation and other defects, such as limb defects and tracheal stenosis, occur when maternal ingestion includes days 28–33 of gestation (Keeler and

much less likely to induce birth defects. The structure–activity relationship is very important in potency to produce birth defects. It is now known that this structure–activity relationship is key in the mechanism of action, which is the inhibition of the sonic hedgehog signaling pathway (Gaffield and Keeler, 1996). This sonic hedgehog gene pathway and the subsequent downstream regulation of other genes' expression have been implicated in numerous cancers, birth defects, and other anomalies. The toxin cyclopamine has become a significant tool in the study of this very complex sonic hedgehog pathway. Clinical trials have been proposed and studies are ongoing to further identify the hedgehog complex of genes and to understand its mechanism and function in formation and growth of numerous cancers, childhood birth defects, and manipulation of regulatory pathways.

Clinical signs of poisoning are most likely caused by the neurotoxic cevanine alkaloids present in most species of *Veratrum*. Typical signs begin with excess salivation with froth around the mouth, slobbering, and vomiting progressing to ataxia, collapse, and death. The elimination half-life of cyclopamine in sheep is approximately 1.1 h (Welch *et al.*, 2009b). Consequently, 8 h after consuming *Veratrum*, greater than 99% of the toxins should be eliminated from the animal.

## Prevention and treatment

Control of *Veratrum* is relatively easy with herbicides such as broad-leaf herbicides, and long-term control has been demonstrated. The teratogenic effects of *Veratrum* can be avoided by keeping sheep and other livestock species off pastures containing the plants during the first trimester of pregnancy. Observation of toxicoses in the field is rare unless herders move the animals soon after exposure. The neurological signs, which are likely produced by the cevanine alkaloids (both *Veratrum* and *Zigadenus* spp.), can be treated with atropine to improve the cardiovascular output. Activated charcoal to adsorb toxins and administration of picrotoxin to improve respiration have been recommended (Burrows and Tyrl, 2001).

Stuart, 1987). The solanidine alkaloids are also found in many *Solanum* spp. and are toxic and teratogenic. The cholestanes have been used as hypotensive drugs but are

## BRACKEN FERN (PTERIDIUM AND AQUILINUM)

### Distribution and habitat

The bracken fern family is worldwide in distribution and includes approximately 20 genera and more than

400 species. Although most species described are found in the tropics, there are 4 genera and 6 species described in North America (Burrows and Tyrl, 2001). The bracken fern most associated with toxicoses in the United States is *Pteridium aquilinum* (Kuhn), which is distributed throughout North America. It is reported to be one of the most widespread species of vascular plants, only exceeded in geographical range by a few annual weeds. Four varieties of *P. aquilinum* have been described: var. *pubescens* (western bracken fern), found throughout the western United States; var. *caudatum* (lacy bracken), restricted to southern Florida; var. *latiusculum* (eastern bracken), distributed throughout the eastern United States; and var. *pseudocaudatum* (tailed bracken), located mostly in the southeastern quarter of the United States.

Western bracken grows best in rocky, gravelly, well-drained soils in dry, open woodlands to semishaded habitats. Extensive stands frequently grow along pasture edges, in logged areas, or where fires have opened up the canopy. Moisture needs are modest in comparison with those of many of the ferns, and good soil drainage is important.

## Description

Bracken plants are deciduous and grow from brown to black woody rhizomes, forming large, often dense patches. The leaves emerge from erect fronds and are pinnately compound, scattered, erect, coarse, narrowly or broadly triangular, to 2 m in height. Fronds (leaves) are pinnules (ultimate segments), oblong, entire in the apices of the pinnae, and lobed toward the stalk. Reproduction is by spores produced in sporangia lining the undersurface margins of the photosynthetic fronds; when reproductive, they are covered by the narrow recurved edge of the leaf (Burrows and Tyrl, 2001).

## Toxicology

Toxicity of bracken fern was first recognized in the 1800s and described in horses as a neurological condition. Contaminated hay was believed to be the cause, and the condition was described in the United Kingdom and Pacific Coast states of the United States (Taylor, 1990). Early research determined that 20–25% bracken for 3 or 4 weeks would induce a neurological disease followed soon after by death. Although the neurological condition is mostly described in horses, low hematocrits and reddish-brown urine have also been described in suspected cases of bracken poisoning.

Bracken causes a wide range of syndromes that have been described in livestock, including thiamine deficiency in monogastrics, acute hemorrhagic disease

associated with bone marrow aplasia and ulceration of the upper GI tract, “bright blindness” progressive retinal degeneration, and neoplasia of the urinary bladder and upper digestive tract. The major toxin is the sesquiterpene glucoside, ptaquiloside (13). Other toxins, carcinogens, and mutagens may also be implicated in the disease conditions.

People have consumed the rhizomes or croziers of bracken fern as a traditional food or out of necessity, and the toxin is transferred through milk of cows grazing the plant. Epidemiological evidence suggests that some cancers in humans probably result from primary or secondary consumption of the carcinogens. Ptaquilosides form adducts with DNA, binding to certain base sequences, resulting in mutated codons associated with known oncogenes. This hypothesis has been proposed in the pathogenesis of the disease.

Syndromes of bracken poisoning are well recognized in livestock. Many factors must be considered in the genesis of the disease, such as quantity consumed, phenological stage of the plant, time of year, consumption rate and length of time consumption occurs, animal species, age, and sex of the animal. The disease conditions described include thiamine deficiency in monogastrics, acute hemorrhagic disease, bright blindness, enzootic hematuria, and small intestine carcinoma. These conditions have been experimentally produced by feeding bracken fern and ptaquiloside to livestock species and rodent models. Bracken fern feeding studies in rodents have produced neoplasms in the ileum, urinary bladder, mammary glands, and lungs of rodents.

The toxin ptaquiloside was isolated, characterized, and the structure published in the early 1980s (Saito et al., 1990). Different species and varieties of *Pteridium* have been compared for ptaquiloside concentration, and all examined to date contained ptaquiloside. Large variations in concentration were demonstrated between locations, altitude, season, etc., suggesting a genetic component or another factor, such as endophyte-produced compounds. These differences were maintained when bracken fern rhizomes were transferred to a greenhouse and soils were changed; thus, the ptaquiloside differences

were still evident for the next 3 years. Ptaquiloside concentrations are highest in young growing parts (i.e., the tips of the croziers and immature fronds), whereas concentrations diminish as the plant matures and as samples are taken from more mature pinnae and toward the base of the lamina. In all samples of rhizome, the apices of the fronds or primordia taken from below the soil surface had no ptaquiloside; however, very immature croziers only a few centimeters above the surface showed the presence of the toxin. The emergence of the crozier apices and exposure to light apparently influence the biosynthesis of the toxin. The spores have not been shown to contain ptaquiloside, but they have caused cancer and formed DNA adducts, suggesting that carcinogenic or mutagenic derivatives are present. Ptaquiloside and other ptaquiloside-like compounds with carcinogenic activity have been isolated from other ferns from the genera *Histiopteris*, *Cheilanthes*, *Cibotium*, *Dennstadtia*, *Hypolepis*, *Pteris*, and *Pityrogramma* (Saito *et al.*, 1990).

Although bracken fern poisoning occurs in the United States, the most serious risk is in countries such as Australia, New Zealand, Japan, and the United Kingdom, where bracken is more prevalent and utilized for human food or animal feed. Epidemiology studies have associated increased esophageal and gastric cancers with direct ingestion, secondary ingestion (i.e., milk from cows grazing bracken), or living in bracken fern-infested areas. Bracken fronds steeped in water or treated with wood ash or sodium bicarbonate have reduced toxicity, but this process only reduces the concentration and does not eliminate the toxins.

Lesions in horses poisoned by bracken fern are indicative of thiamine deficiency and include congestion of the brain, a swollen and edematous cerebrum grossly, and necrosis of some neurons microscopically. Acute hemorrhagic disease in cattle is characterized by extensive hemorrhage of the mucous membranes and subcutaneous hemorrhage and edema.

Pathology of the bracken-induced enzootic hematuria includes desquamated and proliferative bladder epithelium, and areas of vascularized epithelial proliferation appear as polyploid, papillary, or fungoid reddened foci. Microscopically, columns of transitional epithelium infiltrate into the lamina propria along with mononuclear cells. Neoplasia, when it occurs, is most commonly the noninvasive papillomatous type, but other papillary types of transitional cell carcinoma, squamous cell carcinoma, adenocarcinoma, or hemangiomas may also develop (Burrows and Tyrl, 2001).

## Treatment

Bracken-induced thiamine deficiency in horses is treatable with administration of thiamine parenterally at

**FIGURE 77.9** Narrow leaf (left) and broad leaf (right) milkweeds (*Asclepias* spp.) represented.

0.5–1g, followed by decreasing doses during the next few days. Symptomatic care with good feed and fresh water accompanied by administration of a laxative but not mineral oil is helpful. In ruminants, the bone marrow suppression and deficiency of blood platelets and neutrophils is best treated with antimicrobials to counteract any bacterial infection that might occur because of diminished immune function. Good veterinary care, symptomatic treatment, clean water, and quality feed in a quiet, clean environment are recommended.

## MILKWEEDS: ASCLEPIAS SPP.

### Description

Milkweeds are classified into two broad groups: (1) narrow-leaved, with narrow, linear, lanceolate leaves, and (2) broad-leaved, with leaves approximately 4cm wide throughout much of their length (Figure 77.9). There are more than 150 species of *Asclepias*, of which 108 occur in North America. Milkweeds are perennial, summer or early autumn flowering herbs with a milky latex-like cream in the stems. Of the many species found in North America, several are important toxicologically and are represented in Table 77.12. The stems of the plants are erect and range from 4 to 150cm tall; leaves are opposite or whorled. Flowers are of various colors, umbellate

TABLE 77.12 Milkweeds: *Asclepias* spp., common name, distribution, habitat, and toxin

Species	Common name	Distribution	Habitat	Toxin; content <sup>a</sup>
<b>Narrow-leaved milkweeds</b>				
<i>A. labriformis</i> Jones	Labriform milkweed	Southeastern UT	Along old streambeds in sandy soils	Cardiac glycosides, digitoxin; very high
<i>A. verticillata</i> L.	Eastern whorled milkweed, spider milkweed	From TX to MI, east to FL and MA	Dry open areas	Cardenolides; very low
<i>A. subverticillata</i> Vail	Western whorled milkweed, horsetail milkweed	Western KS and OK, UT, AZ, TX and into Mexico	Dry plains and foothills, spreads rapidly along waterways and canals	Cardenolides; very low
<i>A. pumila</i> Vail	Low whorled milkweed, plains whorled milkweed	East of the Rockies from TX and NM north to southeast MT and southwest ND	Small patches in draws and ravines	Cardenolides; very low
<i>A. mexicana</i> Cav.	Mexican whorled milkweed	Southern TX to central Mexico	Open areas and dry soils	Cardenolides; unknown
<i>A. asperula</i> Woodson	Antelope horn milkweed	KS, AR to NV and AZ	Open areas and dry soils	Cardenolides; very high
<i>A. fascicularis</i> Decne.	Mexican milkweed	CA, western OR through eastern WA, ID and NV		Cardenolides; very low
<i>A. brachystephana</i> Engelm.	Short-crown milkweed	West central TX, southern AZ into NM and Mexico		Cardenolides; very high
<i>A. subulata</i> Decne.	Desert milkweed, yamate, ajamete	Southern CA, AZ, west coastal region of Mexico		Cardenolides; very high
<b>Broad-leaved milkweeds</b>				
<i>A. eriocarpa</i> Benth.	Woolly pod milkweed	CA	Dry soils	Cardenolides; very high
<i>A. latifolia</i> Brit.	Broadleaf milkweed	KS, CO to TX and AZ	Dry plains	Cardenolides; high
<i>A. speciosa</i> Torr.	Showy milkweed	MN south to MI and TX; west to CA	Prairies and open spaces	Cardenolides; intermediate
<i>A. syriaca</i> L.	Common milkweed	Widely distributed in central and eastern U.S.	Open areas and along roadsides	Cardenolides; intermediate
<i>A. incarnata</i> L.	Swamp milkweed	IN	Cool damp soils	Cardenolides; very low
<i>A. vestita</i> Hook and Am.	Woolly milkweed	Central and south western CA		Cardenolides; very high

<sup>a</sup>Cardenolide content mg/g plant from <0.25 (very low) to >4 (very high).

clusters or solitary, and terminal or extra-axillary. Numerous seeds are contained in an inflated milkweed-type pod and are flat and large, with each bearing a tuft of long, silk-like hairs for wind distribution.

## Distribution and habitat

Milkweeds are adapted to a broad range of habitats and environmental conditions and are found in most plant communities. Occupied habitats include prairies, woodlands, open areas, rocky plains, sand dunes, swamps, marshes, seeps, canyon bottoms, dry washes, desert lands, and waste lands. Most species are weedy and form small to large patches often along roadsides, in disturbed areas, or in overgrazed pastures.

## Toxicology

Some species of milkweeds have been used as medicines, food, or a source of poison. Most species contain a mixture of steroidal glycosidic cardenolides (**14**) that are toxic and induce two syndromes – one with GI/cardio-toxic effects and the other with neurological effects. The early literature suggested that the broad-leaved group was cardiotoxic, whereas the narrow-leaved type was neurotoxic. However, most narrow-leaved species have now been shown to also contain cardiotoxins (Ogden *et al.*, 1992).

Historically, naturalists observed as early as the mid-1800s that birds avoided eating certain butterflies, such as the monarchs, whose larvae fed on milkweeds. It was later learned that the feeding larvae were able to

concentrate some of the cardenolides that were potent emetics and thus created an effective defense against herbivory. As of the late 1980s, 27 species of milkweed were recognized as common feed for butterfly larvae, and the most toxic species were often preferred. Milkweeds are also host to many other insect species.

The basic structure of the series of identified cardenolides is a 23-C steroidal backbone with a five-membered, singly unsaturated lactone ring at the C-17 position, a hydroxyl group at C-14, and methyl groups at C-10 and C-13. Glycosidic linkage usually occurs at the C-3 or C-2 positions and may include glucose, rhamnose, or thevetose as the sugars. Additional functionalities attached to the backbone further influence solubility and binding, thus increasing or decreasing toxicity. The cardenolides inhibit  $\text{Na}^+/\text{K}^+$ -ATPase, and the structure-activity relationship is believed to reside in the unsaturated lactone ring at C-17 and the hydroxyl group at C-14 (Joubert, 1989).

Sheep, goats, cattle, horses, and domestic fowl have been poisoned with milkweeds. Clinical signs usually begin with depression, weakness, and labored breathing accompanied by ataxia and loss of balance, progressing to recumbency, seizures, and death. The order of clinical signs is dependent on the type of animal affected, the toxicity of the plant, the time of ingestion, and the amount of the toxin consumed. Clinical effects appear within a few hours of ingestion, and death may follow within 1 to a few days later in fatal cases.

## Treatment and control

There are two syndromes of milkweed poisoning – a neurological one and a cardiac one. Treatment for the cardiotoxic signs is approached similar to that of digitalis glycoside toxicity – that is, activated charcoal, atropine for atrioventricular block, and/or antiarrhythmic drugs. There is no specific treatment for the neurological

syndrome except symptomatic treatment to control seizures and supportive therapy. A field test with a detection threshold of 0.057% is available for detecting cardenolides in the latex of milkweeds (Sady and Seiber, 1991). Knowledge of the milkweed species in the pasture, stage of plant growth when consumed, and history of grazing and clinical effects are all important in developing a diagnosis and eliminating other causes.

In most cases, knowledge that the plant exists in one's pasture and prevention of ingestion is the best way to avoid poisoning. Purchase of weed-free hay to avoid poisoning via contamination is also important. Know where the hay comes from, and always be alert as to the content of the hay. Control of milkweeds can be accomplished with herbicides such as 2,4-D, picloram, amitrole, or glyphosate, depending on the other forage it has infested and the circumstances. Always follow the manufacturer's recommendations.

## NIGHTSHADES

The nightshade family comprises more than 80–90 genera and more than 2300 species worldwide. Some of the more common poisonous genera are *Brugmansia*, *Brunfelsia*, *Capsicum*, *Cestrum*, *Datura*, *Hyoscyamus*, *Lycium*, *Lycopersicon* (tomato), *Nicotiana* (tobacco), *Solandra*, *Solanum*, *Nicandra*, and *Physalis*. Some common nightshade species are listed in Table 77.13. In the United States and Canada, the nightshades can be annual, perennial, or shrubs with alternate, simple or compound leaves, axillary inflorescences, radially symmetrical flowers composed of five free sepals, five free petals, and usually five stamens with anthers grouped conically about the stigma and berry-like fruits of variable colors.

## Toxins

The nightshades have a variety of toxins known to affect people and animals, including the tropane alkaloids, which affect the autonomic nervous system by blocking the action of cholinesterase (Knight and Walter, 2001). This results in accumulation of acetylcholine and subsequent inhibition of the parasympathetic nervous system, causing dry mouth, decreased intestinal motility, dilated pupils, and tachycardia. The tropane alkaloids also affect the GI tract, causing colic in horses, constipation, and/or hemorrhagic diarrhea. The *Nicotiana* spp. contain neurological toxins including the pyridine and piperidine alkaloids that are responsible for toxicoses and teratogenesis. Some species of *Solanum* cause a neurological disease in cattle, sheep, and goats characterized by loss of equilibrium,

TABLE 77.13 Nightshade species with known links to toxicosis in humans or animals: common names, distribution, and toxins

Species	Common name	Distribution	Toxins
<i>Solanum elaeagnifolium</i>	Silverleaf nightshade	Southern U.S.	Solanine and solanidine
<i>S. nigrum</i>	Black nightshade	Throughout North America	Tropane and glycoalkaloids
<i>S. dulcamara</i>	Bittersweet; climbing nightshade	Eastern half of U.S.; areas of OR, WA, NV, CA, UT and WY	Glycoalkaloids
<i>S. rostratum</i>	Buffalo bur	Central U.S. to north and south borders	Glycoalkaloids
<i>S. triflorum</i>	Cutleaf nightshade	Central U.S. to north border	Glycoalkaloids
<i>S. americanum</i>	Huckleberry; wonderberry	Southern U.S.	Glycoalkaloids
<i>S. physalifolium</i>	Tropical soda apple	Throughout U.S.	Glycoalkaloids
<i>S. sarrachoides</i>	Hairy nightshade		Glycoalkaloids
<i>S. carolinense</i>	Horse or bull nettle	Eastern half of U.S.; west coast	Tropane alkaloid solanine
<i>S. tuberosum</i>	White or Irish potato	Worldwide	Glycoalkaloids
<i>Datura wrightii</i>	Sacred datura	Southwestern U.S.	Tropane alkaloids
<i>D. stramonium</i>	Jimson weed; thorn apple	Southeastern half of U.S.; west coast	Tropane alkaloids
<i>Nicotiana tabacum</i>	Cultivated or burley tobacco	Southern U.S.	Pyridine alkaloids (nicotine)
<i>N. glauca</i>	Tree tobacco	Southern U.S.	Piperidine alkaloids
<i>Capsicum annum</i>	Green or chili pepper	Cultivated in U.S.	Capsaicinoids
<i>Cestrum parqui</i>	Willow-leaved jessamine	Southern Gulf states	Glycoside of vitamin D
<i>Atropa belladonna</i>	Deadly nightshade; belladonna	Cultivated as an ornamental	Tropane alkaloids
<i>Hyoscyamus niger</i>	Black henbane	Northern U.S.	Tropane alkaloids, calystegins
<i>Physalis virginiana</i>	Ground cherry	Plains states and eastern U.S.	Glycoalkaloids, calystegins
<i>P. lobota</i>	Chinese lantern	Southern regions; cultivated throughout U.S.	Glycoalkaloids
<i>Lycopersicon esculentum</i>	Tomato	Worldwide	Glycoalkaloids

Adapted from Burrows and Tyrl (2001) and Knight and Walter (2001).

tremors, ataxia, collapse, opisthotonus, seizures, and death. *Solanum malacoxylon* and *Cestrum* spp. contain vitamin D-like compounds that cause abnormal calcium absorption and metabolism resulting in calcified tissues, lameness, and weight loss. Green potatoes, sprouts, and vines contain steroidal glycoalkaloids that are both toxic and teratogenic. Table 77.13 provides a limited overview of selected species, their distributions, and their toxins (Burrows and Tyrl, 2001; Knight and Walter, 2001).

## Clinical signs

The toxins in the Solanaceae family contribute to various clinical effects depending on the amount of plant/toxin ingested, the plant species eaten, and the animal species consuming the plant. Signs range from mild digestive upset to severe colic in horses when contaminated hay is fed; neurological dysfunction, seizures, and death in sheep and cattle; big head and calcification of the blood vessels; and teratogenesis.

## Treatment

Animals showing severe neurological signs, such as tremors, ataxia, and dilated pupils, may be treated with physostigmine. Oral activated charcoal as an adsorbent

may be effective if administered in a timely manner. However, most animals will recover if treated symptomatically and if the animals are not overly stressed.

## KNAPWEEDS: CENTAUREA SPP.

The knapweeds are a large group with primarily noxious, invasive characteristics. Although this genus is not a great risk for livestock producers, a serious disease of horses called nigropallidal encephalomalacia warrants its inclusion in this chapter. There are 450–500 species of *Centaurea*, and 29 species have been described in North America (Burrows and Tyrl, 2001). Most of these have been introduced and have had a huge negative impact on rangelands in the western United States. Although most species are opportunists and will aggressively invade rangelands, especially those that have been overgrazed, burned, or disturbed, only 2 species are of any toxicologic significance – *Centaurea repens* (Russian knapweed) and *C. solstitialis* (yellow star thistle).

## Habitat and distribution

Yellow star thistle is most abundant in the western United States from central California north through

Oregon, Washington, and Idaho. Smaller invasions are reported in many states east of the intermountain region, and although these have not received the attention of the larger invasions in the west, they have the potential to rapidly spread under the right environmental conditions (Panter, 1991; Burrows and Tyrl, 2001; Knight and Walter, 2001). Russian knapweed has invaded very large areas of the intermountain region of the western United States and the Great Plains. Again, smaller populations have invaded areas of the Midwest and northeastern United States and have the potential to expand rapidly. Although the aggressive nature of these species threatens rangelands and prohibits optimum utilization, a greater threat is the risk to sensitive or threatened native plant species and the balance of plant biodiversity.

## Toxicology

The compounds isolated from knapweeds include a large class called sesquiterpene lactones. Although the putative toxin causing the neurological disease in horses has not been specifically identified, six of these compounds have been screened for cytotoxicity in an *in vitro* neuronal cell bioassay. The rank order of activity is repen > subulateolide > janerin > cynaropicrin > acroptilin > solstitialin (Riopelle and Stevens, 1993). Toxicity of solstitialin A-13 acetate and cynaropicrin to primary cultures of fetal rat substantia nigra cells has been demonstrated. These sesquiterpene lactones are quite unstable, and it has been hypothesized that they are precursors to the ultimate neurotoxin. Also, there are aspartic and glutamic acids present in these plants, and they possess neuroexcitatory properties.

## Clinical signs

Thus far, only yellow star thistle and Russian knapweed have been implicated in toxicoses in the United States and only in horses. Apparently, ruminants are not affected, and the *Centaurea* spp. may be useful forage for sheep and goats. However, in other countries, toxicoses in ruminants have been reported. For example, in South Africa, *C. repens* fed to sheep at 600 g dosages for 2 days caused an acute digestive upset and pulmonary edema and ascites. In Azerbaijan, *C. repens* is reported to cause a neurological disease in buffalo similar to that which has been described in horses. However, no neuropathology similar to that seen in horses was observed in the buffalo.

Toxicity generally occurs in summer and fall when forage is depleted and horses are forced to graze less palatable species. Ingestion often occurs for several months or more before an abrupt onset of neurological dysfunction is observed. Impaired eating and drinking are often the first observable signs. Depression and hypertonicity

of the lips and tongue follow, and a constant chewing may be observed, hence the name "chewing disease." Abnormal tongue and lip postures may be observed, and other neurological signs include locomotor difficulties such as aimless walking, drowsy appearance, and inactivity with the head held low. The neurological disease is considered permanent, and although some improvement may be seen, difficulty eating and drinking may preclude long-term recovery. Often, the disease progresses to dehydration, starvation, and bizarre behavior including submergence of the head in water to allow water to flow into the esophagus or lapping water like a dog. *Centaurea repens* appears to be more toxic than *C. solstitialis*, but prolonged ingestion is required by both before disease appears. The amount of plant ingested to induce the clinical effects is reported to be 60% or more of body weight for *C. repens* and 100% or more of body weight for *C. solstitialis*. Intermittent grazing can prevent disease, indicating that there is not a cumulative effect but, rather, a threshold must be exceeded before neurological signs are observed (Cordy, 1978). Once neurological signs are observed in horses, prognosis for recovery is poor and euthanasia should be considered.

## Pathology

The lesions are very specific and limited to the globus pallidus and the substantia nigra (nigropallidal encephalomalacia), where distinct pale yellowish to buff-colored foci or softening and cavitation are seen (Cordy, 1978). The lesions are typically bilateral and symmetrical. This specificity of the lesions for the basal ganglia has prompted more investigations into unraveling the mysteries of human diseases associated with dopaminergic pathways, such as Parkinson's or Huntington's disease, and tardive dyskinesia. This disease in horses is often called equine parkinsonism. This unusual disease is manifest by an almost immediate onset after prolonged ingestion, suggesting an all-or-none type of acute neurological crisis. The lesions develop quickly and completely, and progressive stages of degeneration rarely occur except for some changes in the adjoining neurons adjacent to the necrotic foci in the globus pallidus and the pars reticularis of the substantia nigra (Cordy, 1978). Microscopically, there is extensive necrosis of neurons, glia, and capillaries within sharply defined margins of the involved brain centers. Occasionally, lesions may be observed in the gray and white matter of the brain.

## Prevention and treatment

Good veterinary care and supportive therapy including good feed, easy access to water, supplemental

vitamins, and good nursing care is essential for survival. Treatment of the disease once it is manifest is not generally successful. However, in Argentina, affected horses have been treated with glutamine synthetase and a bovine brain ganglioside extract given daily intramuscularly for 1 month with some success. When animals are first observed grazing *Centaurea* spp., they should be immediately removed to better pastures. Prevention of the disease is easily accomplished by knowing the plants that exist in one's pastures, by providing good quality and adequate amounts of forages and feed, and by frequent observation of one's animal's grazing patterns and behavior.

Control of plant invasion by good range/pasture management to prevent overgrazing and loss of other competitive grasses and forbs is important. Herbicide control is quite easily accomplished with broadleaf products including 2,4-D, dicamba, and picloram applied according to label. These plants are prolific seed producers, and follow-up treatment is required to eliminate the populations. Seeds are often distributed through contaminated hay or other feed sources, and initial populations often start near feed bunks and spread from there. Because of their morphology, size, and parachute-like structures, seeds are easily spread by wind and water. Understanding one's weeds and close monitoring of populations will help in the control of these highly invasive species.

## CONCLUSIONS

Even with our ever-increasing knowledge about poisonous plants and their toxins, poisonings continue to occur, some catastrophic, on livestock operations. Poisoning in humans and companion animals from toxic plants also continues to be a significant risk, especially to pets and children. As the influx of small-acreage farmers onto native rangelands increases and ranchettes become more common, the potential risk for poisonous plant problems increases. Lack of understanding and increased grazing pressure on these small acreages often contribute to the consumption of toxic plants by animals. In some cases, novel or unusual animal species are exposed to unfamiliar forages, further contributing to potential poisonings. Plant poisonings will undoubtedly also increase in wild-life populations as humans continue to encroach on their native ranges and interrupt their migratory pathways.

The following basic concepts can help reduce risk of poisoning:

- 1 Understand and recognize the plants on your range or pastures and know the potential hazards of grazing

where poisonous plants grow. Know the conditions under which poisoning may occur.

- 2 Do not introduce unfamiliar animals onto ranges where poisonous plants may present a hazard.
- 3 Avoid introducing animals to poisonous plant-infested ranges when adequate, good-quality forage is not available.
- 4 Do not throw grass, shrub, or tree clippings into paddocks where animals reside (yew clippings are a common cause of poisoning in many animals).
- 5 Provide free access to fresh water and minerals/salt.
- 6 Do not overstock the range or pastures.
- 7 Avoid bedding, lambing/calving, watering, salting, or unloading hungry animals near poisonous plant populations.
- 8 Avoid excess stress to those animals showing clinical signs of poisoning, and contact your veterinarian.
- 9 If economically feasible, control poisonous plants through hand grubbing, mechanical clipping, or herbicide treatment.

## ACKNOWLEDGMENTS

We thank Ms. Terrie Wierenga for technical assistance in preparing the manuscript and Holly Broome Hyer for artistic representation of selected poisonous plants.

## Poisonous plants of Europe

Arturo Anadón, María Rosa Martínez-Larrañaga and Victor Castellano

### INTRODUCTION

European flora is less rich in species and less dangerous than the American and African flora; however, the number of plant poisons is considerable.

Poisoning of livestock and companion animals by plants is a sporadically occurring clinical problem. Most plants cause poisoning only when they are eaten. The possibility of plant poisoning is usually neglected in a differential diagnosis because plant poisoning is uncommon. In intensive rearing of animals such as swine or poultry, contact of the animal with a toxic plant is unlikely. Also, the maintenance in confinement of some semipermanent stall dairy cattle and young beef cattle minimizes this risk. The common uses of herbicides destroy some poisonous plant species. However, in many cases, it must be determined whether animals may be in contact with toxic plants either in the pasture or by means of poisonous plants mixed with forage and distributed in conserved forage.

Plant poisoning in small animals is usually accidental. Accidents can be prevented by understanding the conditions in which poisoning may be expected to occur and then taking steps to prevent its occurrence. Moreover, problems can occur with animals in ornamental, garden, and natural environments and homes. Pets are usually the victims of this type of accident. Many veterinarians are not familiar with plants found in and around the home that may be potentially harmful if ingested; therefore, they are responsible for being prepared to deal with plant poisoning should it occur. Many house and garden plants grown in Europe contain chemical substances in sufficient quantities that lead to toxic effects in animals. Dogs and cats are not herbivores and infrequently consume large

quantities of plant materials. It is recognized, however, that they do occasionally ingest plant materials, especially grass. When conditions are favorable, both dogs and cats will consume other herbaceous materials that cause toxic conditions. Although plant poisoning of adult dogs and cats is unlikely, puppies often taste anything they encounter and are the principal candidates for accidental ingestion of toxic plant materials.

Occasionally, a client may observe a pet consuming a fruit or leafy material. A frantic call to the veterinarian may prove fruitless if the plant cannot be identified by visual description. The amount consumed is of importance. Rarely will a single bite of any plant prove to be lethal. Fortunately, most plants do not cause toxicity, or they may cause mild to moderate gastrointestinal irritation. A few plants in certain localities, regions, or countries can produce serious toxicity, including oleander (*Nerium oleander*) and castor beans (*Ricinus communis*).

Household pets are exposed to the same harmful substances as young children. Puppies and kittens, like children, seem to have a predilection to ingest attractive foreign materials, such as parts of house and garden plants (berries, fruits, seeds, and leaves). Both older and immature animals may suffer from boredom or behavioral abnormalities or may simply be investigating a new addition to the environment, all of which may lead to ingestion of poisonous plant material.

Small pet animals are at greatest risk with exotic plants. They are not herbivores, and as a result, they never develop detoxification mechanisms for plants. By contrast, most herbivores have co-evolved elaborate detoxification mechanisms to cope with the thousands of alkaloids, glycosides, amines, and resinoids found in plants that they usually eat. When animals and plants evolve together, a

commensal relationship often develops. Such relations are interrupted when plants are introduced into new environments, exposing the resident animals to substances for which they lack detoxification mechanisms.

Finally, many poisonous substances found in plants are also used medicinally as drugs. Cardioactive glycosides, atropine, and acetylcholine are three examples. Poisoning from plant material presupposes consumption of sufficient quantity of one or several active ingredients that in turn can act synergistically. The toxic dosage varies with the species of the plant, the stage of plant growth, the part of the plant consumed (i.e., leaves, roots, etc.), the type of soil, and other environmental factors.

Plants can be roughly classified depending on which body system they affect. The pharmacology and toxicology of commonly found plants are known. However, even if a plant is suspected of causing an adverse outcome, without information about similar cases, toxicological analysis of biofluids, or pharmacological or toxicological effects of the plant, further investigation might prove difficult or impossible.

## Plant identification

Plant toxicity occurs consistently at the genus level, although species variation may alter toxicity. Consequently, accurate identification of the plant is necessary (genus and species), which often requires recognition of the scientific name and the plant parts by a qualified person. Usually, a family member knows the common names of household and garden plants, but the problem is that the same common names are used for many different plants (e.g., milk plant and milkweed). Some are hazardous to livestock, and other ornamentals may be hazardous to small animals. Still others are edible or innocuous (Fowler, 1981). For this reason, therapeutic decisions are sometimes based on imprecise common names. Currently, plant toxicology is changing; knowledge of poisonous plant names is important to ensure that the same name is universally applied. Both common names and scientific names are needed for communication with the public and for scientific exchange.

Ornamental plants are not easily identified botanically. Standard botanical keys are not very helpful. If the species of an ornamental plant is in question, it should be taken to a qualified person for identification. Botany or horticultural herbaria in museums, colleges, or universities are helpful resources for plant identification (Forsyth, 1968).

## Diagnosis of plant poisoning

The following information is usually required for diagnosis: region, time and amount of exposure, type of

plant, part of plant ingested, onset of symptoms, type of symptoms, and the presence of insecticides or herbicides. A formal diagnosis of poisoning must be made using a thorough history, clinical signs, and laboratory analysis of samples (Table 78.1). The owner may be able to provide data on what intoxication may be in the environment in which animals are rearing or living. However, owners are usually not aware of potential toxic plants that are present.

### Pet animals

The diagnosis of dog poisoning by plants or plant products is not always easy because symptoms are rarely characteristic. Their treatment is often disappointing. The clinical signs of poisoning produced by ornamental plants certainly were not noticed in the past, either because the clinical examination was lacking or because symptoms that presented in the poisoned animal were not sufficiently alarming to consult or notify veterinarians. The frequency and severity of poisoning are extremely variable. The toxicity of a given ornamental plant varies from one variety to another and from one organ to another, and it also depends on the state of maturity. Animals react differently depending on the species, age, health status before poisoning, their sensitivity to the plant and the amount ingested, and whether the plant has been chewed or not. It is difficult to make a diagnosis of poisoning by an ornamental plant in view of the few symptoms and lesions presented by a sick animal. It is essential to perform an accurate clinical examination and to detect pieces of plant identified in the stool or vomit to diagnose by checking if the symptoms correspond with those observed in similar cases in previous experiments. The symptoms and lesions are varied;

TABLE 78.1 Diagnosis of plant poisoning

#### General approach

History: After stabilization of vital signs. The questions addressed to the animal owner should be accurate.

Plant identification: Accurate identification of the plant is needed (genus and species) as well as recognition of the scientific name, common name, and plant parts.

Clinical signs (including odors).

Laboratory tests: Toxicant isolation, search for toxic plants (in the meadow or forage), and search of toxicant in animals (rumen and stomach).

#### Treatment

Decontamination, especially gastrointestinal tract: emesis, gastric lavage, activated charcoal, enemas, and laxatives/cathartics.

Elimination enhancement: Diuresis, urine acidification, and urine alkalization.

Antidotes.

they predominantly affect the digestive tract when the poisoning is benign and the nervous and cardiovascular systems when poisoning is serious. At necropsy of the intoxicated animal, gastroenteritis lesions are often observed. For the previous reasons, prevention must play an essential role. It is necessary to know the plants that are poisonous to pets and avoid planting them in kennels or maintaining them in the home. It is also necessary to ensure that animals receive a sufficient and balanced diet, corresponding to their specific needs, and that they have regular daily exercise. Finally, hazardous material, whatever its nature, should not be dragged on the ground because dogs, and especially infants, can be the first victims.

*Liliacea* spp. and *Araceae* spp. were the major plant families involved in poisoning; most of the cases were related to accidental ingestion of ornamental plants rather than wild plants, particularly during certain times of the year. Cats appeared to be more sensitive than dogs, probably due to the tendency to chew on plant leaves. *Convallaria majalis* and *Nerium oleander* were also commonly reported to cause severe and potentially lethal cardiac disorders, whereas *Ricinus communis* and *Datura stramonium* cases were also frequently observed (Gault *et al.*, 1995).

Small animal veterinarians must deal with a number of potentially poisonous, commonly occurring household and garden plants (Table 78.2). In many cases, the client cannot name the plant that the animal encountered in his or her house or property. As indicated, veterinarians should familiarize themselves with the most potentially toxic plants and their clinical signs and any naturally occurring dangerous plants in their area (Flood and Fitzgerald *et al.*, 2006).

Livestock

Livestock can be poisoned by many different plant species, but an analytically confirmed diagnosis is not always easy, and most cases are only suspected following necropsy and identification of leaves, stems, or pods in the rumen. A diagnosis of plant poisoning can rarely be made by the clinical syndrome alone. Signs accompanied by a history of exposure to the plant are usually necessary. If a client presents a short-haired hunting dog with trembling and salivation and explains that the dog has been in a field trial all day, stinging nettle toxicity should be an obvious diagnostic possibility.

Judicious questioning of the client may be necessary when a poisonous plant is suspected. The client may not know the plants in the home or garden if a spouse or other family member is the gardener, and further inquiry is necessary to establish the presence of a suspected plant in or around the home.

Conditions conducive to plant poisoning

Cross-breeding, environmental conditions, and seasonal variation in toxin content may also alter toxicity outcome. Although plant poisoning of adult dogs and cats is possible, puppies may eat anything they encounter and are prime candidates for accidental ingestion of toxic plant material. Kittens are less likely than puppies to ingest such foreign material but occasionally will do so (Fowler, 1981).

Caged birds present special problems. Psittacines (budgerigars, cockatiels, parrots, and macaws) are generally seed-eaters. As a rule, they are fed seeds from a

TABLE 78.2 Household plants

Family	Genus/species	Clinical presentation
Amaryllidaceae	<i>Amaryllis</i> , <i>Clivia</i> , <i>Crinum</i> , <i>Hippeastrum</i>	Digestive disorders (vomiting and diarrhea).
Apocynaceae	<i>Allamanda cathartica</i> , <i>Dipladenia sanderi</i>	Skin (dermatitis) and digestive disorders.
Araceae		
Dieffenbachia	<i>Dieffenbachia sanguine</i> , <i>D. picta</i>	Keratoconjunctivitis, edema of the eyelids, and corneal ulceration; reactions of mouth (lips, tongue, palate, and pharynx), esophagus, and stomach injuries (vomiting and diarrhea). The cat is particularly sensitive.
Other dangerous Araceae	<i>Alocasia</i> spp., <i>Anthurium</i> spp., <i>Arisaema</i> spp., <i>Caladium</i> spp., <i>Monster</i> spp., <i>Philodendron</i> spp., <i>Xanthosoma</i> spp., <i>Zantedeschia aethiopica</i>	They can cause similar disorders to <i>Dieffenbachia</i> and sometimes dermatitis as a result of animal contact with the plant.
Ericaceae	<i>Rhododendron obtusum</i> , <i>R. simsii</i>	Vomiting, diarrhea, violent equilibrium changes and convulsions, paralysis, and dyspnea; coma and death (at high doses).
Euphorbiaceae	<i>Euphorbia pulcherrima</i>	Irritating to skin and projected into the cornea; local disorders and vesicular dermatitis, conjunctivitis; stomatitis, vomiting, and diarrhea.
Liliaceae	<i>Tulipa</i> sp., <i>Hyacinthus</i> spp.	Vomiting with gastroenteritis.
Moraceae	<i>Ficus elastic</i> , <i>F. lyrata</i>	Similar to those caused by Euphorbiaceae and also urinary signs.

commercial source, and the likelihood of poisoning is remote. Sometimes a well-meaning owner collects and feeds wild seeds, which can pose a slight hazard if the person is unable to identify all of the plants from which the seeds are collected (Fowler, 1981).

Higher concentrations of any poisonous substance are frequently found in seeds than in the rest of the plant. Thus, seed-eaters such as psittacine birds are at particular risk when such plants are the source of food.

Birds that are allowed to fly free in the home or that escape from a cage may peck at and ingest poisonous houseplants.

## Predictive and toxicity factors

### Age

By nature, puppies and kittens continually explore with their mouths. Teething irritation may be relieved by chewing on objects in the environment. Any available plant materials, such as seeds, pits, bulbs, branches, and even leaves, may be chewed and ingested. Puppies and kittens have low activities of the hepatic biotransformation enzymes as well as low levels of conjugating moieties. A poorly developed blood-brain barrier, weak biotransformation activity, and immature mechanisms for excretion combine to make puppies very vulnerable to toxic effects of poisonous plants. Owners should be informed of the necessity to “pet proof” the surroundings of young animals by removing or preventing access to hazardous substances, including toxic plants (Fowler, 1981).

### Species

Some species are very susceptible to toxic plants, whereas others are not susceptible. For example, rabbits are insensitive to the effects of *Galega officinalis*, and certain species of birds can consume *Cicuta* spp. without toxicity occurring.

### Boredom

Both older animals and immature animals may suffer from apathy. Dogs, in particular, have problems resigning themselves to continuous confinement compared to others that have unlimited freedom. A dog with nothing to do may resort to aberrant behavior, such as ingestion of any available plant material(s). If these plants are poisonous, toxicity may result. Clay (1977) described three instances of dogs poisoned by plants within their confined space.

### Changes in surroundings

New objects placed within the environment of a pet are novel and subject to a thorough investigation. During the holiday season, new plants are often brought into

the home, and some of them are potentially dangerous. When a family moves into a new home or goes on vacation with its pet(s), new plants are often encountered.

Pets used to “star billing” in a household may feel neglected when a new baby arrives and receives all the attention. In such circumstances, many pets resort to pica. Illness of an owner may require “pet sitting” by others and thus initiate the same response (Fowler, 1981).

### Behavioral abnormalities

Behavioral abnormalities are increasingly being recognized as specific clinical entities. A few behaviorist-trained veterinarians are beginning to unravel some of the complex interrelationships of pet behavior and disease. Ingestion of foreign materials is one such manifestation of deranged behavior. Plant poisoning may be a consequence of such behavior. The veterinary profession needs to distinguish the many minor exposures from the few serious ones and to treat those toxic exposures appropriately. Such a task may be difficult because the plant involved is not easily identified. Even when it is known, predicting toxicity is difficult because of variation in plant toxicity, amount ingested, and animal/species susceptibility (Fowler, 1981).

### Plants

The following factors of plants are linked to toxicity:

- The concentration of active ingredient varies among different species of plants.
- The entire plant can be toxic, but in some cases, parts of the plant are responsible for the toxicity (e.g., grain, leaves, and fruit).
- The active ingredient content can vary depending on the state of plant development; for example, *G. officinalis* becomes toxic only after flowering.
- Preservation procedures can destroy the active ingredients; for example, drying can reduce toxicity (e.g., *Cicuta* spp.).
- Herbicide treatments may increase the toxic principle content and can make animals crave plants more.

## POISONOUS PLANTS AFFECTING ANIMALS

### *Aconitum napellus* (Ranunculaceae family)

**Common names:** aconite, monkshood, and wolfsbane

*Aconitum napellus* has blue or white flowers bilaterally symmetrical with a prominent upper hood, which gives the genus its name. The perennial herb has palmate

leaves and a tuberous root. Several species are common garden plants, but cases of poisoning in European countries are not common. However, it should be remembered that these plants are potentially poisonous.

#### *Toxicity*

All parts of the plant contain toxic alkaloid aconitine, with the highest concentration in the tubers (roots) and seeds and lower amounts in the leaves and stems, but the alkaloid content and composition vary throughout the year. The alkaloid content is highest when plants are flowering (June and July). Horses, donkeys, and goats are more sensitive to aconitum than are sheep. The plant is not usually eaten (acrid test), and field poisoning is uncommon. Aconitine may also be present when forage or hay is contaminated by it.

#### *Clinical presentation*

The clinical signs produced by this plant include vomiting, colic, bradypnea and dyspnea, muscular weakness, paralysis, pupillary dilatation (mydriasis), and death. Death is due to asphyxia, and postmortem findings are those associated with suffocation. The lesions are not specific, usually appearing to be gastric and renal congestion (Lorgue *et al.*, 1996).

### ***Amianthium muscaetoxicum* (Liliaceae family)**

**Common names:** fly poison, stagger grass, and crow poison

This plant is found in open woods, fencerows, old fields, roadsides, and pinelands, particularly in clay soils, although it can also be found in sandy soils. These plants are perennial, subscapose, and bulbous herb. Leaves are mostly basal and linear. Flowers are white, turning greenish with age; they are borne in dense racemes. Plants are found mostly in moist, wooded slopes, meadows, open fields, and bogs.

#### *Toxicity*

The highest concentration of the toxin, an alkaloid, is found in the bulb of the plant. The alkaloid is also found in the fruit and leaves. Animals consume the plant only when other forage is unavailable. Cases of toxicity occur in the spring, summer, and fall. Cattle and sheep are most commonly affected.

#### *Clinical presentation*

Animals exhibit vomiting, frothing at the mouth, salivation, staggering, dyspnea, subnormal temperature, and weakness. Death is caused by respiratory failure.

### ***Cannabis sativa* (Cannabinaceae family)**

**Common names:** marijuana, marihuana, bhang, hashish, Ganja, and sinsemilla

The term marijuana refers to the dried leaves and flowers of the Indian hemp plant, which is cultivated illicitly for its psychological effects. It is an illicit drug plant, and its leaves, flowers, and seeds contain several cannabinoids that are favored by some people for their psychoactive properties. Originally, the plant *Cannabis sativa* was an annual herb that was native to Asia, but it has spread throughout the world. Marijuana or hemp has been employed for thousands of years as a source of fiber to make rope in Asia and the Middle East and as a medicinal and recreational drug. Only since the 1960s and 1970s has the recreational use of marijuana become common in the Eastern world. It is currently sold in the illicit drug trade and can be found growing in European countries – in out-of-the-way places, in flower beds, or in pots within homes or vacant lots. Marijuana is the term used to describe the dried leaves and flowering heads of the cannabis plant.

#### *Active principle*

The main psychoactive ingredient in the plant is the complex chemical delta-9-tetrahydrocannabinol (THC). This accounts for approximately 3 or 4% of the dry weight of the herbal material, although modern strains of the plant grown indoors under intensive cultivation conditions may contain as much as 15–20%. The pharmacological effect of this agent is to produce central nervous system (CNS) depression and derangement. THC is absorbed when taken by mouth, having a low oral bioavailability resulting from a large first-pass effect because of extensive liver metabolism (taking as long as 3 or 4 h to reach peak blood levels).

#### *Conditions of poisoning*

The quantity of the active ingredient exposed varies markedly according to the variety of the plant, the sex of the plant, the geographical location, the stage of growth, and the nature of the growing season. The greatest concentration of the active ingredient is in the flowering tops of the female plant, whereas leaves are less potent and seeds contain little of the active ingredient.

Individuals involved in the use of illicit drugs frequently keep pets that have access to the plants, or to products made from the plants, and that can potentially cause marijuana poisoning. Some individuals delight in involving their pets in the drug experience with them. In other cases, accidental ingestion results in toxicity to the pet.

### *Clinical presentation*

Clinical signs seen in humans at high doses of marijuana include hallucinations and strange fantasies, and the user can no longer hold a coherent conversation. There is commonly a sudden stimulation of appetite, particularly for sweet foods. These effects may be followed by tiredness and sleep.

Animals show behavioral abnormalities and hyperexcitability. The most affected animal is the dog. The main clinical signs in the poisoned dog are vomiting, salivation, incoordination, alternating somnolence and hyperactivity, muscular weakness, and hyperthermia. Moreover, CNS and respiratory depression is another important sign in the dog. This is followed by coma and possibly death.

### ***Colchicum autumnale* L. (Liliaceae family)**

**Common names:** *colchium, meadow saffron, autumn crocus, and naked ladies*

*Colchicum autumnale* is locally abundant in meadows.

### *Toxicity*

All parts of the plant *C. autumnale* contain the alkaloids colchicine and colchicine, of which the former is more toxic. Colchicine exists in all parts of the plant, but its highest concentration is in the bulb (~0.8% by weight). The pale purple flowers contain approximately 0.1% colchicine by weight. Both alkaloids withstand storage, drying (persist in contaminated hay), and boiling. At doses of 0.25 mg/kg body weight (BW), colchicine has a purgative effect. At higher doses, colchicine is a potent gastrointestinal toxin and causes intractable multiorgan failure. The European native is located in wet meadows and with poisoning occurring during the spring. Poisoning of animals in the spring involves ingestion of the young leaves, whereas in the autumn the flowers of plants growing wild in pastures are implicated (Humphreys, 1988).

### *Clinical presentation*

Poisoning primarily affects cattle but can affect equines and swines raised on pasture. Clinical signs appear approximately 48 h after ingestion. In cattle, the clinical signs of intoxication are predominantly related to the digestive tract and are characterized by salivation, dysphagia, colic, abdominal pain, diarrhea, and fetid feces that are green or black with tenesmus. Death occurs from cardiorespiratory failure and may be delayed for several days depending of the amount of plant ingested. The visible postmortem finding is gastroenteritis. Lesions

that appear are edema and intestinal bleeding. In the horse, abdominal and thoracic serous effusions also occur.

### ***Conium maculatum* (Umbellifereae family)**

**Common name:** *hemlock*

This is a glabrous, branching biennial herbaceous plant, with hollow purple-spotted stems arising from a thick taproot. The poison hemlock usually has only one fleshy taproot, there are no pithy partitions in a hollow area at the juncture of stem and root, and stem and upper stem leaves are divided. Leaves resemble parsley, and they have a parsnip odor when crushed. This is probably more common than spotted water hemlock and found in drier, more upland habitats. It is found in roadside ditches and in damp waste areas.

### *Toxicity*

The poison hemlock contains piperidine alkaloids (coniine and cyanapine) and other compounds that are capable of poisoning livestock, poultry, and humans. The stems, leaves, and mature fruits are toxic. The leaves are more dangerous in spring, and the fruit is most dangerous in fall.

### *Clinical presentation*

Symptoms are gastrointestinal irritation and neurological effects (nervousness, trembling, staggering, and coldness of the extremities), hyperpnea, and tachycardia (Lorgue *et al.*, 1996). Eventually, coma and death occur from respiratory failure. In general, animals can recover within hours.

### ***Convallaria majalis* (Liliaceae family)**

**Common names:** *lily of the valley, may lily, Jacob's lily, and our lady's tears*

This is a native European perennial plant of garden or wood that contains a poisonous substance in the roots and stems. The leaves are long and broad, typical of the Liliaceae family. It is an ornamental and houseplant. The animals most affected are dogs, cats, and poultry. Dogs and cats usually chew and/or swallow the flowers, and birds (poultry, duck, and geese) usually ingest the fresh plants.

### *Toxicity*

The plant contains cardiotoxicants and convallatoxins.

### *Clinical presentation*

Poisoned animals are often found dead. Occasionally, terminal seizures are evidenced. Symptoms vary from mild gastrointestinal perturbation (vomiting and diarrhea) to terminal cardiac dysfunction (arrhythmias and bradycardia).

## ***Coriaria myrtifolia* (Coriariaceae family)**

**Common names:** tanner's herb, Mediterranean coriaria, and redoul

This is an ornamental plant that grows in the Mediterranean countries of Europe.

### **Toxicity**

*Coriaria myrtifolia* contains coriamyrtine, which can cause convulsions similar to those produced by strychnine or picrotoxin. The entire plant is toxic, and the poisoning occurs by ingestion of the stems, branches, and fruits.

### ***Clinical presentation***

The frequency of poisoning is high in goats and low in cattle and horses. Goats of all ages are very sensitive in regions in which redoul (imported breeds) are present. The number of affected individuals in herds varies from 10 to 50%. The lag time is short, 20 min (sometimes <5 min) to 2 h after ingestion of the plant (Faliu *et al.*, 1985).

Mild symptoms are characterized by drunkenness, ptialism, mydriasis, sometimes chills, loss of appetite, and bloating. These symptoms are followed by a severe form characterized by nervous signs such as retching, trembling, violent seizures that last 10–15 min, muscular contractions, ataxia, anorexia, tachycardia, intense tachypnea and dyspnea, nystagmus, mydriasis, ptialism, and bloating. Death can occur within 20 min to 2 h after a crisis by respiratory arrest (20–50% of cases), or there may be a progressive cure. The lesions are not specific and are characterized by severe and generalized congestion, edema and cyanosis of the mucous membrane (Faliu *et al.*, 1985; Lorgue *et al.*, 1996).

## ***Datura* spp. (Solanaceae family)**

**Common name:** thorn apple

All species of *Datura* are poisonous. The following species may be found where pets may be exposed:

- *Datura stramonium* (jimsonweed or Jamestown weed)
- *Datura metaloides* (thorn apple, apple of Peru, and tolguacha)
- *Datura arborea* (trumpet vine and angel's trumpet)

These species and others are grown as ornamentals, such as trumpet vine, or occur as weeds. The plants vary in appearance, but all have large, tubular flowers ranging in color from white to lavender. The fruit is an ovoid spiny capsule, giving rise to the common name thorn apple. Most of the plants emit an objectionable odor.

### *Toxicity*

Poisonous substances found in *Datura* are tropane alkaloids (atropine, hyoscyne, and scopolamine) and hyoscyamine in all parts of the plant, particularly in the seeds. It is found in hay or silage. The foliage may contain as much as 0.25–0.7% alkaloids. The seeds are likely to be the source of toxicity for pets.

### *Conditions of poisoning*

In the illicit drug culture, *Datura* seeds are circulated to produce hallucinations. As with other plants involved in the illicit drug trade, pets are likely to consume toxic material accidentally if their owners are careless in handling the plant. Occasionally, a person may deliberately give the material to his or her animals.

### *Clinical presentation*

Clinical signs associated with *Datura* poisoning are similar to those caused by an overdose of atropine. The signs may occur a few moments after ingestion or may not appear for several hours. The poisoning has an acute course in which there is weak, rapid pulse and intense heartbeat; disturbances of vision (dilated pupils due to mydriatic effects of *Datura*); dry mouth; incoordination; convulsions; and coma.

## ***Hypericum perforatum* (Hypericaceae family)**

**Common names:** St. John's wort, goatweed, and Klamath weed

There are various species of *Hypericum*, but the only species of importance in Europe is *Hypericum perforatum*. This perennial plant has a habitat and distribution in dry soil, wood, pastures, ranges, and along roadsides.

### *Toxicity*

The photodynamic pigment (hypericin), a red fluorescent found in the black dots that are scattered over the surface of the leaves, stems, and petals, can be absorbed and is capable of sensitizing the pigment of animals to sunlight.

### *Clinical presentation*

The clinical signs occur after 48 h to 21 days of grazing the plant or as a result of ingesting contaminated hay

or fodder. This delay depends on the time required for hypericin to reach a critical concentration in the skin and also the intensity and duration of sunlight to which animals are exposed (Faliu *et al.*, 1986).

The animals most affected are cattle, horses, sheep, and goats; pigs are rarely affected. The poisoning occurs exclusively when the animals are exposed to sunlight and is characterized by photosensitization, severe pruritus (head, ears, face, and extremities) and dermatitis with ulceration, erythema, blindness, convulsions, diarrhea, and extreme hypersensitivity to touch and to contact with cold water. The lesions observed are mainly cutaneous (dermatitis), degeneration of liver, and inflammation of the gallbladder. For example, in cattle, the affected skin peels off in patches resembling leather. Deaths have been described. In horses, the white areas or mucous membranes are the site of depigmented erythema pruritis, followed by edema (Faliu *et al.*, 1986).

### ***Galega officinalis* L. (Papilionaceae family)**

**Common name:** goat's rue

*Galega officinalis* is a perennial European legume with a lush alfalfa-like appearance in early growth, but it becomes very rank when mature. It is a perennial herbaceous plant with a hollow stem and elliptical or lanceolate leaves. The flowers are light blue to violet in color. The plant is unpalatable to livestock, particularly when mature, and its use as forage was advocated only for very young plants.

#### *Toxicity*

This leguminous plant contains two nitrogen guanine components, galegin (isoamylene guanidine) and hydroxygalegin, that are present in all parts during flowering and fruit formation. These substances have pharmacological properties as hypoglycemic and galactogenic agents. Galegin decreases blood pressure and paralyzes the CNS. This plant appears in summer, especially during the months of July and August when the plant is in flower or producing pods, and it is found in the southern area of France. Accidental poisoning affects mainly sheep, but some cases have also been seen in cattle (Bezard *et al.*, 2002). *Galega officinalis* L. is generally rejected by cattle, probably because of the plant's nasty smell and bitterness, especially when freshly cut. In case reports describing cattle and sheep fed the same hay, only sheep ate the toxic plant and were poisoned. The poisoning is usually related to feeding dry hay or freshly cut fodder contaminated by *Galega*, and it is assumed that fodder containing no more than 10% *Galega* will be toxic for sheep (Puyt *et al.*, 1981).

#### *Clinical presentation*

The latency period usually lasts 12–24 h after ingestion of the plant. It is characterized by an asphyxic syndrome caused by hydrothorax, which leads to death within hours. A voluminous hydrothorax is observed during postmortem examination.

### ***Nerium oleander* (Apocynaceae family)**

**Common name:** oleander

*Oleander* is a very common ornamental plant in Mediterranean areas of Europe; it is also grown in temperate climates in conservatories and greenhouses. *Oleander* is a large ornamental evergreen shrub. The long, pointed leaves are oblong and contain a prominent midrib. Large clusters of white, pink, or red flowers appear at the end of the branches in summer. It is particularly abundant on sandy soils near the coast. It is widely cultivated and used as landscaping along roadsides and edges of woods and in lawns and gardens.

#### *Toxicity*

Oleander has been a well-known poisonous plant since classical times, with all parts containing very toxic cardiac glycosides (oleandrin, digitoxigenin, neriin, folinerin, and rosagenin) that apparently exert a digitoxin-like effect (cardiotoxic potential) (Langford and Boor, 1996). Toxins may also be inhaled in smoke when plants are burned. Human poisoning occasionally occurs from eating hot dogs roasted on sticks from nearby oleander plants. This extremely toxic plant can poison livestock and humans at any time of the year. Lethal doses in horses, donkeys, and calves were reported to be 30–50 mg/kg BW (Oryan *et al.*, 1996).

#### *Clinical presentation*

Severe gastroenteritis, diarrhea, abdominal pain, sweating, and weakness are the usual symptoms. These signs appear within a few hours after eating the leaves. Cardiac irregularities are common, often characterized by increased heart rate. However, a slower heart rate is often detected in the later stages. In comparison with other species, turkey poults have not been found to be very sensitive to oleander.

### ***Pteridium aquilinum* L. or *Pteris aquilina* L. (Polypodiaceae family)**

**Common name:** Bracken fern

*Pteridium aquilinum* is also classified by some authorities as three separate species: *P. aquilinum*, *P. esculentum*, and *P. yarrabense*.

It is distributed throughout all European countries and is most common in woods, old fields, waste places, and roadsides, particularly on relatively dry sites. The poisoning is common in places where *P. aquilinum* grows naturally.

### Toxicity

In the poisoning by *P. aquilinum*, a polioencephalomalacia occurs because these plants contain the enzyme thiaminase, which inactivates thiamine (vitamin B<sub>1</sub>) in cattle, sheep, and horses; this is called "pteridism." The thiaminase hydrolyses vitamin B<sub>1</sub>, leading to a depletion of vitamin B<sub>1</sub> and producing a clinical syndrome of thiamine deficiency primarily in horses.

Ingestion of the green plant, during periods of food shortage or when dried plant material (dryness does not reduce toxicity) is mixed in with hay or straw, over a prolonged period (15–30 days) is toxic. Toxic effects by the plant appear to be cumulative, and symptoms may not appear until several weeks or months later (1–3 months), depending on the species of the animal, the amount ingested, the time of year, and other factors. Clinical cases are most often seen in the spring or late summer or fall, especially after periods of drought when other forage is short or not available. Animals have shown toxicity from consuming hay containing the dried plants.

In ruminants, an aplastic anemia factor causes depression of the bone marrow; this effect is cumulative but appears over a short period of time. Sheep are less susceptible than cattle and horses to the toxic effects.

### Clinical presentation

It causes poisoning in two unique ways. First, ingestion by ruminants over a short period causes depression of bone marrow activity leading to pancytopenia manifested mainly as ecchymotic hemorrhages in mucosae, septicemia, and severe diarrhea. Second, ingestion over a long period causes proliferative lesions in and bleeding from the urinary bladder mucosa.

Cattle may exhibit two types of symptoms. The laryngeal form is often seen in younger animals and is characterized by edema of the throat region, resulting in difficult and loud breathing. The enteric form may be preceded by the laryngeal form and is characterized by bloody feces and urine and excessive bleeding from fly bites. The blood is slow to clot because platelets are deficient. Death usually occurs within a few days after symptoms appear. Sheep have shown blindness due to progressive retinal atrophy after grazing bracken fern; affected animals are permanently blind and adopt a characteristic alert attitude.

Horses exhibit muscular weakness and tremor, motor incoordination, and a crouching stance with arched neck

and feet placed wide apart. Occasionally, a fever up to 40°C is present. Before death, horses may "head press" objects and have spasms with the head and neck drawn backwards. Death is preceded by tonic-clonic spasms and opisthotonus. The disease is almost always fatal, and the lesions in cattle are indicative of a general hemorrhagic syndrome. Necropsy reveals multiple hemorrhages throughout the carcass; necrotic ulcers may be present in the gastrointestinal tract (abomasum and intestine).

In differential diagnosis, other plants, such as *Equisetum arvense* (horsetail) and *Beta vulgaris* (turnip), should be taken into account because these plants also induce thiamine deficiency. In horses, the condition must be distinguished from other neurological disorders produced by poisonous plants, such as *Crotalaria* spp. or *Senecio jacobaea* (ragwort).

## *Quercus* spp. (Fagaceae family)

**Common names:** live oaks (evergreens) and acorns

Different species of oak are responsible for poisoning. Acorns are the fruits of different species of oak, which have a detachable cap covering a hard oval body. Common in England and northern Europe are *Quercus ilex* (holm oak or evergreen oak), *Quercus pedunculata* (pedunculate oak), *Quercus robur* (common oak or English oak), and *Quercus petraea* syn. *sessiliflora* (sessile oak or durmast oak).

### Toxicity

Most animals are susceptible, although cattle and sheep are most often affected. Acorns and oak leaves contain large amounts of tannic acid along with small amounts of a volatile oil. The toxic principle, which appears to be gallotannins or their metabolites, causes gastrointestinal toxicity and renal damage. The incidence of poisoning is often associated with weather conditions; a hot dry summer and an abundant crop of acorns in the fall when grass is rare and also winds cause acorns to fall while still green. Pigs are resistant to pyrogallol and tannic acids (Lorgue *et al.*, 1996). Tannic acid is used as an astringent.

### Clinical presentation

Consumption of large quantities of young oak leaves in the spring or green acorns in the fall produces clinical signs approximately 4 weeks after ingestion. The toxic syndrome is characterized by gastrointestinal and renal dysfunction (Barbier, 2005).

Green and unripe acorns are more toxic than brown acorns and contain the highest levels of pyrogallol acids (up to 8%). In addition, certain species of oak (e.g., the pedunculate oak) are more toxic than others. The age of the tree is significant, with younger trees having the

highest levels of pyrogalllic acids and tannins (Lorgue *et al.*, 1996). The tannin content decreases with maturity. Cattle are most affected, especially young animals (1–3 years); sheep are not sensitive, and goats are rarely affected.

It is considered that the high tannic acid content is responsible for the toxicity. Tannins have a direct action by decreasing digestive secretions and have a constipating effect as an indirect action after hydrolysis in the rumen. The metabolites gallic acid and pyrogallol are water soluble, and they are well absorbed in the gut. The metabolites are responsible for liver and kidney damage as well as necrotic lesions in the intestine.

Clinical signs in cattle include anorexia and prostration often accompanied by low temperature, depression, emaciation, rumen stasis, serous nasal discharge, polydipsia, polyuria, and constipation followed by mucoid to hemorrhagic diarrhea, dark fetid diarrhea, and sometimes blood clots. Nephrosis is another sign of toxicity. In sheep, the clinical signs are characterized by somnolence, leading to staggering and going down (Humphreys, 1988). In horses, the signs observed include dullness, hypothermia, weakness, inability to walk, incoordination, mouth ulcers, mucosa discoloration, patchy sweating but no colic, passage of hard or sloppy feces, and red or brown urine (Warren and Vaughan, 1985). The rumen contains acorns in large numbers. Evolution is frequently fatal. Hemorrhagic lesions of the gastrointestinal tract, nephritis, and perirenal edema may be important.

### ***Ricinus communis* (Euphorbiaceae family)**

**Common name:** *castor bean*

This plant has large, palmately lobed leaves, and it is a robust annual (in southern regions) or perennial (in tropical and subtropical regions) woody herb. It is cultivated and occasionally escapes and persists in pinelands, waste places, and roadsides.

Flowers are green and inconspicuous; staminate flowers are near the base, and pistillate flowers are mostly near the top of a small panicle. The fruit is a three-lobed capsule with a soft, spiny exterior, 1.5–2 cm long. There are three seeds per capsule. Seeds are shiny, grayish brown mottled with reddish brown, and 10 mm long and 6 or 7 mm wide. Seeds resemble engorged ticks and usually tree in a somewhat spiny pod.

#### *Toxicity*

The poisonous principle is a phytotoxin called ricin. In Europe, the plant is commonly planted not only as an ornamental but also in vegetable gardens to repel moles. Horses are most susceptible to poisoning, but all

livestock and humans can be affected. All parts of the plant are toxic, especially the seeds. Toxicity is seen most often in spring and summer.

#### *Clinical presentation*

Animals are most often poisoned when feed grains have become contaminated with the castor bean seeds. Depending on the amount consumed, symptoms appear from several hours to days after animals consume the toxin. Violent purgation in the form of straining and bloody diarrhea is the classical sign. Other signs are dullness, abdominal pain, weakness, trembling, and incoordination.

### ***Robinia pseudoacacia* (Papilionaceae family)**

**Common names:** *false acacia, locust tree, and black locust tree*

This is a large ornamental tree with alternate, compound leaves and unbranched spines resembling rose thorns. This plant has been cultivated and is a common tree in dry woodlands, fencerows, old fields, roadsides, and pinelands, particularly in clay soils, although it can be found in sandy soils.

#### *Toxicity*

Toxic principles include the phytotoxin robinin and the glycoside robitin (emetic and purgative) found throughout the plant, although the flowers have been suggested to contain the toxic principles. Apparently, the toxin is heat labile, and it produces gastrointestinal distress. Horses, cattle, sheep, goats, poultry, and humans may be poisoned by ingesting roots, bark, sprouts, seed pods, or trimmings during periods of drought or food shortage. Horses are most susceptible to the effects of *R. pseudoacacia*.

#### *Clinical presentation*

Symptoms include diarrhea, anorexia, weakness, posterior paralysis, depression, mydriasis, loss of appetite, irregular pulse, and difficulty breathing. Death is not frequent. Postmortem lesions are restricted to the gastrointestinal tract.

### ***Senecio* spp. (Compositae family)**

**Common names:** *ragwort and groundsel*

The genus of this family contains more than 1200 species, of which 25 are known to be toxic and cause seneciosis. Members of the plant family include *S. aquaticus* (marsh ragwort), *S. jacobea* (ragwort or tansy ragwort),

*S. squalidus* (Oxford ragwort), and *S. vulgaris* (groundsel). In the United Kingdom, there have been many reported incidents involving exposure to ragwort.

#### Toxicity

These plants contain pyrrolizidine alkaloids including jacobine, jacidine, jaconine, and retrorsine, which are all hepatotoxic. Retrorsine is the most widely distributed pyrrolizidine alkaloid. Most of the *Senecio* species are also found in *Crotalaria* spp.

#### Clinical presentation

Seneciosis is an acute and chronic hepatic insufficiency caused by ingestion of plants containing senecio. Poisoning occurs when the fresh plant is ingested (in pastures) or when it contaminates hay or silage (Vos *et al.*, 2002). All animals can be affected, but cattle and horses are especially affected.

Poisoning can present after a latent period from weeks to months. The clinical picture is characterized by a syndrome of photosensitization, jaundice, and CNS derangement. Clinical signs are extremely diverse and include anorexia, weight loss, constipation, mild jaundice of the mucosae, reduction in vision followed by blindness, ataxia with trembling, weakness, and drowsiness. Generally, poisoning results in a fatal outcome. The lesions are characterized by enlargement and congestion of the liver, hepatitis (a cirrhotic form) with ascites, nephritis, and edema of the abomasum (Lorgue *et al.*, 1996).

Most outbreaks occur in animals on pasture, but housed animals feeding on hay contaminated by the foliage or seeds may also be poisoned. In horses, photosensitization may develop following plant ingestion. Pyrrolizidine alkaloids can be passed into the milk of lactating animals (Goeger *et al.*, 1982).

### *Taxus baccata* L. (Taxaceae family)

#### Common name: yew

The yew (*Taxus baccata*) has been noted as the most poisonous plant in all of Europe. The yew is a tree or shrub of the family Taxaceae that will accommodate all types of soils and grows in shade and sun. It is planted in parks, gardens, and cemeteries, especially for ornamental fences. Other yew species are also toxic; *T. cuspidata* (Japanese yew) and *T. canadensis* (Canada yew) are widely planted in gardens. Poisoning occurs in animals located in pastures, woods, or gardens or as a result of careless disposal of yew clippings or leaves. All parts of the tree are poisonous, and all species of animals are susceptible. The leaves are harmful at all stages of plant growth, and drying and

storage do not lessen their toxicity. The sexes are separate, and the pistillate plants bear bright scarlet fruit in the fall. The red flesh covers a hard seed, and although the flesh is not poisonous, the seed is extremely poisonous. The sap of the tree contains volatile oils that are irritants, and the leaves contain alkaloids taxines (taxine A and taxine B) and ephedrine and cyanide (hydrocyanic acid). The taxine is found in all parts of the tree except the fleshy red part of the berry. These compounds are capable of causing hypotension, bradycardia, and depressed myocardial contractility and conduction delay, similar to digitalis poisoning (Alexander *et al.*, 1946).

#### Toxicity

Chewing seeds has proven fatal to animals and humans. The foliage is even more toxic, and it is this that proves so poisonous to cattle, sheep, goats, pigs, and horses. There are probably more problems with children eating these berries than any other, except possibly pokeweed. Chewing these seeds and then swallowing can cause serious poisoning. The relatively greater resistance of ruminants is probably due to the dilution of the ingested material by the rumen contents. This effect may also account for the individual variation in susceptibility of different animals and for the delay, sometimes seen in cattle, before clinical signs of yew poisoning become apparent (Humphreys, 1988).

#### Clinical presentation

The conditions of poisoning are by consumption of leafy branches or lying *in situ* (fall) in the soil after harvest or a thunderstorm. The most common feature of yew poisoning is sudden death (1–48 h depending on the amount ingested). The clinical signs observed are nervousness, trembling, ataxia, dyspnea, and collapse (Barbier, 2005). Bradycardia progresses to cardiac standstill, and death ensues without struggle. Death occurs within approximately 5 min. Empty right heart, dark tarry blood in left heart, and limited nonspecific postmortem lesions such as congestion of the kidneys, liver, spleen, and lungs are seen (Ogden, 1988). The presence of yew leaves in the rumen contents may help in making the diagnosis of yew poisoning.

### *Thuja occidentalis* L. (Cupressaceae family)

#### Common name: thuja

Thuja shrubs are found throughout Europe. They are frequently planted in parks and gardens for ornamental purposes, especially in enclosures. Animal species commonly affected are cattle, sheep, and, rarely, goats. Poisonings occur by consumption of branches or

dropped branches dropped on the ground after being cut down or following a storm.

### *Clinical presentation*

Peracute intoxication occurs within a few minutes, especially in sheep. Clinical signs of acute or subacute intoxication are essentially related to the digestive tract (hypersalivation, colics, bloating, and bloody diarrhea) (Jean-Blain and Grisvard, 1973). Toxicity progressing to dyspnea and paralysis accompanied by a cooling of the extremities. Death can occur between 1 and 48h depending on the amount of plant parts ingested. The lesions are characterized by discrete congestive gastroenteritis, which is not specific. The presence of thuja leaves in the rumen contents confirms poisoning.

## TREATMENT

Management of poisoning by toxic plants is complicated by the lack of antidotes for most plant toxins. The effect of treatment may be difficult to determine because of the wide variability in toxic reactions to the same plant. Table 78.3 describes some of the systemic effects of poisonous plants.

### Nonspecific treatment

The most important aspect of emergency medicine treatment is to ensure adequate physiological functioning. Most plant poisonings respond to supportive care. Frequently, the veterinarian must treat the animal before plant identification is done. The recognition of certain syndromes characteristic of specific plants is of importance.

Many plant poisonings will not be diagnosed at the onset of the disease. Therapy will, of necessity, be symptomatic. Even when a positive diagnosis can be made, there are rarely any specific antidotes. The most important step

in therapy for any plant poisoning case is to remove any residual plant materials from the digestive tract as quickly as possible.

Not all plant poisons have antidotes to reverse the toxic effects, but a few general principles might get one through the initial phase of management. Removal of unabsorbed poison from the gut can be achieved by several means, including induction of emesis, gastric lavage, and use of activated charcoal, tannins, and cathartics. Tannins and activated charcoal may be administered in a water slurry via oral route.

In emergency medicine and for critical patients, we typically start resuscitation with the airway and then breathing and circulation in an overdose scenario. The therapeutic management strategies can be summarized as follows: establishment of a patent airway, artificial respiration, cardiac massage, and perhaps the application of defibrillation techniques. Following stabilization of vital signs, the clinician may proceed with subsequent therapeutic measures. In plant poisonings, there is neither a specific treatment nor an antidote. The treatment involves enhancing the removal of the absorbed poison and providing supportive therapy to combat the effects of the poison already absorbed.

### *Decontamination procedures*

Ingestion is the most common route of poisoning in large and small animals. Decisions about gastric emptying depend on an accurate identification of the plant responsible for the poisoning because the majority of casual ingestions require no specific therapy. Once identified, decontamination is based on plant toxicity, symptoms, and time since ingestion. Unless contraindicated, emesis is preferred to lavage because plant pieces are difficult to remove by gastric tube in some animal species, particularly those that are small.

#### *Gastric decontamination*

Vomiting can be induced in the conscious patient by the administration of apomorphine (0.04mg/kg intravenously (i.v.) or 0.08mg/kg intramuscularly (i.m.) or subcutaneously). Apomorphine may cause respiratory and CNS depression and may induce protracted emesis, ultimately resulting in a severely debilitated animal. These effects can be controlled by using a narcotic antagonist such as naloxone (0.04mg/kg i.v.).

There are two decontamination procedures – gastric lavage and irrigation. When it is known that an animal has ingested a potentially poisonous substance within less than 2h, efforts should be made to remove it from the upper gastrointestinal tract. If the animal has not vomited and can swallow, an emetic should be given promptly. In the case of an irritating toxin, rinsing of the mouth with sodium gluconate for at least 2h can be performed.

TABLE 78.3 Systemic effects of poisoning plants

Gastrointestinal irritants	<i>Ricinus communis</i> , Araceae family
Cardiovascular abnormalities	<i>Convallaria majalis</i> , <i>Digitalis purpurea</i> , <i>Aconitum</i> spp.
Renal dysfunction	<i>Datura stramonium</i> , <i>Cicuta</i> spp.
Hepatic dysfunction	<i>Senecio</i> (pyrrolizidine alkaloids)
Convulsions	<i>Cicuta</i> spp.; <i>Coriaria myrtifolia</i> ; <i>Aconitum</i> , <i>Taxus</i> , and <i>Veratrum</i> plant species
Nicotine symptoms	<i>Conium maculatum</i>
Atropine symptoms	<i>Datura stramonium</i>

Gastric lavage is an important emergency procedure, but it is relatively ineffective in suspected poisoning cases in which significant time has elapsed. Changes in techniques (e.g., using a larger tube, more volume, and more frequent lavages) have proven this to be a useful procedure when undertaken within 2h of ingestion of a toxicant (Hanna, 1986). Gastric lavage is recommended if the animal is presented within 60min of a potentially lethal ingestion of a plant. Proper placement of the patient may help prevent aspiration and improve the yield of the procedure. If more than 2h has passed since ingestion of the plant material, it is likely that the stomach will have already emptied into the intestine. In such cases, subjecting the pet to further stress through induced emesis is unwise. The patient should be sedated and as large a gastric tube as possible should be inserted to facilitate aspiration of the ingesta back out through the tube.

The use of activated charcoal has revolutionized the treatment of poisoning. Due to its small particle size and enormous surface area, it can adsorb a large amount of toxins. The usual dose is 1 g/kg body weight or 10 parts of activated charcoal for every 1 part of toxin, whichever is greater (large animals, 250–550 g; small animals, 5–50 g). Activated charcoal will be effective for preventing absorption of toxicant when it is properly utilized. It can be administered after vomiting has occurred or can be used in the gastric lavage solution. Single-dose activated charcoal is more beneficial if given within 60min of a toxic plant ingestion. The “universal antidote” should be avoided because magnesium oxide and tannic acid interfere with the adsorption capacity of activated charcoal. Activated charcoal adsorbs most alkaloids well and should be administered in almost all symptomatic cases. Other adsorbents, such as magnesium oxide and kaolin, are less effective than activated charcoal.

Ipecac syrup and cathartics have not been shown to be of benefit in cases of ingestion of poisonous plants. However, the use of emetics is recommended if the animal is conscious and the absorption time is less than 2h. Apomorphine can be injected subcutaneously at a dose of 0.2 mg/kg, but it is effective only in dogs. Ipecac syrup up to 10% at a dose of 1 or 2 ml/kg can be used in cats and dogs. Xylazine is also an effective emetic, particularly in cats (0.05–1 mg/kg i.m.), but it is less effective in dogs.

Gastric lavage is practical and effective if ingestion of the poison is recent (<2h). Gastric lavage is performed with 5–10 ml/kg of isotonic sodium chloride and contains activated charcoal in suspension. After lavage, a laxative agent may be placed into the stomach to further evacuate the intestine. Mineral oil is a suitable laxative. The dosage for small animals is 5–30 ml in dogs and 2–6 ml in cats. An oral saline cathartic of sodium sulfate (0.5 g/kg) is an efficient agent for evacuation of

the bowel and may be used in an emergency in small animals. Magnesium sulfate (1 g/kg) and castor oil (10–60 g per animal) can also be used; either can be used instead of mineral oil if desired. A high colonic enema is indicated to evacuate the toxicants from the lower gastrointestinal tract. Warm water with castile soap makes an excellent enema solution. Other enema preparations can be useful. The entire digestive tract of a dog can be emptied by a judicious combination of a gastric lavage and a high colonic enema. Care should be taken to avoid the induction of dehydration and electrolyte and the acid–base imbalances once the gastrointestinal tract has been evacuated.

Gastric aspiration and serial activated charcoal are useful in nicotine and related poisonings because of the secretion of nicotine into the acid milieu of the stomach of carnivores.

#### *Enemas*

This is a technique very useful for removing toxins from the lower gastrointestinal tract. The best enema solution is lukewarm water that is infused into the rectum of a patient. The enema should be repeated after 2h.

#### *Laxatives and purgatives (cathartics)*

Laxatives promote the elimination of soft, formed feces, whereas purgatives produce a more fluid evacuation. The following substances may be used for these purposes:

- Lubricant and emollient laxatives (fecal softeners): mineral oil (liquid paraffin) (cattle, 250–500 ml; horses, 250–1000 ml; pigs, 25–300 ml; dogs, 5–30 ml; cats, 2–6 ml).
- Bulk laxatives: methylcellulose (dogs, 0.5–5 g, and cats, 0.5–1 g, per os); carboxymethylcellulose sodium, psyllium, or plantago seed (dogs, 3–10 g, and cats, 3 g, per os); agar; wheat bran.
- Osmotic cathartics (saline purgative) – these are not absorbed and retain water in the intestinal lumen: magnesium sulfate (cattle, 250–500 g; horses, 30–100 g; pigs, 25–125 g; dogs, 5–25 g; cats, 2–5 g), sodium sulfate (cattle, 500–750 g; horses, 250–375 g; pigs, 30–60 g; dogs, 5–25 g; cats, 2–5 g), sugar alcohols (mannitol and sorbitol), lactulose (dogs, 5–15 ml, t.i.d., per os).
- Irritant cathartics: In this context, purgatives can be included with diphenylmethane or anthraquinone.

#### *Enhanced removal and elimination*

This procedure includes pH manipulation of urine or blood or both and other adjunct therapeutic modalities that may be useful in toxic situations. Administration

of fluids and diuretics may enhance the glomerular filtration rate. Fluids such as saline and lactated Ringer's solution are administered to promote urine production.

Osmotic diuresis may be induced by infusion of mannitol 10% solution or hypertonic glucose from 10 to 30% at 20–40 ml/kg. The application of diuretics such as furosemide (3–5 mg/kg) i.m. or i.v. injection may enhance urine production.

Forced acid diuresis to eliminate weak bases can be done with ammonium chloride orally (20–40 g in large animals, 100–200 mg/kg in dogs, and 20 mg/kg in cats) to maintain a urine pH of 5.5–6.5, with arginine choride i.m. or i.v. (7–10 g in large animals and 100–200 mg/kg in small animals), or with ascorbic acid i.v. (40 mg/kg in all animal species).

Forced alkaline diuresis to eliminate weak acids can be done with sodium bicarbonate 1.4% by i.v. infusion to maintain a urine pH higher than 7 (2–4 ml/kg during 24 h in large animals or given by slow, continuous administration for best results in small animals) and with Ringer's lactated by i.v. infusion (5–10 ml/kg per hour in all species).

### Specific treatment

Specific treatment is possible only in rare cases. For instance, in the case of intoxication by *Pteridium aquilinum*, horses can be treated with thiamine intramuscularly at a dosage of 100–200 mg per day for 7–14 days, or the anticyanide treatment can be used with sodium thiosulfate (20% solution), 4 ml/kg BW, strictly intravenously, and sodium nitrite (10% solution), 2 ml/kg BW, strictly intravenously.

## SUPPORTIVE THERAPY

Because antidotes are available only for a few toxins, treatment of most cases of poisoning is largely supportive. The aim of supportive measures is to preserve vital organ function until the poison is eliminated from the body and the patient resumes normal physiological functions, including control of body temperature, maintenance of cardiopulmonary function and renal system, control of acid–base status, alleviation of pain, and control of CNS effects with proper care for coma, seizures, hypotension, arrhythmias, hypoxia, and acute renal failure. Body temperature should be monitored. Hypothermia can be controlled with a circulating hot water blanket and by keeping the animal in a warm and draft-free cage. Hyperthermia is treated with ice bags, cold water baths, and enemas. It is vitally important that

the animal's body temperature be constantly monitored to prevent overcorrection.

Respiratory support requires an adequate patent airway using a cuffed endotracheal tube in an unconscious animal or by performing a tracheostomy under local anesthesia. A respirator is of great value, or an anesthesia machine may be utilized with manual compression of the bag.

It is more appropriate to insert an endotracheal tube and provide positive pressure ventilation if needed. A patient that is depressed sufficiently to require respiratory assistance must be continuously monitored.

Be prepared to supply respiratory support. Although analeptic agents such as doxapram may provide immediate support, the effect is transient and cannot be relied on to sustain a pet free from poisoning.

Cardiovascular support requires the presence of adequate circulating blood volume, cardiac function, tissue perfusion, and acid–base balance. Blood volume and cardiac activity are of most immediate concern.

In the presence of hypovolemia due to loss of both cells and volume, whole blood is needed. A sufficient quantity of whole blood should be given to raise the packed volume to 75% of the animal's estimated normal level. Hypovolemia due to fluid loss alone can be treated with the administration of lactated Ringer's solution or plasma expanders.

Cardiac activity can be aided by the application of closed-chest cardiac massage for immediate cardiovascular support, but administration of calcium gluconate, infused slowly intravenously, can stimulate cardiac activity in most instances. This agent is also a good non-specific treatment for many toxicities.

Control of acid–base balance problems is primarily a matter of physiologically maintaining an animal in a homeostatic condition. The most common acid–base disturbance seen is metabolic acidosis, but alkalosis may also occur in cases of poisoning. In correcting acidosis not of respiratory origin, sodium bicarbonate intravenously is the drug of choice. Caution must be exercised with alkalinizing agents to avoid the induction of alkalosis. For initial therapy, it is usually sufficient to administer 0.9% NaCl (physiologic saline) intravenously, followed by oral administration of divided doses of ammonium chloride.

Control of pain with a minimal dose of morphine or meperidine is used in animals. Management of CNS disorders in cases of intoxication is complex. Therapy depends on the presence of CNS depression or hyperactivity. Either disorder can easily be reversed to the extreme by overzealous treatment. CNS depression can also be considered with respiratory depression because the management of the two conditions is very similar. Although the intravenous administration of analeptic agents, such

as doxapram, is reported to be efficacious, their actions are short-lived, and CNS depression returns if the animal is not monitored continuously. Bemegride is also occasionally used to stimulate the respiratory centers in the medulla. Analeptics can also induce convulsions.

Cases of CNS hyperactivity, including convulsions, can be managed by the administration of CNS depressants or tranquilizers. Pentobarbital sodium, phenobarbital, phenytoin, and primidone are the agents of choice for convulsions and hyperactivity; care must be taken, however, because a respiratory depressing dose may be required to alleviate all adverse signs. Inhalant anesthetics are excellent for long-term management of CNS hyperactivity. Centrally acting skeletal muscle relaxants and minor tranquilizers (methocarbamol, glyceryl guaiaacolate, and diazepam) are also used for convulsant intoxicants. The animal should be placed in a quiet, dark room to reduce excitation due to auditory or visual stimuli.

## CONCLUSIONS

Compared to North American and African flora, European flora has fewer dangerous species; however, the number of plant poisons is considerable. Plant identification, the diagnosis of plant poisoning, the conditions conducive to plant poisoning, and predictive and toxicity factors are relevant in the field of plant toxicology. In general, plants cause poisoning only when eaten and affect livestock and companion animals. Many wild plants, houseplants, or illicit drug plants grown in Europe contain chemical substances in sufficient quantities to cause toxic effects in animals. *Liliacea* spp. and *Araceae* spp. are the major plant families involved in poisoning of companion animals; most cases are related to accidental ingestion of ornamental plants than wild plants, particularly at certain times of the year. In addition to the previously mentioned poisonous plants for dogs, the following plant families are also implicated: Euphorbiaceae, Apocynaceae, Solanaceae, Ericaceae, and Amaryllidaceae. Both specific and nonspecific treatments, including decontamination procedures, used in animal poisoning by plants are considered essential in veterinary toxicology.

# Poisonous plants of Australia and New Zealand

*Rhian Cope and Kathy Parton*

## INTRODUCTION

Due to space constraints, this chapter largely focuses on the indigenous flora of Australia and New Zealand that has been noted to produce significant livestock losses and some of the major problematic introduced plants. It is not possible to cover all of the poisonous plants in Australia and New Zealand that are known to have caused livestock losses in a single chapter, and the reader is referred to more authoritative references for this. To allow for reasonable coverage of the most important species, the information is presented in tabular form (Tables 79.1 and 79.2).

The climate of Australia is unique compared with those of the other continents, and this has a substantial impact upon plant poisonings in grazing livestock. Australia is easily the driest of all continents: most of Australia is desert or semi-arid, and 40% of the landmass is covered by sand dunes. Eighty percent of Australia's landmass has an average annual rainfall of less than 600mm, with 50% of the landmass having less than 300mm. Rainfall for much of the continent is highly variable, and droughts, which may last several years, are a regular feature over much of the agriculturally productive areas of Australia. Accordingly, many of the toxicologically problematic indigenous plants are well adapted to this climate: they are extremely drought resistant (or their seeds are resilient), and they are able to very rapidly grow during the short periods of relatively suitable conditions. In these circumstances, poisonous indigenous flora often outcompete introduced fodder plants or it emerges earlier than more suitable fodder plants and poisonings result. Other common circumstances are that the indigenous plants can often be the last remaining plants available to livestock and again poisoning

results or those indigenous plants are cut and fed to livestock during drought, or that under drought conditions, cuttings of native plants are used as survival food for livestock.

The long biogeographic isolation of the Zealandia continent and the islands of New Zealand has resulted in a unique variety of native flora. Inevitably, this has resulted in a number of unique toxicological problems.

## REDUCING LIVESTOCK LOSSES ASSOCIATED WITH POISONOUS PLANTS IN AUSTRALIA AND NEW ZEALAND

The key factors in reducing losses due to plant toxicoses are an awareness of the types of potentially toxic plants relevant to the geographical area of production, an understanding of both the plant and the animal factors that influence the risk of poisoning, and an understanding of what indigenous plants can and cannot be used as feed for livestock under drought conditions.

A common, important plant-related factor in Australia is the ability of indigenous plants in the semi-arid and arid areas of the country to outgrow and outcompete introduced fodder plants, particularly following the onset of good conditions following drought. Often in such circumstances, the new plant growth contains relatively high amounts of relevant toxins. This situation, combined with hungry stock or stock that are new to a particular geographic area or both, is a recipe for significant stock losses. This type of scenario has been classically associated with the rangeland northern cattle

TABLE 79.1 Summary of major Australian plants that are hazardous to livestock

Common name of disease	Species and identification	Diseases	Toxins	Distribution	Risk factors	Toxidrome	Association with other diseases
Paterson's curse poisoning	<i>Echium plantagineum</i> (Paterson's curse; salvation Jane) Winter growing annual; grows initially as a rosette; flowering stems are produced in early spring; seeds in late spring; dies after flowering; rosettes have green to light green hairy egg-shaped leaves up to 30 cm long; flowers are generally purple; 2–3 cm long and shaped like curved trumpets; a stout taproot with numerous lateral roots is present.	Hepatogenous pyrrolizidine alkaloid (PA) toxicosis	Pyrrolizidine alkaloids; plant often has a high copper:molybdenum ratio; all parts and stages of the plant are toxic.	Widespread; highly invasive; introduced; high economic losses in sheep and cattle; significant infestations in temperate, winter rainfall areas of VIC and NSW, as well as the southwestern parts of WA, southern QLD, and the eastern half of TAS.	Overgrazing, drought and fire increase the pasture dominance of the plant; PA content is highest when flowering; not particularly palatable; pasture dominance of the plant in combination with reduced availability of alternative forages increases the risk; pigs, poultry, and horses (monogastric animals) are regarded as highly susceptible, cattle moderately susceptible, and sheep and goats the least susceptible; merino sheep and wethers relatively resistant compared with British breeds and Merino/British breed crosses; large variability in individual animal susceptibility.	Acute, subacute or chronic megalocytic hepatopathy. Horses: characterized clinically food refusal; depression; irritability; ill-thrift; evidence of hepatic insufficiency (icterus, secondary photosensitization, repeated yawning, head pressing, aimless wandering, compulsive walking, dyspnea secondary to recurrent laryngeal nerve dysfunction, and other signs of hepatic encephalopathy). Pigs: rarely seen except in grazed animals. Cattle: general ill-thrift; chronic weight loss and/or failure to thrive; unpredictable bouts of aggression; evidence of persistent diarrhea with tenesmus and secondary photosensitization. Sheep: deaths directly related to Paterson's curse are uncommon; PAs cause decreased productive life span; most common clinical issue found in sheep is copper toxicity rather than PA toxicity per se; PAs do not enhance copper accumulation per se, but they modulate the disease; <i>E. plantagineum</i> often contains a high copper:molybdenum ratio, which can induce copper toxicity in sheep; no effective treatment.	Relative copper excess/relative molybdenum deficiency toxidrome ("copper toxicity") in sheep due to high copper:molybdenum ratio in the plant; increased risk of ammonia poisoning (particularly when using nonprotein nitrogen dietary sources in ruminants); increased risk of pregnancy toxemia in sheep.

Viper's bugloss poisoning	<i>E. vulgaris</i> Similar to <i>E. plantagineum</i> Perennial or biennial rather than annual; Unlike <i>E. plantagineum</i> ; flowers are not arranged in a violin neck.	Hepatogenous PA toxicosis	Pyrrolizidine alkaloids; all parts and stages of the plant are toxic.	Less common than <i>E. plantagineum</i> ; mostly confined to the temperate tablelands of southeastern Australia.	As per <i>E. plantagineum</i> .	As per <i>E. plantagineum</i> .	May influence relative copper excess/ relative molybdenum deficiency toxidrome ("copper toxicity") in sheep; increased risk of ammonia poisoning (particularly when using nonprotein nitrogen dietary sources in ruminants); increased risk of pregnancy toxemia in sheep.
Blue heliotrope poisoning	<i>Heliotropium amplexicaule</i> Summer growing perennial; many hairy, branched stems radiating from a woody rootstock with a sender taproot; highly aromatic; extends over 1–2 m in diameter; leaves are alternate, dull green, and tapered at both ends; flowers are bluish-purple with yellow centers and are arranged in dense clusters along one side of a coiled stalk that resembles a violin neck; drought resistant.	Hepatogenous PA toxicosis	Pyrrolizidine alkaloids; all parts and stages of the plant are toxic.	Widespread in southeastern QLD and northern NSW; scattered colonies can be found in central and southern NSW, near Adelaide, in the Flinders ranges, and around Victor Harbour in SA.	As per <i>E. plantagineum</i> .	As per <i>E. plantagineum</i> . Significant causes of loss of young cattle; not a source of high copper:molybdenum ratio fodder, but like most PA-containing plants, can influence copper toxicity in sheep.	May influence relative copper excess/ relative molybdenum deficiency toxidrome ("copper toxicity") in sheep; increased risk of ammonia poisoning (particularly when using nonprotein nitrogen dietary sources in ruminants); increased risk of pregnancy toxemia in sheep.
European heliotrope poisoning; European turnsole poisoning	<i>H. europaeum</i> Summer-growing annual; prostrate to ascending up to 60 cm high; well-developed root system; emits a foul odor when crushed; leaves 1.5–9 cm long, 0.8–3 cm wide; ovate; paler below; leaf stalk to 4 cm long; flowers are arranged in two rows on either side of a caterpillar-like cyme; flowers are white with yellow throats; drought resistant.	Hepatogenous PA toxicosis	Pyrrolizidine alkaloids; all parts and stages of the plant are toxic; PA content is generally lower than <i>H. amplexicaule</i> .	Major noxious weed of temperate Australia; common in overgrazed or fallow land; recorded in all states except NT and TAS; greatest concentration is west of the Great Dividing Range in NSW and Victoria.	As per <i>E. plantagineum</i> .	As per <i>E. plantagineum</i> . Significant cause of loss of young cattle; not a source of high copper:molybdenum ratio fodder, but like most PA-containing plants, can influence copper toxicity in sheep.	May influence relative copper excess/ relative molybdenum deficiency toxidrome ("copper toxicity") in sheep; increased risk of ammonia poisoning (particularly when using nonprotein nitrogen dietary sources in ruminants); increased risk of pregnancy toxemia in sheep.

(Continued)

TABLE 79.1 (Continued)

Common name of disease	Species and identification	Diseases	Toxins	Distribution	Risk factors	Toxidrome	Association with other diseases
Heliotrope poisoning	<i>Heliotropium ovalifolium</i> Native to Australia; ascending to spreading perennial or annual (in adverse conditions) herb; 0.15–0.8 m high; flowers are white.	Hepatogenous PA toxicosis	Pyrrolizidine alkaloids; all parts and stages of the plant are toxic.	Kimberley region of WA	As per <i>E. plantagineum</i> .	As per <i>E. plantagineum</i> . Primarily associated with disease in horses, but other species are likely to be susceptible.	As per <i>E. plantagineum</i> .
Tansy ragwort poisoning	<i>Senecio jacobaea</i>	Hepatogenous PA toxicosis	Pyrrolizidine alkaloids; all parts and stages of the plant are toxic.	Humid temperate regions with annual rainfall > 750 mm; generally occur on heavy soils of moderate fertility; commonly found in areas cleared for pasture but never on properly developed or on poorly managed and/or; degraded pastures.	As per <i>E. plantagineum</i> . Somewhat less important in Australia compared with Paterson's curse and heliotropes.	As per <i>E. plantagineum</i> .	May influence relative copper excess/relative molybdenum deficiency toxidrome ("copper toxicity") in sheep; increased risk of ammonia poisoning (particularly when using nonprotein nitrogen dietary sources in ruminants); increased risk of pregnancy toxemia in sheep.
Fireweed poisoning	<i>S. linearifolius</i>						
Groundsel poisoning	<i>S. lautus</i>						
Cotton fireweed poisoning	<i>S. madagascariensis</i>						
African daisy poisoning	<i>S. quadrientatus</i> <i>S. pterophorus</i>						
Fiddleneck poisoning	Daisy-like; flower heads are normally rayed; completely yellow; the heads are borne in branched clusters.						
Fiddleneck poisoning	<i>Amsinckia calycina</i> <i>A. lycopsoides</i> <i>A. intermedia</i> <i>A. menziesii</i> Short-lived autumn/winter perennials; 20–70 cm tall; grow as a rosette from which a flowering stem is produced; flowers are tube-shaped, yellow or orange, and are arranged along a curved flower spike (a fiddle neck).	Hepatogenous PA toxicosis	Pyrrolizidine alkaloids; all parts and stages of the plant are toxic.	All of NSW and VIC; southern QLD; southeastern SA	As per <i>E. plantagineum</i> . Plants are unpalatable and poisoning occurs mostly when there are few or no other food sources.	As per <i>E. plantagineum</i> .	As per <i>E. plantagineum</i> .

<p>Kimberley horse poison</p> <p>Kimberly horse disease</p> <p>Crotalism</p> <p>Walkabout disease</p>	<p><i>Crotalaria crispate</i></p> <p><i>C. ramosissima</i></p> <p><i>C. dissitiflora</i></p> <p><i>C. linifolia</i></p> <p><i>C. mitchellii</i></p> <p><i>C. spectabilis</i></p> <p><i>C. verrucosa</i></p> <p><i>C. pallida</i></p> <p><i>C. juncea</i></p> <p><i>C. montana</i></p> <p><i>C. novae-hollandiae</i></p> <p><i>C. brevis</i></p> <p><i>C. eremaea</i></p> <p><i>C. retusa</i></p> <p>Herbaceous plants and woody shrubs; commonly known as rattlepods due to the fact that the seeds become loose in the pod as they mature and rattle when the pod is shaken; flowers are typically yellow and have the classical legume “pea-like” flower form.</p>	<p>Hepatogenous PA toxicosis; monocrotaline-induced proliferative pulmonary vasculitis; pulmonary hypertension and pneumotoxicity</p>	<p>Pyrrolizidine alkaloids; monocrotaline</p>	<p>Most areas of Australia with the exception of TAS</p>	<p>Kimberley horse disease/ walkabout disease is a major cause of mortality in horses in northern Australia; in general, all Australian <i>Crotalaria</i> species regarded as toxic to horses until proven otherwise; the plants are not palatable; poisoning usually occurs when there is a shortage of feed, which causes horses to graze indiscriminately; poisoning may occur when toxic plants are accidentally incorporated with conserved fodder such as hay; horses are 30–40 times more susceptible to the disease than are sheep and goats.</p>	<p>Clinical signs in horses relate to PA hepatopathy/ hepatic encephalopathy and include dull and depressed; often stand with their heads held down; anorexia; weight loss; icterus; muscle tremors (especially of the head and neck); frequent yawning; head pressing; copper-colored or red urine; episodes of frenzy and violent, uncontrollable galloping; difficulty swallowing (stop eating halfway through a mouthful of hay or grass); may appear to be blind; may aimlessly wander (walking in circles or bumping into objects); drag their hind legs (hooves have worn tips). Disease is untreatable; occasionally, horses develop pulmonary toxicity following ingestion of some <i>Crotalaria</i> sp.; the introduced plant <i>C. spectabilis</i> is most noted for this effect; pigs tend to develop nephrosis rather than a hepatopathy; disease in cattle often resembles that of <i>E. plantagineum</i>, although pulmonary disease can occur if monocrotaline is present.</p>	<p>Death from misadventure; increased risk of ammonia poisoning (particularly when using nonprotein nitrogen dietary sources in ruminants); increased risk of pregnancy toxemia in sheep.</p>
<p>Yellow wood poisoning</p> <p>McKenzie River disease</p>	<p><i>Terminalia oblongata</i></p> <p>Bushy tree 12m high; branching close to the ground; bark is dark gray and furrowed; leaves alternate, pale green to yellow green, with rounded tips; deciduous; flowers are tiny; fruits have a wing on both sides.</p>	<p>Hepatogenous photosensitization; nephrosis</p>	<p>Hydrolyzable tannins</p>	<p>McKenzie River Basin of QLD</p>	<p>Used as drought fodder will keep the sheep alive, but produces chronic kidney disease; cattle should be kept away from fallen leaves in winter if possible.</p>	<p>Nervous symptoms in sheep; acute disease in cattle (McKenzie River disease): abdominal pain; photosensitization; dehydration; dark brown urine, depression, limb stiffness, tremor; icterus, collapse; nephrosis; chronic disease in cattle is characterized by liver disease, nephrosis, and long-term ill-thrift.</p>	
<p>Poison peach</p>	<p><i>Trema</i> sp.</p>	<p>Hepatotoxic</p>	<p>Unknown</p>	<p>Coastal and inland north and eastern Australia</p>	<p>Potentially poisonous at all times.</p>	<p>Liver damage (periacinar hepatocyte coagulation necrosis); most animals die; death is usually rapid.</p>	<p>Resembles yellow daisy poisoning.</p>

(Continued)

TABLE 79.1 (Continued)

Common name of disease	Species and identification	Diseases	Toxins	Distribution	Risk factors	Toxidrome	Association with other diseases
Yellow daisy poisoning	<i>Wedelia asperima</i> Erect herb; yellow daisy-like flowers.		Kaurene (diterpenoid glycoside)	Northern Australian grasslands		Liver damage (periacinar hepatocyte coagulation necrosis)	Resembles poison peach.
Swainsona poisoning Darling or swainson pea poisoning	<i>Swainsona galegifolia</i> <i>S. canescens</i> <i>S. luteola</i> <i>S. greyana</i> <i>S. procumbens</i> Stout-stemmed; erect plant; 30+ cm tall with numerous hairy leaflets; large purple, blue, pink, or red pea-shaped flowers; long woolly seed pods; plants tend to grow from August to October especially after winter rains.	Swainsonism	Swainsonine (indolizidine alkaloid)	Subtropical and temperate regions of all states	Individual animals may develop a craving for the plants; horses especially selectively graze swainson pea; there are approximately 85 native <i>Swainsona</i> sp. in Australia; all should be regarded as poisonous until proven otherwise.	Swainsonine, which acts in two ways: blocks the enzyme mannosidase, which produces an acquired mannose lysosomal storage disease and interferes in the normal production of enzymes, hormones and immunoglobulins. Cattle: can graze the plant for several weeks before development of clinical signs; signs after ~6 weeks of grazing include paddling gait, hyperexcitability, loss of condition, charge when approached; clinical signs progress to depression, incoordination, some deaths; animals that survive are poor in condition; long-term effects include infertility and abortion. Toxidrome is reversible if exposure is up to 4 weeks. Horses develop clinical signs after ~2 weeks of grazing; initial signs include paddling gait, hypersensitivity to touch, tremor, forced respiration; these progress to depression, incoordination, head pressing, hind leg dragging, front leg high-stepping, recumbency, death; long-term effects include emaciation, difficulty eating, lowered head, ventral swelling, apparent blindness, walking in circles.	Toxidrome in horses resembles Birdsville disease ( <i>Indigofera linmaei</i> poisoning); animals may have concurrent access to both plants; Birdsville disease occurs only in horses, whereas swainsona poisoning occurs in both horses and cattle; swainsona poisoning is mostly a disease of late winter to early summer, whereas Birdsville disease occurs primarily in summer, particularly after the first summer rains; mannose lysosomal storage disease is histologically identifiable in swainsona poisoning, whereas there are no specific anatomic pathology changes associated with Birdsville disease.
Weir vine poisoning	<i>Ipomea calobra</i> Slender vine with heart-shaped leaves and trumpet-shaped pink flowers.	Swainsonism	Swainsonine (indolizidine alkaloid)	Maranoa district of QLD	As per swainsona poisoning.	As per swainsona poisoning.	As per swainsona poisoning.

Birdsville disease Birdsville indigo poisoning	<i>Indigofera linnaei</i> Low; spreading plant; thick taproot; numerous thin woody stems forming a mat up to 1.5m across; leaves fern-like; flowers are very small and occur in dense clusters in the forks of the leaves; flowers are red turning blue as the leaves dry out; seed pods are gray, very narrow, sharply pointed at the tip, and contain two cube-shaped seeds.	3-Nitropropionic acid toxicity in horses; indospicine poisoning in dogs fed raw or cooked meat from poisoned horses or from camels grazing <i>I. linnaei</i>	Indospicine (hepatotoxin); 3-nitropropionic acid (neurotoxin); horses are resistant to the hepatotoxic effects of indospicine; toxins are present in the leaves and seeds of the plant at all times (green or dry).	Widespread in subtropical and arid regions of WA; NT and QLD	Drought resistant and responds rapidly to rain; disease outbreaks commonly occur in spring or summer after rains because of the rapid response of the plant to moisture; up to 100% mortality in horses; under normal conditions, the plant does not cause clinical disease in cattle; raw and cooked meat from poisoned horses is toxic to dogs because of the indospicine – secondary poisoning may occur.	In horses, clinical signs can develop after 10 days of feeding; clinical signs include general weakness, nervousness, depression, incoordination, shivering, twitching, and swaying; neuromotor signs are more evident when the animal is, or has been, under physical stress; bad breath; toe dragging (tracks are characteristic) and excessive wear on the front of the hoof; continuous ingestion will result in death; neurological signs are irreversible; secondary indospicine poisoning in dogs is characterized by acute fulminant and sometimes fatal hepatic failure.	Can be confused with swainsona poisoning, and it is possible for the two diseases to occur concurrently; see swainsona poisoning.
Bitter bark poisoning Quinine tree poisoning Quinine bush poisoning	<i>Alstonia constricta</i> Tree to 12m height; suckers from the roots producing thickets; leaves are narrow, lanceolate, 5–20 cm in length; flowers white to cream, 2–4 cm diameter; bark has a corky textured; white sap.	Indole alkaloid poisoning in ruminants and dogs fed meat from poisoned animals	Indole alkaloids (alstonine; altonidine; reserpine); does not contain quinine (common name derived from the bitter taste of the bark); alstonine and reserpine are used as antipsychotic drugs.	Eastern Australia from the Tropic of Capricorn southward to northern NSW	Leaves and fruit are poisonous; poisoning usually occurs when there is a shortage of feed; meat from poisoned animals is toxic to dogs.	Tetanus-like toxidrome: excitability, nervousness, stiff legs, saw horse gait, staggers, redness of the ocular mucous membranes.	
Wax flower poisoning Waxvine poisoning	<i>Hoya australis</i> Evergreen climbing vine; shiny round succulent leaves; milky sap; clusters of white flowers 1.5–2.5 cm in diameter, with five thick, waxy, triangular petals; strong sweet scent and produce copious nectar.	Tetanus-like toxidrome	Unknown neurotoxin	Popular garden plant; natural distribution is from Grafton in northern NSW to Cape York; grows on the edges of rain forest and in rocky exposed habitat.	Unpalatable; poisoning usually occurs when there is a shortage of feed.	Tetanus-like toxidrome: incoordination, knuckling of fetlocks, tremoring, collapse of either fore- or hindquarters, recumbency, tetanic spasms; no effective treatment, although mildly effected animals may recover.	
Poison morning glory Australian morning glory poisoning	<i>Ipomoea muelleri</i> Slender vine with heart-shaped leaves and trumpet-shaped pink flowers.	Neurological toxidrome in ruminants and horses	Calystegines implicated	Northern Australia; found in open forest; margins of monsoon forest and vine thicket; garden plant	Often the only green feed at the start of the wet season and the end of the dry season.	Animals appear inebriated and develop hindquarters ataxia that may be permanent in cattle; associated with transient staggering toxidrome in sheep; affected animals appear during the wet season and die by the following dry season.	

(Continued)

TABLE 79.1 (Continued)

Common name of disease	Species and identification	Diseases	Toxins	Distribution	Risk factors	Toxidrome	Association with other diseases
Floodplain staggers Stewart Range syndrome Pacific bent grass poisoning Blown grass poisoning	<i>Agrostis avenacea</i> Native to Australia and New Zealand; invasive weed in California, Texas and Hawaii; tufted perennial grass to 65 cm tall; inflorescence is a panicle of wispy strands terminated by 2–3 mm long fuzzy spikelets; grass is most commonly found in flat low-lying areas that are flooded up to 30 cm during winter and in channels and depression where water collects.	Corynetoxin poisoning in ruminants, pigs, horses	Corynetoxins (tunicaminyluracils) produced by <i>Rathayibacter toxicus</i> in nematode ( <i>Anguina funesta</i> ) induced galls in the seed heads and crowns of the plant.	Southeastern SA, northern NSW	Toxin production is greatest when the grass is haying off; most outbreaks occur ~1 week after the start of haying off; bacteria is identifiable as a yellow slime on the seed heads that dries to an orange-colored material; nematode galls can be identified in the seed heads; unlike annual ryegrass toxicity, the plant can become infected two times per year; outbreaks occur with favorable weather conditions; hay from affected pastures is poisonous.	Resembles annual ryegrass toxicity: onset of toxidrome delayed up to 4–5 days; reluctant to move; uncoordinated gait; limb weakness; muscle fasciculations; stand with a backwards and forwards rocking motion; individual muscle movements rigid; irregular and abrupt; whole limb movements excessively pronounced; high stepping or “rocking horse” gaits; loss of hind limb control; sudden collapse while running; intermittent episodic convulsions; movement or exercise exacerbates the clinical signs; high mortality (up to 90%); triggers abortion; lambing and calving losses to 30%.	Resembles annual ryegrass toxicity; Identical to annual beard grass ( <i>Polypogon monspeliensis</i> ) toxicity.
Caustic bush poisoning Caustic vine poisoning Milk vine poisoning	<i>Sarcostemma australis</i> Leafless succulent scrambler or bush; with smooth, jointed, succulent stems; flowers are pale green to cream-white, star shaped and waxy; in clusters at the stem joints; sap is corrosive to skin and eyes.	Neurological toxidrome in sheep, cattle; toxic to horses	Unidentified neurotoxin; may resemble cynanchoside.	Northern Australia extending southwards to northern NSW	Moderately palatable; rarely grazed except in very dry seasons when fodder is scarce; fresh shoots may be more toxic than the old shoots.	Toxidrome consists of restlessness, staggering and collapse, rapid breathing, paddling legs, jaws may be clamped shut, excessive salivation, seizures, convulsions, limb paddling.	Plant can be confused with <i>Euphorbia sarcostemmoides</i> ; <i>Euphorbia</i> sp. in Australia produce acute GI irritation (and cyanogenic glycoside toxicity in some species).
Grass tree poisoning Called “wamps” in NT (after the sound that cattle make when they collapse and hit the ground)	<i>Xanthorrhoea johnsonii</i> <i>Xanthorrhoea fulva</i> Grass trees	Neurological toxidrome in cattle	Unidentified	Coastal and subcoastal eastern Australia	Flower spikes are the most toxic parts, but leaves have caused problems.	Toxidrome consists of transient spinal cord dysfunction with associated posterior ataxia and urinary incontinence; delayed onset after access may be up to 10 weeks; clinical signs: constant sideways lurching of hindquarters, fall easily, have difficulty rising, urinary incontinence, weight loss; toxidrome is reversible within 2–3 weeks after cessation of exposure in most cases.	

Byfield fern poisoning Zamia fern poisoning Zamia staggers	<i>Bowenia serrulata</i> <i>Bowenia spectabilis</i> Fern-like cycad; distinctive among cycads because they have bipinnate leaves.	Neurological toxidrome in cattle is most common disease observed.	Unidentified neurotoxin (neurotoxin possibly related to $\beta$ -methylamino-L-alanine and/or $\beta$ -oxalylamino-L-alanine); cycasin (a pro-toxin that is transformed by plants and intestinal flora to methylazoxymethanol, an inhibitor of protein synthesis).	QLD rain forest; located on protected slopes; usually near a stream.	Leaves are toxic and remain neurotoxic even when dried; <i>B. spectabilis</i> is a cultivated ornamental plant; cycasin is destroyed by drying of the plant, but the dried plant remains neurotoxic.	Clinical signs consist of hindquarters ataxia consisting of an unusual swaying motion of the hind limbs, flexion of the hock and fetlock, wobbling and malpositioning of the hind legs.	Resembles poisoning by other members of the cycadales order (cycads); i.e., zamia poisoning, lepidozamia poisoning, cycad poisoning; possibly similar to human amyotrophic lateral sclerosis/parkinsonism–dementia complex (Guam disease, lytico-bodig disease).
Zamia staggers Burrawang staggers	<i>Macrozamia</i> sp. Palm-like cycad with slender leaves; seeds red to yellow in male or female cones. <i>Lepidozamia</i> sp. Unbranched tall tree-like cycads with persistent leaf bases.	Neurological disease in cattle and liver disease in sheep are the most common presentations; horses and pigs are also susceptible.	As per <i>Bowenia</i> sp.	<i>Macrozamia</i> sp.: QLD and NSW; mainly in coastal areas; Bega to Macleay River; and westward toward Goulburn <i>Lepidozamia</i> sp.: rain forests of QLD and NSW	As per <i>Bowenia</i> sp.; may be found as a contaminant in chaff; cultivated as ornamental plants; all species are regarded as toxic unless proven otherwise.	A slowly developing, irreversible nervous paralysis of the hind legs similar to <i>Bowenia</i> sp. OR Clinical signs relate to chronic liver damage: loss of appetite, ill-thrift, diarrhea, chronic weight loss, eventual death due to hepatic insufficiency. Poisoning may eventually be irreversible.	As per <i>Bowenia</i> sp.: seed cones from <i>Macrozamia</i> sp. were used as a food source by indigenous Australians (notably the Cadigal) but require extensive processing to render them safe.
Corkwood poisoning	<i>Duboisia myoporoides</i> <i>D. leichhardtii</i> Small tree members of the nightshade family; cork-like bark; simple leaves; white tubular flowers in bunches at the branch ends; fruits are black and berry-like.	Deliriant anticholinergic tropane alkaloid poisoning	Tropane alkaloids including hyoscyamine and scopolamine	Coast and tablelands of NSW; central and coastal QLD; found in high rainfall areas near rain forests; up to 1000 m altitude; and also in rain forest regrowth areas	Toxic to cattle, sheep, horses, camels, pigs, dogs, and cats; generally unpalatable; rarely grazed except in very dry seasons when fodder is scarce; may be grazed by animals inexperienced with the plant; sheep somewhat resistant compared with other species; used in herbal remedies.	Classical deliriant anticholinergic toxidrome: that is, hyperthermia, tachycardia, bizarre and possibly violent behavior, severe mydriasis, photophobia, muscle trembling, muscular weakness, staggers, colic and scours, death within 12 h but may recover with no long-term effects; can be treated using physostigmine; mnemonic for the toxidrome: “blind as a bat; mad as a hatter; red as a beet; hot as hell; dry as a bone; the bowel and bladder lose their tone; and the heart runs alone.”	Resembles atropine and <i>Datura</i> sp. (e.g., jimson weed or Jamestown weed) poisoning; leaves are harvested commercially for production of scopolamine and hyoscyamine; workers handling the leaves have been affected with dry throat, headache, and loss of visual acuity; plant is a target for recreational drug users.

(Continued)

TABLE 79.1 (Continued)

Common name of disease	Species and identification	Diseases	Toxins	Distribution	Risk factors	Toxidrome	Association with other diseases
Pituri poisoning Pitchuri thorn apple poisoning Pitcheri poisoning	<i>D. hopwoodii</i> Erect shrub; 1–3 m high; long, narrow leaves; flowers are white, bell-shaped with violet-striped throats; flowers June to November; berries are black, 3–6 mm in diameter.	Nicotine poisoning	Nicotine; nornicotine	Arid interior regions of Australia	Toxic to cattle, sheep, horses, camels, pigs, dogs, and cats; generally unpalatable; rarely grazed except in very dry seasons when fodder is scarce; may be grazed by animals inexperienced with the plant; plants with high nornicotine:nicotine ratios are generally more poisonous.	Classical nicotine poisoning (depolarizing neuromuscular block): tremoring, weakness, stumbling and/or incoordination, depression or hyperactivity, tachypnea, respiratory insufficiency, excessive salivation, dilated pupils, apparent blindness, vomiting, diarrhea, colic, seizures, collapse, bradycardia or tachycardia; ruminants may bloat; some animals may be found dead with no history of neurological signs (presumably from lethal cardiac arrhythmias).	Dried leaves from plants in the Mulligan River area (high nicotine and low nornicotine content) were mixed with <i>Accacia</i> sp. ash and used by indigenous Australians as a form of chewing tobacco; in areas where the plants have a high nornicotine:nicotine ratio, the plants were used as an animal poison for food gathering.
Finger cherry poisoning	<i>Rhodomyrtus macrocarpa</i> Small tree; opposite broad leaves with oil glands; white flowers with five petals; red fruit.	Blindness	Unidentified	Northern QLD rain forest	Also cultivated as a garden plant.	Produces permanent blindness within ~24 h of consumption due to optic nerve degeneration.	Native guava causes a similar disease.
Native guava poisoning	<i>R. psidioides</i> Resembles <i>R. macrocarpa</i> except leaves are narrow, lance-shaped, and 25 cm long.	Blindness	Unidentified	Northern QLD rain forest		Produces permanent blindness within ~24 h of consumption due to optic nerve degeneration.	Finger cherry produces a similar disease.
Blind grass poisoning	<i>Stypandra</i> sp. Tufted perennial herb, with rhizome and fibrous roots; up to 1 m diameter; erect aerial stems with opposite leaves; small blue to white flowers, in spring.	Neuromotor disease plus blindness	Stypandrol	WA; eastern NSW, QLD, VIC, and TAS; forest and woodland	Plants vary in their toxic content; most toxic times seem to be when shoots are young and green and when plants are flowering.	High-stepping gait; rapidly developing hind leg weakness; difficulty in raising head; progresses to total paralysis; depression; permanent blindness, death; some animals may recover if exposure stopped.	<i>Dianella</i> sp. (blue flax lily) and <i>Hemerocallis</i> sp. (day lilies) cause similar problems.
Austral bracken fern poisoning; bright blindness in sheep; chronic hematuria syndrome in ruminants	<i>Pteridium esculentum</i>	Thiamine deficiency polioencephalomalacia; bright blindness in sheep; chronic hematuria syndrome in ruminants; immunodeficiency; chronic anemia/neutropenia; mutagenic and carcinogenic	Thiaminase; ptaquiloside; norsequiterpene glucocides	All states; particularly in wet areas with well-drained soils	Rhizomes are very toxic; poisoning develops after protracted feeding; often symptoms do not appear until days or weeks later; cattle and horses most affected, sheep less so; 2–4 weeks of intake required for toxicity.	Depressed bone marrow functions in cattle and sheep resulting in anemia, thrombocytopenia, neutropenia, and immunotoxicity; polioencephalomalacia; bladder cancer in sheep and cattle (chronic hematuria syndrome); progressive retinopathy in sheep (bright blindness).	Similar disease with mulga (rock) fern.

Mulga fern poisoning Rock fern poisoning; blindness in sheep	<i>Chelilanthes</i> sp.	As per bracken fern.	Thiaminase; norsequiterpine glucocides (particularly ptaquiloside)	Throughout Australia	Generally avoided but eaten in drought periods when there is little else available; low-level ingestion is safe, but too much is dangerous; fern-infested paddocks can be grazed safely if animals are moved after ~10 days and rested in fern-free areas for ~3 weeks.	Resembles bracken fern toxicity.	Bracken fern toxicity
Nardoo poisoning	<i>Marsilea drummondii</i> A water fern, or herb; short creeping rhizome; leaves have a slender stalk tipped with four wedge-shaped leaflets that float on the surface, or spread on dry land and look like a four-leaf clover.	Thiamine deficiency polioencephalomalacia; chronic nonresponsive anemia due to bone marrow depletion; immunotoxic; mutagenic/ carcinogenic; beriberi (human)	Thiaminase; norsequiterpine glucosides	Inland areas; in depressions or river flats subject to flooding; different <i>Marsilea</i> sp. found in all mainland states; all species should be considered potentially toxic; sporocarps are very drought-resistant, surviving up to 100 years in dry conditions.	Toxin levels highest in summer, lowest in winter; often grazed without ill effect, but if they are the only plants available, there will be overdosing and stock losses; mainly sheep and horses are affected; good fodder plant under normal conditions.	Typical polioencephalomalacia toxidrome in ruminants; chronic anemia/neutropenia/ thrombocytopenia; chronic hematuria/bladder neoplasia syndrome in cattle; was an important food source for indigenous Australians (Cooper Creek and the Yandruwandha peoples), who rendered the plant safe by cooking it into “cakes” called “padlu”; famous as a potential cause of death of the explorers Burke and Wills.	Other causes of polioencephalomalacia (e.g., dietary sulfur); other sources of thiaminase (e.g., bracken ferns).
Stinging tree Gympie stinger	<i>Dendrocnide</i> sp. Five species in Australia; large trees, but early stages and low, new growth are common sources of exposure; leaves are large, heart-shaped, with two rounded lobes at the base, margins may be toothed, and young leaves are covered with large, stiff, stinging hairs.	Extreme pain	Hemolytic saponins; morodoin; stinging hairs contain acetylcholine, histamine and 5-hydroxytryptamine.	Cape York to Kiama and Nepean area in NSW; grows on the edges of rain forests and in clearings	Generally not palatable, except for goats; simple contact with skin is extremely painful; horses are particularly vulnerable to the skin effects; leaves still dangerous when dried (remain dangerous for at least 40 years).	Contact with leaves of the plant is extremely painful; irritant toxins are injected through the skin by hollow plant hairs; pain is often intolerable, long-lasting, and recurrent for many weeks; horses often display a frenzied agony after skin contact with the plant; pain is difficult to control or treat, particularly in horses.	

(Continued)

TABLE 79.1 (Continued)

Common name of disease	Species and identification	Diseases	Toxins	Distribution	Risk factors	Toxidrome	Association with other diseases
Georgina gidgee poisoning	<i>Acacia georginae</i>	Fluoroacetate poisoning	Organic fluoroacetates	Northwest QLD and adjacent eastern NT	Toxic to most animals (with the exception of some native Australian marsupials); most deaths occur during the dry season; most dominant animals are most likely to be affected; meat from poisoned livestock is poisonous to dogs and cats.	Death within minutes of first clinical signs; animals often found dead; tachypnea; trembling; sudden heart failure; cardiac arrhythmias; bloat; frequent urination.	1080 poisoning; 1080 is the sodium salt of monofluoroacetate; the number "1080" was the original catalog number for the substance; identical toxidrome to poison pea ( <i>Gastrolobium</i> sp.) toxicity; several other Australian native plant genera contain the toxin: <i>Gompholobium</i> sp., <i>Oxylobium</i> sp., <i>Nemcia</i> sp.
Poison pea toxicity; desert poison bush; heart-leaf poisoning; wallflower poisoning; and numerous other species and/or location-specific names	<i>Gastrolobium</i> sp. More than 100 Australian native species; leafy shrub to 2 m high; dull-green opposite leaves, notched at the tip; leaves are thick and stiff; several stems arising from lignotubers; flowers are pea-shaped, dark red to purple.	Fluoroacetate poisoning	Organic fluoroacetates; one of the most toxic plants in Australia.	Southwest region of WA	As per Georgina gidgee poisoning; mostly affects sheep; plants are most toxic when flowering; flowers and seeds are highly toxic; suckers are very poisonous; leaves are less palatable and less toxic; most species are potentially toxic, although toxicity is often intermittent and seasonal; goats have been used to control the plant, but with some animal losses.	As per Georgina gidgee poisoning.	As per Georgina gidgee poisoning.
Billy button poisoning Plains plover daisy poisoning	<i>Leiocarpa (Ixiolaena) brevicompta</i> Low growing, branched, annual or short-lived perennial; woody base; woody stems with white cottony hairs; green narrow leaves with no stalk; circular single yellow flower head with basal bristles; multiple angular hairless seeds.	Striated muscle myopathy	Crepenynic acid and other toxic unsaturated fatty acids	Common in inland Australia, from central QLD to central NSW to SA	Mostly affects sheep; lambs are usually the first affected; only mature dried seed heads are poisonous; toxins are concentrated in the seeds.	Toxidrome occurs within 2 weeks after start of grazing; sudden collapse and death during herding, exercise intolerance, muscle weakness; short strides; staggering; hind limb collapse; cardiac arrhythmias; hyperthermia, tachypnea; movement and mustering exacerbate the toxidrome; treatment with selenium may be helpful in some cases.	Can be confused with white muscle disease (nutritional muscular dystrophy, vitamin E/selenium deficiency).

Cyanogenic glycoside poisoning	<i>Brachyachne</i> sp. (native couches) <i>Eremophila maculate</i> (spotted emu bush) <i>Eucalyptus cladocalyx</i> (sugar gum) <i>Euphorbia</i> sp. (some species) <i>Heterodendron oleifolium</i> (rosewood) <i>Lotus</i> sp. (birdsfoot trefoils)	Acute cyanide poisoning	Cyanogenic glycosides	Most areas of Australia contain a cyanogenic glycoside-containing plant species.	Ruminants generally more susceptible; consumption of water following ingestion of plants increases the hydrolysis of cyanogenic glycosides to cyanide; the following generally increase the cyanide content of the plants: damage to plant, young rapid growth, seeds, regrowth after cutting, cool moist growing conditions, nitrate fertilization.	Sudden death with few clinical signs is the most common toxidrome; animals may have “cherry red” venous blood due to high venous pO <sub>2</sub> ; “cherry red” venous blood is often a necropsy finding, hence “cherry-red equals dead.”	
Nitrate poisoning	<i>Dactyloctenium radulans</i> (button grass)	Acute nitrate poisoning	Nitrate	Widespread native pasture grass in all states	Dangerous only when heavily fertilized.	Classical nitrate poisoning	
Pimelea poisoning	<i>Pimelea trichostachya</i> <i>P. simplex</i> <i>P. elongata</i> Annual herbs; opposite leaves on multiple branches; branches end in a flower spike with many flask-shaped yellow-green flowers.	Chronic right-sided heart failure, anemia and persistent diarrhea in cattle only	Simplexin (diterpenoid)	Inland northeastern regions; often in disturbed areas	Unpalatable; poisoning usually after the plants die and contaminate other pasture plants or hay; poisoning more likely after winter rains.	In cattle only, produces chronic right-sided heart failure, anemia, and chronic diarrhea; produces only diarrhea in other species.	
Cardiac glycoside poisoning	<i>Adonis microcarpa</i> <i>Asclepias curassavica</i> <i>Thevetia peruviana</i> <i>Cryptostegia gandiflora</i> <i>Glyceria maxima</i> <i>Gomphocarpus</i> sp. <i>Homeria flaccid</i> <i>H. miniata</i> <i>Bryophyllum</i> sp.	Cardiac glycoside poisoning	Cardiac glycosides	Most regions of Australia have at least one cardiac glycoside-producing plant; many are introduced plants that have been important causes of stock losses.	Generally not palatable; often only grazed during dry seasons when fodder is scarce; may be grazed by animals inexperienced with the plants; potential contaminants of hay.	Typical cardiac glycoside poisoning; may show signs of GI distress (e.g., scouring) due to other irritants present in the plant.	Camel poisoning
Camel poison	<i>Erythrophleum chlorostachys</i> (Cooktown ironwood) Large tree; smooth white or yellow-brown bark; discolorous leaves; white flowers; barrel-like fruit.	Cardiac glycoside-like poisoning	Diterpenoid alkaloids and cinnamic acid derivatives	Northern Australia; open woodland	All parts of the plant are toxic; aggressively suckers and suckers are toxic and accessible to grazing animals; affects ruminants and horses.	Resembles cardiac glycoside poisoning.	
Cattle bush poisoning Whitewood poisoning	<i>Atalaya hemiglauca</i> Small to medium sized tree; gray bark; leaves alternate, varying shape, dull gray, or bluish green; flowers are cream green, in large panicles; very hardy and drought resistant.	Cardiac failure syndrome particularly in horses and to lesser degree in ruminants	Unknown	Inland WA, QLD, NT, western NSW	Young shoots and fruit are toxic; poisoning occurs when plant forms a large part of the diet; high palatability; used as a drought fodder for cattle but should not be fed to horses.	Either no effects or death; in horses: vague signs of distress, staggers, severe swelling of the head, muscle weakness, myoglobinuria, followed by fairly rapid death; staggers in cattle.	

(Continued)

TABLE 79.1 (Continued)

Common name of disease	Species and identification	Diseases	Toxins	Distribution	Risk factors	Toxidrome	Association with other diseases
Poison sedge	<i>Schoenus asperocarpus</i> Tufted perennial; grass-like or herb (sedge); 0.15–1 m high.	Pneumotoxin	An isoprenyl guanidine: galegine	Southwestern WA		Toxin affects pulmonary vascular permeability; acute massive pulmonary edema and thoracic effusion.	
Stinkwood poisoning; panting disease	<i>Zieria arborescens</i> Tall shrub or small tree; to 4 m high, 3 m across; branches covered with star-shaped hairs; highly aromatic; fast growing; leaves have unpleasant odor when crushed.	Pneumotoxin	Unknown	TAS, VIC, southeast NSW, wet forest areas		Acute massive pulmonary edema and emphysema	
Soluble oxalate poisoning	<i>Neobassia proceriflora</i> (soda bush) <i>Portulaca oleracea</i> (inland pig weed, munyeroo) <i>Salsola kali</i> (soft roly-poly) <i>Setaria sphacelata</i> <i>Chenchrus ciliaris</i> (buffel grass) <i>Oxalis</i> sp. <i>Rumex</i> sp. <i>Acetosella vulgaris</i> <i>Trianthema</i> sp.	Calcium oxalate tubular nephrosis; hypocalcemia; <i>C. ciliaris</i> is noted for producing secondary nutritional hyperparathyroidism in horses ("big head").	Soluble and absorbable oxalates	Most areas of Australia have at least one soluble oxalate-containing plant.	Typically, the plants are more palatable when young.	Typical soluble oxalate acute hypocalcemia + crystalline tubular nephrosis toxidrome; chronic renal nephrosis toxidrome	Milk fever (post-parturient hypocalcemia)
Alkali disease; blind staggers	<i>Morinda reticulata</i> (mapoon, adaa) <i>Neptunia amplexicaulis</i> (selenium weed)	Selenium toxicity: alkali disease and blind staggers	Selenoamino acids in <i>M. reticulata</i> ; ethanol-soluble selenium compounds in <i>N. amplexicaulis</i>	<i>M. reticulata</i> , Cape York; <i>N. amplexicaulis</i> , central QLD	Cases often occur after burning back of scrub and in the spring.	Classical alkali disease and blind staggers; alkali disease is more common.	
Poison sage; lamb poison	<i>Isotropis</i> sp. Shrubs or herbs; pea-type flowers; flowers are purple, yellow, or orange.	Irreversible nephrosis	Iforrestine	Not found in VIC or QLD	Most toxic when flowering.	Anorexia; anuria; renal failure; gastroenteritis; sudden death can occur.	
Gastroenteritis (partial list)	<i>Castenospermum australe</i> (black bean tree) <i>Euphorbia</i> sp. <i>Stemodia kingii</i>	Acute and severe gastroenteritis	Cucurbitacins in <i>Stemodia kingii</i>	Most areas of Australia contain plants capable of triggering acute gastroenteritis.		Acute, often severe, diarrhea	

NSW, New South Wales; NT, Northern Territory; QLD, Queensland; SA, South Australia; TAS, Tasmania; VIC, Victoria; WA, Western Australia.

TABLE 79.2 Summary of major New Zealand plants that are hazardous to livestock

Common name of disease	Species and identification	Diseases	Toxins	Distribution	Risk factors	Toxidrome	Association with other diseases
Strathmore or Pimelea or New Zealand Daphne poisoning	<i>Pimelea prostrata</i> Small, prostrate, branched woody shrub; to 50 cm in diameter; branches are scarred, dark brown to black; leaves pointed oval, greenish-gray, ~5 mm long; waxy white flowers, 3–4 mm long, red or white ovoid berries.	Irritant (mucous membranes and skin); hypersensitivity; strong effect on cardiovascular function	Prostratin (dipterene acetate) in the leaves and bark	North and south islands; grasslands; open shrubland; along river terraces; up to an altitude of 1500 m	Poisonings more common in winter when feed is restricted. Formerly a toxicity of primarily horses, it is now reported more often in cattle; sheep are resistant to poisoning.	Horses: profuse watery diarrhea, blistering and irritation of oral mucous membranes and eyes, depression, loss of appetite, muscular pain, strong disinclination to move; necropsy features include gastric ulceration and gastroenteritis, fatty degeneration of liver; toxidrome in cattle resembles that of horses.	Differentials include <i>Pieris japonica</i> poisoning, causes of jaundice (e.g., facial eczema), allergic hypersensitivity reactions, bacterial or viral enteritis, systemic bacteremias, and viremias including foot and mouth disease.
Tutu toxicity	<i>Coriaria arborea</i> Leaves opposed, vary from narrow or filiform to ovate to lanceolate; flowers axillary or terminal racemes; fruit usually black or purple.	Tetanus-like with CNS excitation (blocking of spinal glycine and CNS GABA <sub>A</sub> receptors)	Tutin (lactone from the picrotoxin group); localizes in the CNS, causing medullary excitatory poisoning.	Throughout New Zealand; often found in stony areas	Toxicity usually in hungry or starved cattle and occasionally sheep; all parts are poisonous except the petals surrounding the seeds and the roots; toxin is concentrated in leaves (particularly young seeds); horses are not attracted to tutu; circus elephants have been poisoned.	Picrotoxin-like: salivation, nausea, excitement, convulsions, coma, and death; sudden onset 24–48 h after ingestion; cattle may exhibit blind charging, muscle twitching, extreme excitement, epileptiform convulsions, bloating, and regurgitation; produces amnesia in humans; stock losses of 5–10% of beef herds in the South Island high country; honey produced from tutu is toxic.	
Ngaio toxicity	<i>Myoporum laetum</i>	Hepatogenous damage and photosensitization	Ngaione and several other furanosesquiterpenoid essential oils. Ngaione is a protoxin that requires hepatic metabolic activation.	Common in coastal areas and lowland forests as far south as Otago; common in gardens	Toxicity of individual plants varies; leaves normally most toxic part; serious losses in cattle, sheep, pigs, and horses; most poisonings occur after storms blow down tree branches or when clippings are thrown out where stock have access to them.	Hepatogenous secondary photosensitization; recovery among survivors is very slow; severe constipation, abdominal pain, dullness, loss of appetite, no rumination; occasionally icterus.	Exposure to sporidesmin (facial eczema), ragwort, microcystis or nodularin (algal blooms), and other hepatotoxic compounds may exacerbate Ngaio toxicity.
Karaka poisoning	<i>Corynocarpus laevigatus</i> Tree to 15 m tall; leaves oblong, 10–15 cm long, dark green, thick, and glossy; flowers are small, yellow green; orange fruit, 25–40 mm long with three layers (outer skin, fleshy layer, and hard inner layer enclosing the seed).	Neurological problems; paralysis	Karakin (glucose ester of 3-nitropropionic acid)	Lowlands, especially the coasts; abundant in the North Island; found in Nelson, Marlborough, and Banks Peninsula in the South Island	Risk of ingestion is higher in autumn; fruit and seeds are main toxic parts; fruits remain toxic for months; fruit used as food by the Maori but require extensive processing to render them safe; nectar is toxic to bees.	In cattle, paralysis of the hind limbs and an end to lactations may occur. In dogs, convulsions and spasms may precede paralysis of the hind limbs and muscle incoordination. Death may occur. A goat that ate karaka berries showed pain, depression, and diarrhea.	

(Continued)

TABLE 79.2 (Continued)

Common name of disease	Species and identification	Diseases	Toxins	Distribution	Risk factors	Toxidrome	Association with other diseases
Kowhai toxicity	<i>Sophora sp.</i> Twenty-seven (very similar) species; trees or shrubs to 20 m tall; leaves are $\geq 15$ cm in length, with each bearing 20–40 pairs of leaflets; flowers ostentatious yellow in drooping racemes or panicles in spring; pods are long and winged; seeds yellow.	Stimulation of respiration; excitation of muscle; paralysis of peripheral sympathetic ganglia	Cytisine (acts like nicotine); also anagryne, matrine, <i>N</i> -methylcytisinesophoramine, and sophochrysine	Throughout New Zealand in open forests, along forest margins, riverbanks, and in open damp or rocky places; commonly grown as an ornamental	All parts are poisonous; most poisonings are caused by seeds; children, livestock, and bees have been poisoned by seeds, plant material, or nectar, respectively; all species are toxic until proven otherwise.	Resembles nicotine poisoning; recumbency, ataxia, tachycardia, increased respirations, abdominal pain, and hypomotility have been reported; death is due to nicotinic stimulation of the nervous system.	
Tree nettle toxicity Ongaonga poisoning	<i>Urtica ferox</i> Bush to 2 m tall; plants are much branched; stinging hairs up to 6 mm long covering the stalks and margins of the leaves; flowers are small and green.	Nervous and gastrointestinal signs as well as local irritation	Histamine, serotonin; acetylcholine, and other unidentified pain-producing agents; toxins are concentrated in the stinging hairs.	Throughout New Zealand and abundant; particularly on waste and neglected land; extend south to Otago	Contact with plant causes toxicity; all species susceptible.	Horses: excitable and restless; lesions can be seen in sheep on the udder and hairless parts. Dogs: trembling, vomiting, difficulty breathing, and general pain; convulsions and death may follow in severe cases; temporary loss of scenting ability in dogs; survivors have muscle pain for several days.	
Poroporo toxicity Bullibul; Bullibulli; large kangaroo apple (Australia)	<i>Solanum laciniatum</i> and <i>S. aviculare</i> Soft wooded shrub to 3 m tall; leaves narrow, lanceolate, 15–30 cm long; flowers blue-purple; fruit pale yellow or orange berry.	Irritant, hemolytic, CNS depression with cardiac and respiratory failure	Solasonine, solamargine, and $\beta$ -solamargine	Lowland forest margins and shrublands throughout New Zealand	Not normally palatable; all parts are poisonous; toxins concentrated in unripe berries; fully ripe fruit are probably not toxic; poisoning associated with ingestion of green fruit and plant material by hungry or naive stock.	Profuse diarrhea with abdominal pain, depression, weakness and incoordination, trembling, rapid respiration and heart rate, dyspnea, excessive salivation, nasal discharge, and jaundice; sudden death.	
Bushman's friend Rangiora toxicity	<i>Brachyglottis repanda</i> Shrub or small tree; to 6 m height; branches are covered in soft white hairs; leaves ovate, 10–25 cm long, obvious veins; dull gray/green above and covered with white hairs on the underside; flowers white to creamy white in large drooping panicles.	Hepatogenous pyrrolizidine alkaloid (PA) toxicosis	Senkirkine and other PAs	Abundant in the North Island and found as far south as Kaikoura and Greymouth in the South Island	PAs most concentrated in young growing tips, leaf petioles, and in the cortex of thin stems; PAs not present in the flowers and only in low concentrations in the mature leaves; all species susceptible, although sheep somewhat resistant.	Senkirkine causes irreversible hepatic damage and altered vitamin A metabolism; typical PA toxidrome.	Other liver toxicants, such as sporidesmin, copper, phosphorous, iron, and phenolics, increase the risk of toxicity by PAs.
Buttercup poisoning Waoriki poisoning	<i>Ranunculus rivularis</i> (syn. <i>amphitrichus</i> ) Perennial, creeping, hairless buttercup; it prefers wet places.	Gastrointestinal tract irritant	Ranunculin (protoanemonin)	Ubiquitous; most poisonings in the North Island	Most toxic during flowering; hay containing the plant is safe when dried.	Severe gastroenteritis; milk has taste taint	

industry and the arid zone and semi-arid zone sheep industries. The following are approaches to reduce the risks associated with these circumstances:

- Mechanical methods of plant removal: Because of the sheer physical size of livestock properties in the semi-arid and arid regions of Australia, such methods are often impractical. However, on a small scale, such techniques may be valuable. A notable use of physical removal of poisonous plants over relatively large land areas is the use of “scalping” in the wheat belt of Western Australia. Scalping involves the removal of all topsoil that may contain *Gastrolobium* sp. seeds and replacing the topsoil with new poison pea-free soils sourced from elsewhere. This extreme and expensive technique has been historically used with some success.
- Use of herbicides: Again, because of the sheer physical size of livestock properties in the semi-arid and arid regions of Australia, such methods are often uneconomic. Herbicide use may, in fact, increase the toxicity (and in some cases the palatability) of some plants (e.g., the notable association between the use of some herbicides and nitrite poisoning).
- Use of biocontrol agents: A number of biocontrol agents are being developed in Australia for the control of introduced poisonous plants, notably for Patterson’s curse. Biocontrol agents are unlikely to be developed for indigenous plants.
- Sheep, cattle, and goats are somewhat more tolerant of some poisonous plants than are other livestock. The use of goats to control *Gastrolobium* sp. and the use of sheep on pastures containing heavy growths of Patterson’s curse and heliotrope are common examples. However, some stock losses are often encountered in these types of enterprises, and they require careful management.
- Supplementary feeding (including the use of safe but not normally consumed native plants) during drought is also regularly and successfully used to avoid the effects of drought and poisonous plants on livestock. This has led to the common practice of “droughtlotting” – the creation of temporary feedlots in order to maintain key livestock. Registers of safe native plants that can be used for drought feeding are commonly maintained by the various relevant state government departments. The leaves of *Acacia aneura* (mulga) have historically been extensively used as drought feed for sheep in the arid, central zone of Australia. Although the plant is effective for this purpose, consumption results in nutritional lipofuscinosis of the liver and kidneys of sheep (commonly called “black liver”). The pigment accumulation is benign and the animals suffer no adverse effects, but the liver and kidneys from affected animals cannot be sold for human consumption for aesthetic reasons, resulting in some financial loss.
- A long-standing and well-proven strategy to reduce the risk of stock losses due to drought conditions and/or when poisonous plants are present has been to physically relocate livestock from properties/regions that are entering into drought conditions to geographic areas where there are better prevailing conditions. This technique was pioneered by S. Kidman and Company cattle company in the early 1900s. Kidman, whose cattle company at one time owned 3% of the Australian landmass, and others developed and expanded a network of connected stations and traveling stock routes (TSRs) stretching across northern Australia, Queensland, and New South Wales to South Australia near the Flinders Ranges and also across New South Wales. Kidman could grow and fatten the cattle on the remote stations in the north and bring them down the lines of stations and TSRs to markets in the south, providing good feed and water during transport and avoiding the effects of drought on his livestock. TSRs (known colloquially as “long paddocks”) in Australia are authorized thoroughfares for the walking of domestic livestock such as sheep or cattle from one location to another. TSRs are a critical source of feed for livestock during drought conditions. Traveling stock on a TSR must travel 6 miles a day (by law) in order to avoid the grazing off of all fodder within a particular TSR area. However, the use of TSRs under drought conditions is not foolproof. There have been many notable large-scale stock losses on TSRs due to animals that are unfamiliar with a particular geographic area grazing the local poisonous plants.
- Another long-standing and well-proven strategy to reduce the risk of stock losses due to the rapid emergence of indigenous poisonous plants following a break in a drought is to not allow livestock into a grazing area until safe fodder plants dominate the pasture. Again, the ability to geographically relocate stock into safe areas and hold them there until the pastures return to a good and safe condition, as well as knowledge of the local flora and physical inspection of the pastures, is critical to the success of such a strategy.
- Good pasture management is often a key factor in reducing the impact of many poisonous plants. Critical factors include not overgrazing pastures, not overstocking pastures, and pasture spelling/rotation.

Another common problem in Australia has been the introduction of toxic weeds into a hitherto clean area. Effective integrated weed management programs are critical to reducing risks of this nature.

One of the important animal-related factors that are amenable to human intervention is to ensure that

livestock are familiar with the local fauna. Large-scale stock losses that have occurred when naive stock are moved or released into a new geographic area are commonplace in the history of poisonous plants in Australia. Limited, staged, and well-controlled introduction of naive livestock into a new geographic area may reduce the risk of such events. It is also critical to ensure that the new geographic area has plenty of safe forage and that relevant poisonous plants do not dominate the edible local flora. Particular care should be taken to ensure livestock are not hungry when they are introduced into a new area.

Another animal-related factor that is amenable to human intervention is boredom in horses. Horses that are not active or have low levels of environmental stimulation may indiscriminately graze on plants simply due to boredom.

## CONCLUSIONS

Based on Australian Bureau of Agricultural and Resource Economics (ABARE, 2006) economic data, the livestock industries of Australia generated approximately \$AU 15.4 billion for the 2004–2005 financial year, representing approximately 56% of the income from the top 10 Australian agricultural commodities by value. Unfortunately, recent economic data on the impact of poisonous plants on the Australian livestock industries appears to be lacking, but the current anecdotal estimate is approximately \$AU 100 million per year, or approximately 0.6% of the total income generated from the Australian livestock industries in 2004–2005. Poisonous plants continue to be an important cause of financial loss within the livestock industries in Australia.

Compounding the pure financial losses is the fact that “outbreaks” of plant poisonings are often tied to climatic conditions, such as droughts and floods, when producers are focused primarily on maintaining the minimal core herds of livestock that will allow them to rapidly restock and take advantage of good climatic and pasture conditions when they return. Currently available practical techniques are partially successful in reducing livestock losses, although well-proven techniques such as geographic relocation of livestock are economically expensive and capital intensive.

Historically, the investigation of plant poisoning in the Australian and New Zealand livestock industries has generally focused on death or severe acute events as key endpoints. There is little doubt that within these contexts, there is still much to learn regarding the poisonous plant flora of Australia and New Zealand. However, sub-clinical losses (e.g., diminished growth rates rather than outright stock losses) and the use of indigenous plants as safe sources of fodder (particularly during adverse climatic conditions) are also likely to be areas of future investigation.

# Cyanogenic plants

Steven S. Nicholson

## INTRODUCTION

Cyanide, hydrocyanic acid, HCN, and prussic acid are terms relating to the same toxic principle. Cyanide is used as a fumigant and in chemical synthesis. Fifty to 60 parts per million (ppm) in air, as in fumigants, may cause poisoning. Cyanide salts are used in metal cleaning, hardening, refining, and in the recovery of gold from ores. Jewelers use potassium cyanide to clean products (Coentrão and Moura, 2011). Tailings and wastewater from recovery of gold from ores is a potential threat to wildlife. Wildlife deaths associated with cyanide-bearing mine waste solutions have plagued the gold mining industry for many years, but there is little published data showing the relationship between wildlife mortality and cyanide toxicity. A gap in knowledge exists with regard to monitoring, understanding the causal relationships, and managing risks to wildlife from cyanide-bearing waste solutions and tailings (Donato *et al.*, 2007). Burning nitrogen-based polymers used in plastics, fabrics, and seat covers releases HCN, which along with oxygen depletion, carbon monoxide, and other compounds, contributes to fire smoke toxicity (Alarie, 2002). Cyanide blocks molecular oxygen transfer in cytochrome oxidase systems in mitochondria causing tissue anoxia. The process is reversible. Various cyanogenic glycosides, which can hydrolyze to form hydrogen cyanide, are present in a number of plant species. These compounds probably developed as a defense against excessive grazing by herbivores. Only a few of these plants are a significant risk to livestock. Some are grasses cultivated as forage for livestock and horses, and others are ornamentals, commercial fruit trees, shrubs, weeds,

and range plants. All animal species are susceptible to cyanide poisoning. The ability of rumen microbial flora to rapidly hydrolyze cyanogenic glycosides makes ruminants particularly at risk of cyanide intoxication from plant sources. A review of the risks and effects of cyanogenic plants in animals was published by Burrows and Tyrl (2001).

## BACKGROUND

In general, the location of cyanogenic glycoside in plants is the epidermis, with highest levels in seeds, leaves, bark, and twigs, and lowest levels in fruit. Seeds of grain sorghum and other grasses do not contain these glycosides. Seeds of members of the Rosaceae family, including apple (*Malus* spp.), cherry (*Prunus* spp.), peach (*Prunus persica*), and apricot (*P. armeniaca*), do contain cyanogenic glycosides. Laboratory test results of plant tissues for the presence of cyanide are reported as cyanide potential because free cyanide is not present in plants but is generated from glycoside during testing.

HCN potential of cyanogenic plants ranges from a few parts per million to 8000 ppm dry weight from the glycoside dhurrin in foliage of a grain sorghum (Burrows and Tyrl, 2001). Similar levels may occur in Johnson grass (*Sorghum halepense*), which is considered a weed but also utilized for grazing and hay. Related sorghum hybrids and sudangrass forages have been developed that have less cyanide potential, but most may be a hazard under certain conditions. Bermudagrass (*Cynodon* spp.) and other grasses and clovers are known to produce

cyanogenic glycosides in immature forage. African star grass (*Cynodon nlemfluensis*) is an example of one of the species grown in the tropics and Florida that can cause a cyanide problem. Nitrogen fertilization increases glycoside content. Cyanide potential in these forages is greatest during early growth. Concentrations of the glycoside prunasin in leaves of *Prunus virginiana* may be as high as 6% dry weight (Majak *et al.*, 1981). During a growing season, glycoside levels in plants are generally highest in early growth and decline as maturity approaches. Fluctuations in glycoside levels during a growing season occur associated with climatic changes such as periods of drought. Shortages of forage caused by a 2-year drought in Kansas were further exacerbated by increases in nitrate and cyanide in the feed based on analyses of samples submitted to a laboratory (Pickrell *et al.*, 1991).

Physical damage to plant tissue (freezing, crushing, macerating, cutting, and drying) allows plant enzyme  $\beta$ -glycosidase to come in contact with and hydrolyze the glycoside to hydroxynitrile and free volatile HCN. The first step in this process yields a sugar and an aliphatic or aromatic  $\alpha$ -hydroxynitrile aglycone (cyanohydrin); then, formation of an aldehyde or a ketone, such as benzaldehyde, and hydrogen cyanide occurs (Conn, 1979). Generally, hay loses most of the HCN prior to feeding. In some situations, toxic levels may remain in large bales of *Sorghum* spp. when the cut forage dries rapidly and is immediately baled. Properly ensiled silage loses cyanide potential. Green chopping immature sorghum forage and feeding it the same day to ruminants is a serious potential hazard.

## PHARMACOKINETICS/ TOXICOKINETICS

HCN is rapidly absorbed from the gastrointestinal tract, lungs, and slowly through the skin. Acid stomach contents in monogastric animals limit the hydrolysis of cyanogenic glycosides and release of HCN. The rumen microflora rapidly hydrolyzes cyanogenic glycosides, releasing HCN, which is quickly absorbed and distributed to the tissues. Lower ruminal pH in cattle fed high-grain diets reduces the action of microbial enzymatic activity and release of HCN (Majak *et al.*, 1990).

## MECHANISM OF ACTION

Cyanide combines with the ferric ion in mitochondrial cytochrome oxidase, preventing electron transport in the

cytochrome system and thus blocking oxidative phosphorylation and ATP production. The effect is cellular hypoxia or histotoxic anoxia. This is a reversible action in sublethal doses or when successfully treated. The inhibition of oxidative metabolism puts increased demands on anaerobic glycolysis, which results in lactic acid production and may produce severe acid-base imbalance. The central nervous system is particularly sensitive to hypoxia, and exposure to toxic levels of hydrogen cyanide generally produces symptoms within minutes.

Arterial blood is normally bright red because of the presence of oxyhemoglobin. In cyanide toxicosis, oxygen is not released from oxyhemoglobin to the tissues and the bright red color remains in venous blood. This process, from ingestion of a toxic dose of plant material to release of cyanide in the rumen and onset of clinical signs, can occur within a few minutes.

Some cyanide is detoxified by an endogenous thiosulfate limiting process. Thiosulfate combines with cyanide to form thiocyanate, which is excreted in the urine. The reaction is catalyzed by the enzyme rhodanese. The ability to detoxify cyanide allows animals to safely metabolize small amounts of cyanide.

## TOXICITY

Ruminants are more likely to be poisoned by plant-origin cyanide than are other animals because rumen microorganisms readily release cyanide from the glycoside. An active microbial flora in the gut allows considerable but somewhat delayed and slower hydrolysis of cyanogenic glycosides in humans and hamsters and lesser amounts in mice, rats, guinea pigs, and monkeys (Stavric and Klassen, 1980; Adewusi and Oke, 1985; Frakes *et al.*, 1986). Although uncommon, there are reports of cyanide toxicosis in horses, pigs, and dogs. Cyanide poisoning possibly killed two adult wether alpacas that ate a garden-cultivated variety of South African daisy (*Osteospermum ecklonis*) with a cyanide potential of 6800 mg HCN/kg dry matter (McKenzie *et al.*, 2004). Eating raw plant material containing  $\beta$ -glycosidase along with crushed apricot, cherry, peach, or apple seeds has proved fatal in humans, dogs, and cattle. In general, monogastric animals including horses are poisoned by 1–3 mg/kg body weight (BW) of preformed HCN or cyanide salts. The lethal dose of sodium cyanide, 3 or 4 mg/kg BW to ruminants (Burrows and Way, 1977), is quite similar to the lethal dose of cyanide from the glycoside prunasin in plant material, 5 mg/kg BW in cattle (Majak *et al.*, 1990). Plant material containing more than 20 mg per 100 g (200 ppm) cyanide potential is considered hazardous. A level of 500 ppm has been used more

specifically for the sorghums (Burrows and Tyrl, 2001). The effects are not cumulative. One-half the lethal dose can be given repeatedly during the course of a day such that a total dose of four or five times the single lethal dose does not induce clinical signs. Tolerance does not develop (Burrows and Tyrl, 2001).

Eight Alpine cross-bred female goats were divided into two equal groups and were treated with ground frozen cassava leaves at a target dose of 6.0 mg HCN/kg/day by gavage for 30 consecutive days. Clinical signs were observed in all goats treated with cassava on the first day of the experiment. From the second day, the dose of cassava leaves was reduced to 4.5 mg HCN/kg/day. No changes were found in the blood chemical panel. A mild increase in the number of resorption vacuoles in the thyroid follicular colloid, slight vacuolation of periportal hepatocytes, and spongiosis of the mesencephalon were found in goats treated with cassava (Soto-Blanco and Górniak, 2010).

Death may occur within minutes after ingestion of a toxic amount of a plant containing high cyanide potential. An exception may occur when ruminants grazing arid rangelands ingest a toxic amount of chokecherry or arrowgrass while rumen contents are quite dry and release of HCN by rumen flora is delayed until the animal drinks water later in the day. Affected animals may be found dead in or near the water source.

Cattle may become apprehensive and excitable at the sight of herd mates that are suddenly affected and collapsing. Onset of clinical signs is peracute and includes apprehension, pronounced polypnea, and then dyspnea because initially there is stimulation of chemoreceptors in the carotid body and respiratory centers. The pupils dilate, and mucous membranes may be pink and venous blood a bright red, like that of normal arterial blood. Weakness, voiding of urine, collapse, paddling, and death follow within a few minutes. Sublethal cases may recover within 1 h.

Lesions of cyanide toxicosis are few. Mucous membranes may be pink, and venous blood may be bright red and clot slowly. Subendocardial and subepicardial petechial and ecchymotic hemorrhages typical of an agonal death may be present. A bitter almond or "cherry coke" odor from stomach contents is detectable in some cases. Venous blood may not be bright red in animals that have been dead for several hours. At necropsy, blood of animals that died of some other cause may develop bright red color when exposed to the air for several minutes.

Differential diagnosis of cyanide toxicosis in ruminants may include acute toxicoses caused by insecticides, nitrate and nitrites, urea and ammonia, ipomeanol, perilla ketone, 3-methylindole, blue-green algae toxins, and electrical shock or lightning strike.

When cyanide toxicosis is suspected, one should submit to the laboratory, along with the usual specimens,

refrigerated heart or skeletal muscle and rumen contents for cyanide ion detection. In blood, concentrations of 1 ppm or higher are consistent with severe intoxication in mammals and birds (Burrows and Tyrl, 2001). Blood should be kept in airtight containers at 4°C (Egekeze and Oehme, 1979). Continued hydrolysis of glycoside and loss of HCN may make necropsy samples less useful for confirming the diagnosis. Specimens can be immersed in mercuric chloride to prevent hydrolysis from continuing. Rumen or stomach contents can be examined for the presence of material from cyanogenic plants. For example, black cherry (*Prunus serotina*) intoxication in a goat was diagnosed by identification of leaf fragments in rumen contents (Radi *et al.*, 2004). A sensitive field test using alkaline picrate-treated filter paper strips can be prepared for testing plant materials and fresh rumen contents (Burrows and Tyrl, 2001).

Chronic cyanide poisoning (or a nitrile compound) may be involved in equine ataxia and urinary incontinence seen in horses grazing sorghum hybrid pastures (Van Kampen, 1970; Wheeler and Mulcahy, 1989). There are reports of a similar condition in cattle and sheep (Bourke, 1995). After grazing grain sorghum regrowth, 54 of 330 breeding cows became ataxic and developed urinary incontinence. Wallerian degeneration of the white matter of the spinal cord, cerebellar peduncles, and cerebellum was seen histologically (McKenzie and McMicking, 1977). In humans, long-term consumption of the cyanide-containing plants tropical lima beans and cassava root is associated with well-documented conditions involving the spinal cord, optic nerves, and other lesions. A study of children in Mozambique evaluated the possible association of high cyanide and low sulfur intake in cassava-induced spastic paraparesis. The study results supported the hypothesis that the epidemic was due to the combined effects of high dietary cyanide exposure and sulfur deficiency (Cliff *et al.*, 1985). Teratogenic effects of cyanide have been demonstrated in hamsters (Frakes *et al.*, 1986).

## TREATMENT

Rapid response to intravenous antidote solution can be striking, although the opportunity to treat is rare because of the peracute nature of the poisoning. The antidote of choice in humans, dogs, and probably most other animals is 10–20 mg/kg BW of sodium nitrite in combination with sodium thiosulfate (Baskin *et al.*, 1992; Burrows and Tyrl, 2001). Ruminants can be treated with thiosulfate alone using a 30–40% solution intravenously at a dose of 25–50 g/100 kg BW (Burrows and Tyrl, 2001).

## CONCLUDING REMARKS AND FUTURE DIRECTIONS

Cyanide poisoning is an uncommon event in livestock production, but the potential for sudden economic loss to individual farmers and ranchers is significant. Veterinarians, agricultural educators, and consultants should continue to remind clientele of the risks to ruminant species associated with forages, shrubs, and trees of known cyanide potential.

# Nitrate and nitrite accumulating plants

Steven S. Nicholson

## INTRODUCTION

Ruminants are particularly at risk of acute, fatal nitrate–nitrite poisoning. Microorganisms in the rumen reduce nitrates to nitrites and then ammonia for microbial growth. Excess intake of nitrates may cause toxic levels of nitrite to accumulate and be absorbed into the blood. Cattle graze a variety of grasses and weeds that under certain conditions, especially excessive fertilization or reduced growth rate because of drought, herbicide damage, or reduced sunlight, can accumulate levels of nitrate in the stems that may prove toxic to animals that eat a sufficient dose. Excess levels of nitrate may be present in grazed forages and weeds, in hay, or in fresh cut forage brought to the animals as greenchop. Ensiling may reduce nitrate levels by 30% or more. Sheep and rabbits can convert nitrate to toxic levels of nitrite. Goats browse leafy portions of plants and may not ingest toxic levels of nitrates in stalks and stems of forages. In horses, some bacterial reduction of nitrate to nitrite does occur in the large bowel (Bruning-Fann and Kaneene, 1993). Nitrate toxicosis in horses is rarely reported as a clinical entity (Hintz and Thompson, 1998). Monogastric species are susceptible to the toxic effects of nitrites ingested as nitrites from nonplant sources. Nitrates and nitrites are water soluble and may contaminate water sources. Forages and weeds growing in soil rich in manure waste or in holding pens are a potential source of poisoning. Nitrate fertilizers are commonly found on farms and ranches, and accidental ingestion or feed contamination does occasionally occur. Three cases of accidental acute fertilizer poisoning in cattle resulted in substantial death loss. Water hauled in tanks previously contaminated with a nitrogen-based fertilizer was the source in all cases. In two cases, analysis

of the water measured urea at 1640 and 2300 ppm and ammonia nitrogen at 640 and 750 ppm, respectively. Confirmation of urea toxicosis was made by measurement of toxic levels of ammonia nitrogen in the rumen contents (>800 ppm) and blood (>8.0 ppm). In the third case, no urea was detected in the water, but ammonia nitrogen was measured at 1670 ppm and nitrate at 1.1%. Toxic levels of nitrate were measured in ocular fluid from two animals (60 ppm). The rapid progression of signs to death with ammonium nitrate poisoning may explain the lower levels of nitrate attained in ocular fluid than observed with pure nitrate intoxications (Villar *et al.*, 2003).

## BACKGROUND

Plants take up nitrogen from the soil primarily in the form of nitrate. Nitrate accumulation in the stems and leaves of plants may be associated with high levels of nitrates, or ammonia, in the soil. Young plants are more likely to have high nitrate levels than are more mature plants. Nitrate concentrations decline considerably in all parts of sudangrasses (*Sorghum* spp.) following heading (Mizukami *et al.*, 1997). Plants growing in soil where livestock manure and urine were applied as fertilizer or where accumulations occur in holding pens may accumulate nitrates. Hungry cattle and sheep introduced to stockyards containing a dominant or pure growth of button grass (*Dactyloctenium radulans*) suffered acute nitrate–nitrite toxicity in four incidents in inland Queensland between 1993 and 2001 (McKenzie *et al.*, 2004b). The nitrate content of the button grass from within the stockyards ranged from 4.0 to 12.9% as KNO<sub>3</sub> in dry matter

and from outside the stockyards ranged from less than 0.2 to 0.4%. Three cows fed *Chenopodium album* hay died 30 min after showing ataxia, bluish-brown mucous membranes, rapid and difficult breathing, increased heart rates, tremors, and coma. Brown-colored and badly coagulated blood was the prominent necropsy finding. Slight pulmonary edema was prominent, and all visceral organs were hyperemic. The hay contained 2500 ppm nitrate–nitrogen and 11 ppm nitrite–nitrogen (Ozmen *et al.*, 2003). After harvesting corn in Nebraska, cornstalks remaining in fields had an average decrease in potassium nitrate content of only 30% in 90 days (Johnson *et al.*, 1992). Nitrate–nitrite poisoning killed four adult alpacas and induced the abortion of a full-term fetus after access to oaten hay (*Avena sativa*) containing 3.2% KNO<sub>3</sub> equivalent in dry matter. Necropsy findings were cyanosis, dark-colored blood, and pulmonary congestion and edema. Aqueous humor from two adults contained 25 ppm NO<sub>3</sub> and that from the fetus contained 10 ppm NO<sub>3</sub> (McKenzie *et al.*, 2004a).

Plant growth may be slowed, and nitrate accumulation increased, when growing in soil that contains nutrient deficiencies or excesses. For example, molybdenum is a component in enzymatic reactions of nitrate reductase in plants. Nitrate accumulation in stalks and stems may follow herbicide damage to plants or loss of leaves due to hail.

A major reason why plants accumulate nitrates is drought. During periods of drought, the growth of forages and weeds is reduced, but the roots may continue to collect and store nitrate in the stems. This is particularly true of well-fertilized sorghum hybrid (*Sorghum* spp.) and millet (*Pennisetum* spp.) forages grown for temporary summer grazing and for hay production (Clay *et al.*, 1976). Shortages of forage caused by a 2-year drought in Kansas were further exacerbated by increases of nitrate and cyanide in forages based on analyses of samples submitted to a laboratory (Pickrell *et al.*, 1991). Within a given field or pasture, forage nitrate levels may vary considerably, requiring multiple forage samples for testing to achieve accurate assessment of the risk of nitrate–nitrite intoxication. Determining the nitrate status of bales of stored hay can be a challenge because only the forage growing in a portion of a hayfield may have been affected. Bales must be labeled, sampled, and tested for nitrate content. Obtaining a representative sample requires using a hollow handheld commercial tool that cuts through to the center of the bale and recovers a core sample of approximately 1 oz. of hay. At least two samples from each bale should be collected. Investigation might reveal, for example, that one-third of the bales have nitrate levels less than 0.5%, one-third perhaps 0.5–1.0%, and the remaining portion greater than 1%.

Plants may accumulate nitrates during periods of reduced sunlight. Sunlight is needed to drive photosynthesis and the energy-dependent nitrate reductase system

in the plant. Forage or weeds growing in the shade of trees in an orchard may be subject to nitrate accumulation. Nitrate poisoning is occasionally a problem in areas of the United States where winter grazing for cattle consists of fertilized pastures of ryegrass (*Lolium multiflorum*), oats (*Avena* spp.), turnips (*Brassica rapa*), or wheat (*Triticum* spp.). During extended periods of overcast weather, perhaps several days, the nitrate content of the forage may increase to potentially toxic levels. Accumulation is more likely when temperatures are mild (>55°F) and the root systems are actively taking up nitrates. Growth slows or stops, but the roots continue uptake of nitrate, which is stored in the stems until there is adequate sunlight and growth resumes. Generally, a day or two of sunlight with temperatures above 55°F allows plant growth to continue, converting excess stored nitrate into plant protein.

To reduce trampling of forage, farm management may employ limited grazing periods, allowing hungry cattle to consume a large amount of green forage for approximately 2 h each day. This increases the risk because of the time–dose relationship that exists when excess nitrate is present and conversion of nitrate to nitrite exceeds the ability of the rumen flora to convert nitrite to ammonia. Total dietary intake of nitrate should be considered. For example, supplemental feeding of hay that has increased nitrate levels to cattle grazing forages with elevated nitrate levels increases the risk of toxicosis. Nitrate in drinking water adds to dietary intake. Nitrate concentrations in water in excess of 1000 ppm may cause nitrate poisoning in livestock.

Nitrate levels are not reduced by drying and baling as hay. High nitrate hay (>1.5% KNO<sub>3</sub>; 1.0% nitrate) fed to cattle months after baling can cause multiple deaths and abortions. Mortality can be striking, as in a case in Nebraska in which *Amaranthus/Kochia* hay with 4.9% KNO<sub>3</sub> and sudangrass with 8% KNO<sub>3</sub> were fed to 390 cattle, resulting in death of 226 and 42 abortions (Hibbs *et al.*, 1978). High nitrate summer hay fed during the winter of 1977–1978 killed cattle in Oklahoma (Haliburton and Edwards, 1978).

Rumen microorganisms can adapt to and utilize increasing levels of nitrate in the diet. The period of maximum acclimation occurs within 6 days (Allison and Reddy, 1984). Adaptation can be lost within a few days. The ability of rumen microorganisms to safely reduce nitrate and nitrite can be increased by feeding corn-based supplements to cattle (Burrows *et al.*, 1987).

Nitrate content in properly ensiled forage may be reduced by 30% or more during the ensilage process. The silage should be tested before feeding. Silage juices draining from the silo may be high in nitrates. Nitrogen dioxide (NO<sub>2</sub>) and nitrogen tetroxide (NO<sub>4</sub>) gases may be formed from oxides of nitrogen generated during anaerobic fermentation of high-nitrate forages. These pulmonary toxicants are heavy yellow-brown gases.

## PHARMACOKINETICS/ TOXICOKINETICS

Action of the rumen flora reduces nitrate to the much more toxic nitrite, which is normally converted to ammonia and further utilized by the microorganisms. Nitrite is absorbed into the blood when the intake of nitrates and the production of nitrite exceed the capacity of the rumen flora to further reduce nitrite. In some cases, preformed nitrite in hay may shorten the period from ingestion to onset of signs. Nitrates are absorbed into the blood as well but are much less toxic than nitrite. The half-life of nitrate is estimated to be 9 h in adult cattle and more than 24 h in the bovine fetus (Johnson *et al.*, 1992). The half-lives of nitrate and nitrite in the blood of sheep are 4.2 and 0.5 h, respectively (Schneider and Yeary, 1975).

## MECHANISM OF ACTION

The nitrite anion causes vasodilation and oxidizes ferrous iron ( $\text{Fe}^{2+}$ ) in hemoglobin to the ferric iron ( $\text{Fe}^{3+}$ ) state forming methemoglobin, which cannot accept molecular oxygen. As the percentage of methemoglobinemia rises, oxygen starvation to tissues increases and blood becomes chocolate brown in color. In sheep, the half-life of methemoglobinemia is approximately 1.5 h (Schneider and Yeary, 1975). Clinical signs such as exercise intolerance appear at 30–40% methemoglobinemia, with death from hypoxia likely when concentrations exceed 80% (Burrows, 1980). In nonfatal cases, a red blood cell intrinsic NADH-dependent diaphorase or reductase system gradually reduces methemoglobin to hemoglobin, which accepts molecular oxygen and can carry oxygen to tissues.

## TOXICITY

The nitrate level in edible stalks and stems of plants that is generally accepted as safe for all classes of cattle is less than 0.2–0.5% on dry weight basis. It is recommended that pregnant animals not be fed forage or hay with a nitrate content greater than 0.2% on dry weight basis. Forage nitrate higher than 1% (1.5%  $\text{KNO}_3$ ) is considered lethal. The rate of conversion of nitrate to nitrite and then to ammonia is a limiting factor in safe utilization of nitrates by ruminants. Hungry cattle are at greater risk, and intake of dry matter from hay may be faster than from grazing. The additive effect of nitrates in water and other feed sources must be considered when evaluating total dietary nitrate.

The rumen flora can safely utilize higher amounts of nitrate if sufficient dietary energy is present to promote reductive activity. Feeding corn-based supplements to cattle reduced nitrite accumulation (Burrows *et al.*, 1987). In this study, feeding of 3.2 kg of corn protected against nitrate poisoning by reducing intraruminal nitrite and blood methemoglobin ( $P < 0.05$ ).

Clinical signs of nitrate–nitrite toxicosis in cattle include weakness, cyanosis of mucous membranes, ataxia, collapse, and death. Increased respiratory rate may be noted in some animals.

Affected animals may remain standing but then collapse and die within minutes. Dead animals may be found in sternal recumbency or lying on their side. Blood is dark and may have an obvious brown color when drawn into a syringe or spread on a white cloth. At necropsy of animals dead several hours, this color may not be as apparent.

In cattle, abortions may occur in the herd 3–7 days after the acute toxicosis episode. Less oxygen is available to the fetus because of methemoglobinemia in the cow, and nitrite induces methemoglobinemia in fetal blood (Bruning-Fann and Kaneene, 1993). Bovine abortion has been reported to occur with forages containing 0.61–1% nitrate (van't Klooster *et al.*, 1990).

Differential diagnoses to consider include acute toxicoses caused by insecticides, carbohydrate overload, hypomagnesemia in lactating cattle, cyanide, blue-green algae, urea (ammonia), and potent oxidizing agents such as sodium chlorate herbicide and aniline dyes. Lesions are not diagnostic. Blood and tissues may appear brown at time of death, but this becomes less obvious as autolysis proceeds. Dark blood may suggest septicemia. Agonal hemorrhages in the epicardium may be present.

Ocular fluid is an excellent body fluid for nitrate analysis. Plasma and serum are acceptable. Ocular fluid nitrate levels are 35% lower than serum levels (Boermans, 1990). The diphenylamine blue test is widely used for testing fluids and plant tissues (Burrows, 1980; Bhikane and Singh, 1990). The diazotization test has also been used (Bhikane and Singh, 1991). Nitrate concentrations in ocular fluid of 10 ppm are indicative of excessive nitrate exposure, and concentrations greater than 20 ppm are considered diagnostic of poisoning (Burrows and Tyrl, 2001). In abortion and stillbirth situations, interpreting bovine fetal ocular fluid nitrate levels is more problematic because normal levels may approach 20 ppm in weak or stillborn calves (Johnson *et al.*, 1994). A level of 30 ppm or more and additional diagnostic information such as elevated forage nitrates may be needed to confirm nitrate abortion (Casteel and Evans, 2004).

The clinical history may suggest nitrates as a possible cause. All sources of forages, weeds, water, feed supplements, and fertilizers to which the animals had access should be determined and sampled for analysis.

## TREATMENT

Treatment is with intravenous methylene blue in a 1 or 2% aqueous solution at a rate of 1 or 2 mg/kg BW. Up to 10 mg/kg BW can be administered in severe cases. The response to intravenous treatment of a 2% solution of methylene blue at a dosage of 20 mL/100 kg BW is rapid, with reversal of the clinical signs within several minutes (Burrows and Tyrl, 2001). In severe cases, treatment at a lower dose can be repeated. Methylene blue serves as an electron carrier for an NADPH-dependent system to reduce methemoglobin to hemoglobin. Methylene blue is most effective in humans and ruminants (Burrows and Tyrl, 2001). Tissues in the treated animals are stained, and the urine becomes dark green. Treated animals should not be sold for slaughter for 180 days. Other dyes, such as tolonium chloride (tolonium blue), are effective in reducing methemoglobin to hemoglobin but have a narrow therapeutic index (Gupta *et al.*, 1992; Cudd *et al.*, 1996).

## CONCLUDING REMARKS

Safe use and storage of nitrate fertilizers is essential if accidental poisoning of livestock, especially cattle, is to be avoided. Use of liquid fertilizer tanks to deliver water to livestock is a documented hazard for nitrate or urea toxicosis. The potential for nitrate accumulation in weeds and forages intended for feeding or grazing and the risks this poses to ruminants, especially cattle, should be pointed out to farmers and ranchers by university extension and farm industry personnel. Cutter blades can be raised to reduce the amount of edible stalk in harvested forages if conditions suggest the possibility of high nitrate levels in the stalks and stems. Pre-feeding testing of potentially high-nitrate forages is especially important when environmental conditions affect growth. Feeding cattle an energy source such as corn or providing oral product containing *Propionibacterium* can increase the rate of nitrite reduction by rumen flora.

## Toxicity of yew (*Taxus* spp.) alkaloids

Christina R. Wilson and Stephen B. Hooser

### INTRODUCTION

Yews (*Taxus* spp., Taxaceae) are evergreen plants often used for ornamental landscaping in many areas of the United States, Europe, and elsewhere throughout the world. Common varieties in the United States are English yew (*Taxus baccata*), American yew (*Taxus canadensis*), Japanese yew (*Taxus cuspidata*), and Pacific or western yew (*Taxus brevifolia*) (Kingsbury, 1964). These plants can be highly toxic and have been implicated in numerous human and animal poisonings. The poisonous taxine alkaloids have been reported to be present in the foliage, bark, and seeds of the plants but not in the fleshy scarlet aril (berry) (Bryan-Brown, 1932; Kingsbury, 1964).

### Historical background

References to yew toxicity date back more than two millennia (Bryan-Brown, 1932). In the 1st century BCE, Julius Caesar (102–44 BCE) wrote of Catuvolcus, the king of Eburones, who poisoned himself with yew “juice” (Fröhne and Pfänder, 1984). Ancient Celts often committed ritual suicides by drinking extracts from yew plants and applied the poisonous sap to the tips of their arrows during the Gaelic Wars (Foster and Duke, 1990; Hartzell, 1995). Some primitive cultures are reported to have used yew extracts as hunting and fishing aids (Watt and Breyer-Brandwijk, 1962; Hartzell, 1995). During the 18th and 19th centuries, concoctions brewed from yew leaves were documented as having been used as an abortifacient or an emmenagogue by women in Europe and India (Bryan-Brown, 1932; Watt and Breyer-Brandwijk, 1962).

### Chemical characterization

The first preparation of an amorphous, white, noncrystalline powder called “taxine” originated from an analysis of alkaloid content from yew foliage (*T. baccata* L.) in 1856 by Lucas. It was isolated in crystalline form approximately 20 years later by Marmé, a French scientist (Hilger and Brande, 1890); however, it was not until 1956 that Graf and Boeddeker discovered that taxine was a mixture of heterogeneous compounds. Further investigations using electrophoretic analysis of taxine extracts revealed two major bands, thus recognizing the presence of two major types of taxine alkaloids: taxine A and taxine B (Graf, 1956). The farthest migrating electrophoretic band was designated taxine A, which comprised approximately 1.3% of the total alkaloid extract. The other electrophoretic band, taxine B, represented approximately 30% of the total alkaloid fraction extracted from *T. baccata* L. (Graf, 1956; Graf and Bertholdt, 1957). Subsequent analyses elucidated the molecular and structural formula of taxine A as well as its basic physical and chemical properties (Graf and Bertholdt, 1957; Graf *et al.*, 1982). A structural analog of taxine A, 2-deacetyltaxine A ( $C_{33}H_{45}NO_9$ ), was isolated from the leaves of *T. baccata* in 1994 (Poupat *et al.*, 1994). The chemical and structural properties of taxine A and 2-deacetyltaxine A are given in Table 82.1 and Figure 82.1. Although the preliminary structure of taxine B was first reported in 1986 (Graf *et al.*, 1986), the molecular and structural formulas were not completely elucidated until 1991 (Ettouati *et al.*, 1991). Purified taxine fractions from various *Taxus* spp. revealed the presence of several taxine B-related compounds. Isotaxine B ( $C_{33}H_{45}NO_8$ ), a structural isomer of taxine B, is present as a major constituent in the alkaloid fractions (Poupat

TABLE 82.1 Physical and chemical properties of taxine alkaloids

Taxine	Molecular formula	Melting point (°C)	Optical rotation	UV maximum (nm)	IR maximum (cm <sup>-1</sup> )
Taxine A	C <sub>35</sub> H <sub>47</sub> NO <sub>10</sub>	204–206	[α] <sub>D</sub> <sup>20</sup> = -140°	220, 255	1780, 1250
2-Deacetyltaxine A	C <sub>33</sub> H <sub>45</sub> NO <sub>9</sub>	–	[α] <sub>D</sub> <sup>20</sup> = -106°	224, 264	1734, 1691

*et al.*, 1994; Jenniskens *et al.*, 1996; Potier *et al.*, 1997; Adeline *et al.*, 1997). Present as minor constituents in *Taxus* spp. are 1-deoxytaxine B and 1-deoxyisotaxine B (Figure 82.2) (Jenniskens *et al.*, 1996; Potier *et al.*, 1997). The physical properties and chemical structures for taxine B and isoforms of taxine B are detailed in Table 82.1 and Figure 82.2. Other minor constituents, comprising approximately 2% of the total concentration, are the taxine B pseudoalkaloids 13-deoxo-13α-acetyloxytaxine B (C<sub>35</sub>H<sub>49</sub>NO<sub>9</sub>), 13-deoxo-13α-acetyloxy-1-deoxytaxine B (C<sub>35</sub>H<sub>49</sub>NO<sub>8</sub>), and 13-deoxo-13α-acetyloxy-1-deoxynortaxine B (C<sub>34</sub>H<sub>47</sub>NO<sub>8</sub>) (Appendino *et al.*, 1997).

## PHARMACOKINETICS/ TOXICOKINETICS

For reasons probably related to their acute toxicity and lack of pharmaceutical uses, pharmacokinetic studies on taxine alkaloids have not been well characterized. However, extensive pharmacokinetic studies have been reported for the widely used antineoplastic drugs

paclitaxel (isolated from *T. brevifolia*) and docetaxel (synthesized via a taxane precursor from *T. baccata*), which are also members of the taxane diterpenoid family. In studies of these two compounds, it has been found that they are both highly protein bound (>95%) in the serum and metabolized by hepatic P450 enzymes. One differentiating characteristic noted was that paclitaxel exhibits nonlinear kinetics at therapeutic doses, whereas the kinetics of docetaxel is linear. The linear kinetics of docetaxel is thought to be the result of metabolism by CYP 3A4 to pharmacologically inactive oxidation products that are excreted in the bile through a P-glycoprotein-dependent mechanism (Gustafson *et al.*, 2003; Baker *et al.*, 2006). Tissue distribution is extensive except for the central nervous system and testes. The elimination half-life for paclitaxel is 5–7h (two-compartment model) or 20h (three-compartment model), whereas the elimination half-life for docetaxel is 12h (two-compartment model) or 13h (three-compartment model). Liver insufficiency or co-administration of compounds that modulate P450 activity may influence the activity of these anti-neoplastic drugs and, presumably, the activity of more acutely toxic members of the family, such as taxines A and B (Brown, 2003).

Taxine Alkaloids	R <sub>1</sub>	R <sub>2</sub>	R <sub>3</sub>	R <sub>4</sub>
Taxine B	OH	Ac	H	H
Isotaxine B	OH	H	Ac	H

1-Deoxyisotaxine B	H	H	Ac	H

FIGURE 82.2 Structural formulas for taxines B.

## PHYSIOLOGY/MECHANISM OF ACTION

Due to their instability and the lack of highly purified taxines A and B for experimental use, research delving into the mechanism of action of taxines has frequently involved the use of crude extracts of taxines from yew. The earliest investigations of crude extracts of taxine alkaloids published in 1921 described cardiovascular effects. When administered by intraperitoneal or intravenous routes in rabbits and dogs, hypotension and cardiac arrest occurred in both species (Bryan-Brown, 1932). In addition, when toxicity was severe enough to result in cardiac abnormalities, it was noted that peristaltic contractions in the gastrointestinal tract ceased. Electrocardiographic analysis of isolated perfused hearts from rabbits and frogs revealed that crude taxine extracts gradually induced bradycardia, resulting in diastolic cardiac arrest. Further investigations have indicated that taxines depress atrioventricular conduction in a dose-dependent manner in isolated frog heart, having the greatest effect on ventricular rate (Smythies *et al.*, 1975; Tekol and Kameyama, 1987). In those studies, the cardiotoxic effect could not be inhibited by the administration of atropine, performing a vagotomy, or through ganglionic/adrenergic blockade (Bryan-Brown, 1932; Vohora, 1972). It was thus concluded that the hypotension induced by taxine extracts was not mediated via the sympathetic or parasympathetic nervous systems but, rather, by a direct action on myocardium (Vohora, 1972).

Significant differences in the cardiotoxicity of taxine A and taxine B have been reported (Bauereis and Steiert, 1959; Alloatti *et al.*, 1996). Through administration of taxine B either *in vivo* or *in vitro*, it was shown that taxine B is more cardiotoxic than taxine A, causing inotropic effects while eliciting marked changes in atrioventricular conduction. In isolated, perfused guinea pig hearts, a 5  $\mu\text{M}$  concentration of taxine B markedly increased atrioventricular conduction time and widening of the QRS interval, whereas a 1  $\mu\text{M}$  concentration (the lowest concentration used) significantly reduced heart rate (Alloatti *et al.*, 1996). These changes led to atrioventricular conduction blocks and complete diastolic cardiac arrest. The marked increase in QRS duration has also been reported in a human case of yew poisoning and also in intravenous administration of yew extracts to pigs (Matthew *et al.*, 1993; Ruha *et al.*, 2002). Taxine B has been shown to cause a marked reduction in the maximum rate of depolarization of the action potential in isolated papillary muscle, which thus resembles the action of class I antiarrhythmic drugs (e.g., flecainide, procainamide, and quinidine) (Bauereis and Steiert, 1959; Tekol, 1985; Alloatti *et al.*, 1996). In contrast, taxine A had a minimal effect on atrioventricular conduction time and QRS duration. Even at the highest concentration used (10  $\mu\text{M}$ ), taxine A induced only mild reductions in heart rate (Alloatti *et al.*, 1996).

More detailed investigations of the effects of taxine extracts on cardiomyocytes and axons indicated that taxines cause an increase in cytoplasmic calcium acting as calcium and sodium channel antagonists (Smythies *et al.*,

1975; Tekol, 1985; Tekol and Kameyama, 1987; Tekol and Göğüsten, 1999). In addition, isolated aorta, atrium, and jejunum from rabbits were used to compare the cardio-selectivity of taxines to verapamil, a known calcium channel antagonist. From these experiments, Tekol and Göğüsten concluded that the mechanism of action of taxines is primarily based on calcium channel antagonistic properties. Therefore, it is likely that the toxicity of taxines in animals and humans also occurs through the same mechanism.

Taxine alkaloids have minimal toxic effects on other organs. In the few studies reported, crude taxine extracts have some adverse effects on involuntary muscle but not on voluntary muscle. Uterine contractions, relaxation of the intestines, and contraction of the duodenum and ileum have been noted in experimental animals dosed with yew extracts (Bryan-Brown, 1932; Vohora, 1972). Tekol and Göğüsten (1999) reported that taxine sulfate inhibited peristaltic movement in rabbit jejunum, with a median inhibitory concentration (IC<sub>50</sub>) of  $1.86 \times 10^{-5}$  g/mL.

## TOXICITY

With the exception of the aril, all parts of the yew plant, including the seed within the aril, contain taxine alkaloids and are extremely poisonous. One study in laboratory rodents indicated that higher toxicity was found in the stems compared to the needles (leaves) (Shanker *et al.*, 2002). Although maximal concentrations occur during the winter (Watt and Breyer-Brandwijk, 1962), toxic amounts of taxines remain in the plants throughout the year and are not appreciably decreased by drying (Alden *et al.*, 1977). It has been reported that the cardio-toxic taxines A and B are relatively abundant in English

yew (*T. baccata*) and Japanese yew (*T. cuspidata*), but only minimal amounts are found in Pacific yew (*T. brevifolia*) (Tyler, 1960; Suffness, 1995; Brown, 2003).

Clinical cases resulting in poisoning are often accidental and are frequently a result of livestock or animals being unwittingly fed clippings from yew bushes. Yew intoxication has been reported in cattle (Casteel and Cook, 1985; Panter *et al.*, 1993), horses (Tiway *et al.*, 2005), sheep (Rae and Binnington, 1995) and goats (Coenen and Bahrs, 1994), dogs (Evans and Cook, 1991; Taksdal, 1994), a bear (Bacciarini *et al.*, 1999), fallow deer (Wacker, 1983), a moose (Handeland, 2008), emus (Fiedler and Perron, 1994), budgies (Shropshire *et al.*, 1992), canaries (Arai *et al.*, 1992), and monkeys (Lacasse *et al.*, 2007). It is interesting to note that yew (*T. baccata*) is often eaten by white-tailed deer and roe deer in the United States without apparent adverse effects (Weaver and Brown, 2004; Angus, 2010). This may be due, in part, to increased ruminal detoxification of the taxines present in the yew (Weaver and Brown, 2004).

Because of the difficulties in obtaining purified, stable taxines in quantities sufficient for mammalian studies, in the past, minimum lethal dose (LD<sub>min</sub>) values were assessed through the oral administration of yew leaves and branches (Watt and Breyer-Brandwijk, 1962; Clarke and Clarke, 1988). Estimating that 1 g of yew leaves contains approximately 5 mg of taxines (Smythies *et al.*, 1975; Tekol, 1985; Jenniskens *et al.*, 1996; Tekol and Göğüsten, 1999), minimal toxic doses of taxines (mg/kg body weight) in animals can be estimated and are summarized in Table 82.2. The body weights of the animals listed are average values for adult animals only (Spector, 1956). From Table 82.2, it is evident that the minimal toxic dose of taxines varies among species. Comparatively, horses are more sensitive (LD<sub>min</sub> of 1.0–2.0 mg/kg) and chickens are least sensitive (LD<sub>min</sub> of 82.5 mg/kg) to yew toxins.

TABLE 82.2 Oral lethal doses of yew leaves in animals

Animal	Estimated average body weight (kg) <sup>a</sup>	LD <sub>min</sub> of yew leaves (g)	LD <sub>min</sub> (g yew leaves/kg body weight)	Estimated LD <sub>min</sub> of taxines (mg/kg body weight)	References
Chicken	1.82	30	16.5	82.5	Clarke and Clarke (1988)
Cow	250	500	2.0	10.0	Clarke and Clarke (1988)
Dog	13	30	2.3	11.5	Clarke and Clarke (1988)
Goat	40	480	12.0	60.0	Clarke and Clarke (1988)
Horse	500	100–200	0.2–0.4	1.0–2.0	Clarke and Clarke (1988)
Pig	102	75	0.7	3.5	Clarke and Clarke (1988)
Sheep	40	100	2.5	12.5	Clarke and Clarke (1988)
Mouse	0.025	n.r.	n.r.	0.5 (s.c.) <sup>b</sup>	Tekol (1991), Tekol and Göğüsten (1999)

Rabbit	2.5	1.75	0.7	3.5	Watt and Breyer-Brandwijk (1962)

n.r., data not reported.

<sup>a</sup>Estimated average body weights of adult animals in this table referenced in Spector (1956).

<sup>b</sup>Mouse and rat LD<sub>min</sub>s are based on subcutaneous (s.c.) dose.

Adverse clinical signs in animals can vary depending on the amount of yew ingested. However, in most cases of acute poisoning, animals are often found dead 24h or less after ingestion without demonstrating abnormal behavior or adverse signs of toxicity. In subacute poisonings, which have been reported infrequently, clinical signs may include ataxia, bradycardia, dyspnea, muscle tremors, recumbency, and convulsions leading to collapse and death (Evers and Link, 1972; Casteel and Cook, 1985; Veatch *et al.*, 1988; Evans and Cook, 1991; Tekol, 1991; Arai *et al.*, 1992). In cases of deliberate yew poisoning in humans, adverse symptoms of toxicity are similar to those reported in animals. Documented clinical signs in humans include dizziness, mydriasis, nausea, vomiting, diffuse abdominal pain, tachycardia (initially), severe right ventricular dilatation with biventricular dysfunction, muscle weakness, and convulsions (Blyth, 1884; Czerwek and Fischer, 1960; Fröhne and Pribilla, 1965; Schulte, 1975; Wilson *et al.*, 2001; Panzeri *et al.*, 2010). In some cases, these symptoms proceed to bradycardia, bradypnea, diastolic cardiac standstill, or death (Blyth, 1884; Fröhne and Pribilla, 1965; Schulte, 1975; Sinn and Porterfield, 1991).

## Diagnosis

Diagnosis of yew poisoning in animals is frequently based on history of exposure. Frequently, poisoning is associated with pruning bushes and then feeding the trimmings to the livestock. In some cases, yew fragments (sometimes visible only by microscopic examination) are found in the mouth, stomach content, rumen content, and/or small intestine (Frommherz *et al.*, 2006; Lacasse *et al.*, 2007; Handeland, 2008; Panzeri *et al.*, 2010). Occasionally, exposure may be indicated in the history but gross identification of intact plant material is not observed. This can be especially true in species, such as horses, that masticate their food more thoroughly. In these cases, diagnosis of taxine poisoning often requires a more detailed microscopic and/or chemical evaluation of the gastrointestinal contents (Karns, 1983; Tiwary *et al.*, 2005).

Chemical analysis of biological samples using gas chromatography/mass spectroscopy (GC/MS) or liquid chromatography/mass spectroscopy (LC/MS) has been successful in diagnosing some cases of yew poisoning in mammals (Stahr *et al.*, 1977; Kite *et al.*, 2000; Tiwary *et al.*, 2005). LC/MS has been used to detect taxine B and isotaxine B in blood (Beike *et al.*, 2003; Frommherz *et al.*, 2006) and taxines A and B from yew plant fragments (Hough *et al.*, 2010). GC/MS detection of 3,5-dimethoxyphenol, an aglycon metabolite of taxicaine, has been used as a unique marker for yew exposure in mammals. 3,5-Dimethoxyphenol has been detected in blood, urine,

bile, and gastric contents from mammals exposed to yew plants (Froldi *et al.*, 2010; Panzeri *et al.*, 2010).

At postmortem examination, there are no lesions that are pathognomonic in animals that have died due to yew toxicosis. Indeed, neither gross nor microscopic abnormalities (with the exception of large pieces of yew leaves and stems, if they are present in the gastrointestinal tract) are observed (Kingsbury, 1964; Alden *et al.*, 1977; Ogden, 1988; Rooks, 1994). An exception to this is one case of yew poisoning in a horse in which ecchymotic hemorrhages were visible grossly along the endocardial surfaces of the ventricles, and microscopically, mild multifocal necrosis of the myocardium was identified in the ventricular wall and papillary muscles of the heart (Tiwary *et al.*, 2005). In subacute poisonings, gastroenteritis may be evident; however, the inflammation is probably due to irritant oils present in the yew and not due to taxine alkaloids (Watt and Breyer-Brandwijk, 1962; Kingsbury, 1964; Evans and Cook, 1991). Rarely, other gross changes have been reported at necropsy, including moderate to severe rumenitis, superficial hemorrhages in the right ventricular myocardium and right atrium, and mild focal interstitial myocarditis (Ogden, 1988; Panter *et al.*, 1993). In cases of yew poisoning in humans, the gross anatomic observations documented include acute congestion of internal organs, cerebral edema, and hemorrhagic pulmonary edema (Beike *et al.*, 2003; Wehner and Gawatz, 2003). In these cases, histology of the myocardium revealed interstitial edema, positive staining for troponin C with depletion in areas of the left ventricle, and alveolar hemorrhagic edema.

## TREATMENT

Death is frequently the first adverse clinical sign in animals that have eaten toxic amounts of yew; therefore, opportunities to treat exposed animals are rare. However, in instances in which known ingestion has recently occurred, it is important to remove the plant material from the gastrointestinal tract and limit absorption. Rumenotomy, followed by replacement therapy with a mixture of mineral oil, electrolytes, activated charcoal, and alfalfa pellets, has been effective in treating some cases of yew poisoning in ruminants (Casteel and Cook, 1985). There is no specific antidote for taxine poisoning; however, atropine or lidocaine have been suggested to be beneficial in alleviating the cardiotoxicity (Kingsbury, 1964; Schulte, 1975). In experimental animal studies (Bryan-Brown, 1932; Vohora, 1972) and in human cases in which the cardiac responses to attempted treatment were closely monitored via electrocardiography, classic antiarrhythmic therapy proved ineffective

(Willaert *et al.*, 2002). Extreme extracorporeal life-support measures, in combination with antiarrhythmic therapy, were warranted for complete recovery in one case of yew intoxication (Panzeri *et al.*, 2010).

## CONCLUSIONS

Although advances in analytical toxicology are progressively improving detection of taxine alkaloids and other markers for diagnosis of yew poisoning, toxicoses in animals and humans still occur frequently and are usually fatal. The potent cardiotoxic effects of taxine alkaloids in the yew plant, combined with the absence of an efficacious treatment for poisoning cases, reemphasizes the need to prevent or limit exposure of animals and livestock to these toxic plants.

Fred Reyers and Theuns W. Naudé

### INTRODUCTION

The clinical expression of oxalate poisoning is dependent on a number of factors. These interact with each other to produce a broad spectrum of clinical presentations. Oxalates play significant roles in plant metabolism and survival. Consequently, a large variety of plants contain soluble and/or insoluble forms of oxalates (Table 83.1) that may be present at different levels in different plant parts. Because oxalic acid is a strong organic dicarboxylic acid, it may be present as the acid, the acid ion (hydroxy acid ionic form), the oxalate ion (all soluble), or as a salt with a divalent cation such as calcium (Figure 83.1). Plant oxalates are present as a combination of more than one of these forms, usually with a substantial proportion of insoluble calcium oxalate crystals. The risk of poisoning by plant oxalates is largely determined by the concentration, chemical form (pH dependent), as well as the feeding behavior and gastrointestinal morphology of the exposed animal, all of which contribute to the rate and form of oxalate absorption. In monogastric animals, the ingested oxalate experiences a highly acidic environment early on, whereas in ruminants it is in a mildly acidic, almost neutral, microorganism-rich fermentation tank. In hindgut fermenters (e.g., the horse), this stage occurs after passage through the acidic gastric environment.

### OXALATE CHEMISTRY

In nature, oxalates exist almost exclusively in plant material, involving a large number of species, leading

Franceschi and Nakata (2005) to suggest the possibility that it is found in all plants. These authors published an excellent review, from which much of the information in this section is gleaned, and the reader wanting more detail is urged to obtain a copy. Oxalate is formed endogenously (in plants) through the degradation of ribulose-1,5-biphosphate (from photosynthesis) to phosphoglycine and then glycolate and its oxidation by glycolate oxidase to glyoxylate, which can be used in glycine or oxalate synthesis. A pathway from L-ascorbic acid to oxalate also exists (although not fully explicated) and appears to be a major source of oxalate in many plants (Libert and Franceschi, 1987). Because oxalic acid is a strong organic dicarboxylic acid (Figure 83.1) with two dissociation constants ( $pK_{a1}$  at 1.46 and  $pK_{a2}$  at 4.40), it can exist in several ionic forms depending on the pH of the medium (e.g., cell-sap or intestinal environment) in which it is present:

- At a pH greater than 6, it exists principally as the soluble oxalate ion (as in *Halogeton* and *Mesembryanthemum*) and, if absorbed, is able to complex with divalent cations such as plasma calcium and magnesium to sequester them as highly insoluble salts.
- At a pH between 3 and 6, oxalate exists principally as the hydrogen oxalate anion (acid oxalate ion) and forms soluble salts with sodium and ammonium in several plant species, such as grasses.
- At a pH less than 3, most of the oxalate is present in the soluble oxalic acid form, as is found in *Oxalis* and *Rumex*.

In plant cells, the insoluble calcium oxalate tends to be in the form of the monohydrate (whewellite) in most

TABLE 83.1 Plants rich in oxalates<sup>a</sup>

Family	Genus/species	Common names
Agavaceae	<i>Agave americana</i>	Tequila agave*
Aizoaceae	<i>Mesembryanthemum nodiflorum</i>	Slender ice plant
Amaranthaceae, including former Chenopodiaceae	<i>Amaranthus retroflexus</i>	Pigweed
	<i>Beta vulgaris</i>	Beetroot, mangold, sugar beet
	<i>Bassia hyssopifolia</i>	Smotherweed
	<i>Chenopodium quinoa</i>	Bitter quinoa
	<i>Chenopodium album</i>	White goosefoot
	<i>Spinacia oleracea</i>	Spinach
	<i>Halogeton glomerulatus</i>	Saltlover
	<i>Sarcobatus vermiculatus</i>	Greasewood
Araceae	<i>Dieffenbachia pictus</i>	Dumb cane*
	<i>Philodendron scandens</i>	Heartleaf*
	<i>Philodendron panduriforme</i>	Fiddle leaf*
	<i>Pinella ternata</i>	Cow dipper*
	<i>Pinella pedatisecta</i>	Green dragon*
	<i>Arisaema amurense</i>	Jack-in-the-pulpit*
	<i>Typhonium giganteum</i>	Chinese Jack-in-the-pulpit*
Cactaceae	<i>Opuntia echios</i>	Prickly pear
Euphorbiaceae	<i>Tragia ramosa</i>	Noseburn*
	<i>Tragia urticifolia</i>	Nettleleaf*
Fabaceae	<i>Glycine max</i>	Soy
Oxalidaceaea	<i>Oxalis acetosella</i>	Wood sorrel
Polygonaceae	<i>Rumex acetosa</i>	Sorrel, spinach dock
	<i>Rheum rabaarbarum</i>	Rhubarb
Poaceae	<i>Brachiaria brizanthas</i>	Beardgrass
	<i>Cenchrus ciliaris</i>	Blue buffelgrass
	<i>Cenchrus letigerus</i>	Birdwood grass
	<i>Digitaria decumbence</i>	Pangolagrass
	<i>Panicum antidotale</i>	Blue panic grass
	<i>Pennisetum clandestinum</i>	Kikuyu grass
	<i>Pennisetum purpurea</i>	Napier grass
	<i>Setaria anceps/sphacelata</i>	Golden bristlegrass
Fungi	<i>Aspergillus niger</i>	
	<i>Penicillium</i>	
	<i>Botrytis</i>	
	<i>Rhizopus</i>	
	<i>Pithomyces</i>	
	<i>Mucor</i>	

<sup>a</sup>Most have been reported to have caused poisoning.

\*Plants in which crystal raphides are a significant feature.

FIGURE 83.1 Oxalic acid and its salts.

cases and calcium oxalate dihydrate (weddellite) in some cases. These can be present in a number of morphological crystalline forms, the formation of which appears to be under tight genetic control. The following are the most common forms:

- Block-like rhombohedral/prismatic crystals that may be present as single or multiple crystals in each cell, often in the cell walls
- Masses of small angular crystals (crystal sand)
- Multifaceted, conglomerate crystal “druses”
- Large, elongate, rectangular crystals that can be present in bunches of needle-shaped (acicular) or single, long styloids in special intracellular structures called idioblasts. These forms are referred to as

“raphides,” some of which even have grooves and barbs. The size of these raphides can vary tremendously from microscopic to several millimeters long. They are packed together lengthwise in a gelatinous mass, and if the plant is damaged, the operculum of the idioblast is dislodged, sap of the plant or saliva causes the gelatinous mass to swell, and the needles are expelled under the pressure (Frohne and Pfänder, 1983; Cheeke, 1998). Burrows and Tyrl (2001) reported that in *Tragia* spp. (noseburns) of the Euphorbiaceae, the stinging hair of this unobtrusive creeper contains a calcium oxalate raphide up to 4 mm long that on contact penetrates the skin, allowing the highly irritant proteinaceous cell contents to enter the small wound, causing a transient pruritis.

It is believed that the presence of oxalic acid, particularly insoluble calcium oxalate, fulfills a number of functions, some of which (e.g., plant protection against herbivory by raphides and resisting parasitism (Weir *et al.*, 2006) as well as structural functions) may have been later evolutionary adaptations to the basic functions such as calcium regulation to control the very large range of calcium concentration fluxes that plants can experience as a result of poor root zone entry restriction to calcium and detoxification of potentially toxic metals such as the ubiquitous aluminum.

Plant oxalate occurs in a soluble form (oxalic acid, acid oxalate, or oxalate) and/or insoluble calcium oxalate (solubility only 6 mg/L or 6 ppm) at neutral pH. It is the soluble forms that pose the immediate threat for toxicosis. It has to be borne in mind, based on the dissociation constants, that the highly insoluble calcium oxalate (at neutral pH) becomes reasonably soluble when exposed to typical gastric content pH (<2) in monogastric animals. However, plant oxalates are seldom present as either soluble or insoluble but, rather, in varying proportions of each. For instance, grain amaranth (Gélinas and Seguin, 2007), 0.46 g/kg soluble oxalate, represents 20% of the total oxalates (i.e., 80% (1.83 g/kg) is present as insoluble crystal oxalates); taro (Savage and Dubois, 2006), 2.36 g/kg soluble oxalate, represents 58% of the total oxalates; and spinach (Brogren and Savage, 2003), 7.37 g/kg soluble oxalate, represents 77% of the total oxalates. By contrast, *Halogeton*, the cause of most reported outbreaks of oxalate toxicosis in sheep, contains only 17% soluble oxalates, but the total oxalate level is considerably higher than those of the plants mentioned previously – up to 60 g/kg (James and Butcher, 1972). Furthermore, the concentration in different parts of the plant may differ widely. For instance, kikuyu grass leaf has 15 g/kg soluble oxalate, which represents 63% of total oxalates, and stem has 7 g/kg soluble oxalate, which represents 73% of total oxalates (Marais *et al.*, 1997).

Cooked rhubarb stems owe their pleasant, acrid taste to the oxalic acid content. During World War I, a shortage of greens in Britain led to rhubarb leaves (in which the concentration of soluble oxalates is much higher than in the stems) being widely advocated as a substitute for spinach and other greens until several deaths due to renal damage were attributed to it (Ellenhorn and Barceloux, 1988).

Plants in which crystal raphides are a significant feature are indicated by asterisks in Table 83.1. They are widely grown for either their flowers or their particularly attractive foliage. They are also cultivated for the starch-rich tuberous rhizomes or as green vegetables (e.g., *Colocasia esculenta* (cocojam or taro) and *Xanthosoma* (new cocojam or okumo)). Plants intended for eating are usually cooked or baked beforehand to render them non-irritant (Purseglove, 1972).

In addition to plants, a variety of saprophytic fungi may produce oxalates and render hay toxic even without any obvious moldy appearance (Wilson and Wilson, 1961; Cheeke, 1995; Botha *et al.*, 2009).

## EATING BEHAVIOR AND GASTROINTESTINAL ANATOMY

### Monogastric carnivores

Toxicokinetic studies, in any detail, have only been published for humans. Data from these studies are probably valid as a model for other monogastric species. Studies have shown that the bioavailability from grilled spinach is  $0.75 \pm 0.48\%$  and for *Oxalis tuberosa* it is  $1.44 \pm 1.31\%$  after the first 6 h of ingestion (Albihn and Savage, 2001; Brogren and Savage, 2003). Furthermore, oxalate is absorbed by the gastric mucosa. The acidic environment favors the absorption of oxalic acid (Zhiqiang *et al.*, 2003). Monogastric carnivores have relatively tender buccal, lingual, and oropharyngeal epithelium, and they tend to chew their food. Once swallowed, the food passes into the low-pH gastric environment.

Cats are “pure carnivores” and under natural conditions will eat meat and some of the soft tissue organs of the prey species. They are “finicky” eaters with a significant olfactory component to food preference selection. Eating plants or prey gastrointestinal content is unusual and, consequently, these animals would not be expected to exhibit signs of oxalate toxicosis. It is therefore surprising that oxalate-related pathology is not uncommon. Occasionally, cats do indulge in eating plants, and they certainly do not “know” how to avoid those plants that could be toxic because there are reported incidents of lily poisoning (Langston, 2002), daffodil poisoning

(Saxon-Buri, 2004), golden dewdrop poisoning (Scanlan *et al.*, 2006), as well as *Dieffenbachia* (dumb cane) poisoning (Müller *et al.*, 1998). The latter is particularly pertinent to this discussion because this plant has a singular reputation of causing significant oropharyngeal pain in human exposure (Gardner, 1994). Thus, the contentions reported by Zaghini and Biagi (2005) that cats are such sensitive feeders that they are protected from consumption of toxic substances are open to question.

In contrast, dogs are not strict carnivores and do appear to consume a fair amount of plant material in nature (Silva and Talamoni, 2003; WenBo *et al.*, 2006). It is not clear whether this was linked to eating gastrointestinal content of their prey or simply "browsing." Even the coyote (*Canis latrans*) becomes decidedly "vegetarian" as needs arise (Hidalgo-Mihart *et al.*, 2001). Therefore, finding evidence of oxalate-induced pathology would not be totally unexpected. There are enough confirmed instances of poisoning due to plant toxins (Botha and Penrith, 2009) to expect the occasional accidental oxalate toxicosis, and this is indeed the case with *Dieffenbachia* (dumb cane) (Loretti *et al.*, 2003; Peterson *et al.*, 2009) as well as *Philodendron* (Hanna, 1986).

### Monogastric herbivores

The horse represents herbivorous animals that are both monogastric and hindgut fermenters. Horses are very finicky eaters and very unlikely to ingest anything irritant, although they are unable to select dietary ingredients to meet their nutritional needs (Lewis, 1995). Most cases of oxalate poisoning appear to develop a chronic calcium deficiency due to the trapping of calcium in the equine hindgut by oxalates. This leads to secondary nutritional hyperparathyroidism and is expressed as *Osteodystrophia fibrosa*.

In studies using guinea pigs, previously adapted to a diet high in oxalates (2%), as a model for hindgut fermenters, it has been shown that cecal bacteria could play a role in adaptation. This adaptation was negated by treating animals with gut active antibiotics and certain secondary bile salts associated with ileal diseases (Argenzio *et al.*, 1988). It is likely that if tolerance did develop, it would occur too low in the gastrointestinal tract to allow for sufficient protection from absorption.

### Ruminant herbivores

Among the three ruminant species that have been studied, cattle and sheep have been reported to develop major oxalate poisoning "outbreaks," with sheep apparently being much more commonly involved (James, 1972b). Of these three ruminant species, cattle are primarily grazers, browse eating only occasionally

when allowed the choice (Casasús *et al.*, 2009). Sheep browse less than goats (Gouri *et al.*, 2008). This implies that in terms of exposure to the Amaranthaceae/Chenopodiaceae in shrubland pastures, goats should be affected more often than sheep, which does not appear to be the case, possibly because sheep appear to actively seek diversity in their diet (Favreau *et al.*, 2010).

The lingual and oral mucosa of herbivores, especially ruminants, is highly keratinized (as a physical protection during grazing and browsing) and would likely prevent the peracute oropharyngeal reaction that is seen in dogs, cats, and humans when exposed to raphides (Gardner, 1994; Loretti *et al.*, 2003). In addition, plants that have been grazed or browsed are not chewed on first passage, entering the almost neutral rumen environment before regurgitation.

The belief that ruminants are able to distinguish toxic from nontoxic plants does not appear to be supported by evidence (Jackson *et al.*, 2010). Consequently, both sheep and cattle tend to develop severe outbreaks of toxicity when suddenly exposed to shrubs rich in soluble oxalates and especially when other, possibly preferred foods are in scarce supply. In these instances, it appears that the rumen "buffering" capacity for oxalates is exceeded and severe pathology results.

In the normal healthy rumen, some of the oxalic acid and soluble oxalates can combine with calcium and become insoluble, thereby reducing the chance of toxicity; the pH of approximately 5–7 in the rumen appears to favor the formation of calcium oxalate. This is in contrast to nonruminants with a gastric pH of 1–2 (Phillis, 1976). Ruminants have also developed an additional protective mechanism. If the rumen is adapted by gradual exposure to oxalic acid and oxalates, some microorganisms (e.g., *Oxalobacter formigenes*) which use oxalic acid as an energy source, producing carbon dioxide and formate, thrive. It is only when the microbes are unable to break down oxalic acid that toxicity results (Rekhis, 1994).

## CLINICAL TOXICOSIS CATEGORIES

Oxalates of plant origin have a very broad spectrum of toxic effects on animals and humans. Based roughly on the delay from the time of exposure to the occurrence of pathology, and accepting that there will be some degree of overlap from category to category, these effects include the following:

- 1 Peracute toxicosis, usually within minutes to hours of contact/ingestion
  - a Direct physical contact injury to the skin and oral (including tongue) and oropharyngeal mucosa by calcium oxalate crystals

It is believed that some of the cutaneous and oral/oropharyngeal pathology is caused by the additional entry of irritants, such as saponins, into the puncture wound caused by the raphide crystal (Gardner, 1994; Genillier-Foin and Avenel-Audran, 2007). If plant material containing raphides is chewed prior to being swallowed, masses of these raphides penetrate the mucous membrane of the mouth, causing alarming, severe (but usually transient) local irritation and clinical signs such as excessive salivation in people (Gardner, 1994; Chiou *et al.*, 1997; Salinas *et al.*, 2001) and even laryngospasm.

- b Direct chemical injury to the oral, oropharyngeal, and gastric/rumen mucosae
  - c Precipitation of poorly soluble oxalate crystals in the gastric and ruminal mucosal capillary blood vessels resulting in thrombosis and severe diphtheritic inflammation with invasion by opportunistic microorganisms. The vascular damage appears to precede the crystal deposition (Van Kampen and James, 1969).
- 2 Acute toxicosis, usually evident within 24 h
- a Sequestration of divalent plasma cations (Ca and Mg) leading to severe hypocalcemia and hypomagnesemia, causing muscular tetany/cramping and, in some instances, flaccid paralysis. Van Kampen and James (1969), in an experiment in which sheep were poisoned with a lethal dose of *Halogeton* (containing mainly the oxalate ion) and slaughtered sequentially every 2 h up to 8 h, suggested that Ca oxalate crystal deposition is secondary to vascular and renal cellular damage. They suggested that sequestration of intracellular Ca and Mg results in inactivation of vitally essential Ca- and Mg-dependent enzymes and consequent cell damage. This is further supported by Absan (1997), who stated that approximately half the Mg in the body is intracellular and that it is an essential cofactor in catalyzing approximately 300 enzymatic reactions, particularly those involving ATP production. In a review, James (1972b) noted that it is unlikely that hypocalcemia is the principal cause of death because the same degree of hypocalcemia due to EDTA infusion or dialysis does not result in mortality.
  - b Precipitation of poorly soluble calcium oxalate crystals in the renal tubules, causing acute nephrosis, tubular obstruction, and acute renal failure  
In humans, plasma oxalates are eliminated mainly by urinary excretion. Excretion is biphasic and peaks at 40 min and 3 h after the consumption of a warmed, commercially bought frozen spinach meal in normal healthy individuals. The initial peak, however, was absent in patients who had

undergone gastrotomy due to cancer. This again indicates the importance of the stomach in initial absorption (i.e., the first major peak). The second peak is related to delayed absorption from the intestines. When comparing oral bioavailability between the two groups, it was seen that the area under the curve was 50% greater in patients with a functional stomach. At the 3.5-h post-feeding period, these patients still had a greater extent of absorption, with a difference of 20%. The excretion of oxalates was determined to be  $0.0732 \pm 0.0294$  mg/min (Zhiqiang *et al.*, 2003).

The soluble oxalate is filtered out through the glomerulus but in the tubules binds to calcium to precipitate out as crystals on the damaged cells. Although the physical injury to the tubules may account for the nephrotoxicity, it is unlikely to be the only mechanism because the rapid transit time of 3 or 4 min in the tubules does not seem long enough for the crystals to grow to sufficient size to block tubules (Corley *et al.*, 2005; Jonassen *et al.*, 2005). James *et al.* (1971), however, noted that the original site where the crystals actually form is in the filtered fluid in the lumens of the tubules and not necessarily those associated with the oxalate-damaged cells. These crystals, however, may grow to such sizes that secondary mechanical damage is caused.

In tissue culture, it has been shown that certain chemical changes occur in the renal tubular cells once exposed to the oxalates. One of these is to produce phosphatidylserine, which would normally recruit macrophages to remove damaged cells. However, in cases of oxalate toxicity, the latter appears to promote the attachment of oxalates to the cell membrane. Other changes induced in the cell include the activation of phospholipase A<sub>2</sub>, which eventually leads to the release of bioactive lipids that alter mitochondrial function, activate caspases, and result in apoptosis (Kohjimoto *et al.*, 1999; Cao *et al.*, 2004; Jonassen *et al.*, 2005).

A third pathway may also be present because calcium oxalate induces lipid peroxidation in both renal cell cultures and rodents (Maroni *et al.*, 2005). It was concluded that the compromised cells undergo apoptosis or necrosis as a result and subsequently slough off to form the nidus over which further crystals may precipitate (Jonassen *et al.*, 2005).

- 3 Subchronic toxicosis, which develops in days to weeks, but it may take up to 3 months to develop formation of nephroliths and uroliths with associated tubular and, in some cases, urinary tract obstruction. This can lead to more chronic renal pathology, including secondary fibrosis and eventually chronic renal failure.

4 Chronic toxicosis, which may take more than 3 months or even years to develop. Nutrient deficiencies ascribed to oxalates have long been known in humans (von Unruh *et al.*, 2004). This arises from the ability of the oxalates to bind to various minerals, such as calcium, iron, and magnesium. By binding to these minerals, their bioavailability is decreased (Quinteros *et al.*, 2003). Based on this, oxalate is often classified as an “antinutrient” (Gélinas and Seguin, 2007) because it sequesters/reduces the bioavailability of important dietary constituents, leading to chronic mineral deficiencies such as nutritional secondary hyperparathyroidism in horses on certain pastures (Walthall and McKenzie, 1976). James *et al.* (1968) found that low levels of *Halogeton glomeratus* had a deleterious effect on nutrient balance in sheep. Oxalates can also decrease the absorption of calcium from other dietary sources such as milk. With long-term exposure to plant oxalates (e.g., various grasses; Table 83.1), horses will mobilize large amounts of calcium from the bony apatite, and this will eventually precipitate. In addition, although not always, or necessarily, involving oxalates of plant origin, the medical literature in general recognizes five “hyperoxalurias,” categorized as primary and secondary.

a Secondary hyperoxalurias

i Dietary hyperoxaluria – largely dealt with previously. However, “classical” peracute and acute poisoning does occur in humans and also displays some of the features discussed previously.

ii Digestive (absorptive) hyperoxaluria, which is seen in patients with various intestinal diseases and resections (especially small intestine) as well as in cystic fibrosis. In these cases, there is increased absorption of food oxalate due to a decrease in calcium chelation of the dietary oxalate and possibly an effect of bile acids on promoting oxalate absorption.

iii Idiopathic hyperoxaluria in patients dubbed “stone formers” who simply appear to absorb more oxalate without obvious reason. There is some support for a genetic underpinning cause and, possibly, this should be classified with the primary hyperoxalurias.

b Primary hyperoxalurias: In these inherited metabolic enzyme deficiency diseases, the source of the additional oxalate is usually not diet but, rather, glycine that has its origin in ammonia clearance and 4-hydroxyproline from connective tissue metabolism. In both of the primary hyperoxalurias discussed here, the “lesion” is in the inability to clear glyoxalate and glycolate into harmless glycolic acid with switching to the alternate pathway of oxalate formation. However, there is little doubt that loading such a patient with oxalate from food

would seriously aggravate the situation. In addition, it has been shown that loading idiopathic stone formers’ diets with 4-hydroxyproline aggravates the hyperoxaluria.

i Primary hyperoxaluria – type I due to a relative deficiency of alanine: glyoxalate amino transferase, a pyridoxine (vitamin B<sub>6</sub>) activated enzyme. There is experimental evidence in rodents that “pure” vitamin B<sub>6</sub> deficiency can precipitate a similar syndrome.

ii Primary hyperoxaluria – type II due to a relative deficiency of glycolate reductase-hydroxy pyruvate reductase.

In nonhuman animals, it is possible, although few cases have been thoroughly diagnostically explored, that the hyperoxaluric nephrosis in Beefmaster calves (Rhyan *et al.*, 1992), Tibetan spaniels (Jansen and Arnesen, 1990), and some cats, such as the Ragdoll and domestic short-hair (Blakemore *et al.*, 1988), represent animal equivalents of these inherited oxalate-related abnormalities in humans.

Furthermore, there is evidence that the occurrence of oxalate nephrosis in the cheetah (a pure carnivore) is related to ammonia, glycine, and hydroxyproline metabolic abnormalities (J. Mienie, personal communication).

## SPECIES-SPECIFIC TOXICITY

Based on the literature, there is little merit in supplying toxic doses. The oxalate level varies markedly between plant parts and between plants of the same species in different years and especially different cultivars (Massey, 2007).

### Sheep

Peracute toxicosis is rare, but it is occasionally seen in sheep kept in paddocks with no grazing and force-fed only, or mainly fed, raphide-rich garden prunings (Kellerman *et al.*, 2005).

In circumstances in which sheep have grazed *Halogeton* extensively, up to 1200 animals have been poisoned at a time (James, 1972a). In all cases of soluble oxalate toxicity, unadapted animals have to be abruptly exposed to large quantities of oxalate-containing plants. It is often a problem in low-rainfall areas where these are the dominant or only available plants. During feed shortage, the cut-up leaves of agave and cathodes of prickly pear (*Opuntia ficus indica*), particularly the thornless variety, are fed to stock and in excessive quantities may result in oxalate toxicosis.

According to [Shupe and James \(1967\)](#), *Halogeton* is highly toxic to sheep and produces an acute toxicosis in which animals die within 8–12h of exposure, rarely longer, and no chronic syndrome is seen. The clinical signs are dullness, lowered head, anorexia and ruminal stasis, blood-tinged frothing from the mouth, weakness, stiffness, polypnea, ataxia with jerky extensor rigidity, coma and death, with sheep lying dead where they had grazed. At necropsy, marked edema and hemorrhages are encountered in the rumen, which are caused by severe rumenitis with vascular damage. Oxalate crystals are found in the ruminal wall around the damaged vasculature. Kidneys are pale edematous and enlarged, and histopathology reveals hyalinization of the glomeruli and marked tubular dilation. Calcium oxalate crystals are encountered in the kidneys. Similarly, [Cheeke \(1998\)](#) holds that with oxalate ion poisoning (as in *Halogeton* intoxication), only acute toxicity is seen, but with acid oxalate, both acute and chronic toxicity may occur. According to [Burrows and Tyrl \(2001\)](#), the Chenopodiaceae contain both the oxalate and the acid oxalate ions as toxic principles, and they note that there are subtle differences in the syndromes caused by *H. glomeratus* and other soluble oxalate-containing plants. They maintain that *Halogeton* mainly affects sheep and, to a lesser extent, cattle. [Littledike et al. \(1976\)](#) described similar findings in acute *Halogeton* poisoning of sheep and also described the renal pathology. The kidneys were pale, swollen, and moist. On histopathology, the predominant lesion was nephrosis characterized by the widespread dilation of the convoluted and collecting tubules in the cortex. Although necrosis of the tubular epithelium is rarely seen, the tubular epithelium is generally flat and appears degenerate, particularly where the crystals impact the tubular walls. Birefringent crystals are also observed in the mucosa of the abomasums ([Panciera et al., 1990](#)).

In the case of *Mesembryanthemum nodiflorum* of Western Australia, the pH of the plant sap is 6, and the active ion is thus oxalate. The same acute syndrome as with *Halogeton* is experienced. *Oxalis* and *Rumex* intoxication are reported to cause death due to hypocalcemia. According to [Panciera et al. \(1990\)](#), acute exposure of sheep to *Rumex crispus* may cause sudden death, or animals may show severe clinical signs such as depression, salivation, coarse head tremors and stilted, ataxic gait, and recumbency due to calcium deficiency. When excited, some animals become severely ataxic, fall, and struggle to rise. Sheep affected by the subchronic form of the disease develop azotemia and hypocalcemia.

In experimental *Halogeton* poisoning, [Van Kampen and James \(1969\)](#) noted that the deposition of crystals appeared to be secondary to cellular damage and not vice versa. Some sheep died peracutely with

insignificant morphologic kidney lesions, and even in sheep with severe kidney damage, death occurred too rapidly to be attributed to renal dysfunction. Sheep with a bilateral nephrectomy live longer than those with acute oxalate intoxication. These authors maintained that in *Halogeton* poisoning, the serum calcium is within the range in which tetany should occur but it does not. Signs preceding death are in fact extreme weakness and flaccidity of all skeletal muscles.

A slightly different syndrome was reported by [James \(1972a,b\)](#) with *Bassia actinophylla* of the Chenopodiaceae, in which on an oxalate basis, the lethal dose for sheep is approximately one-half that of *Halogeton*. The signs resembled those of *Halogeton*, but there was a greater tendency to develop tetany and incoordination, and less than half the lethal amount fed per day resulted in a cumulative effect and mortality. Compared to *Halogeton*, this plant was higher in potassium and lower in sodium, suggesting that the difference was due to the cations. *Setaria sphacelata*, with an acidic sap, is believed to contain ammonium oxalate ([James et al., 1971](#)). In Australia, it causes the typical acute syndrome in sheep due to the oxalate ion ([James et al., 1971](#)).

The effect of acutely toxic doses of the different cations of oxalate fed daily by rumen fistula to unadapted sheep was reported by [James \(1972a,b\)](#). In a preliminary trial prior to testing the adaptation of sheep to *Halogeton*, he found that sodium oxalate at approximately 25–45g oxalic acid equivalent on the first day and 40–74g on the last day killed three sheep 3–6 days after they had been off feed all the time. Diarrhea and severe edema and hyperemia of the rumen wall were evident. Two sheep dosed with potassium oxalate at approximately 25 and 42g on the first day and 56 and 67g oxalic acid equivalent on the last day took 6 days to die, and they were only slightly off feed for the last 3 days. There was less diarrhea, and the effect on the rumen wall was less severe. In contrast, magnesium oxalate at 70.6g oxalic acid equivalent, dosed to one sheep for 1 day, caused only diarrhea.

Chronic toxicity has also been reported to occur in sheep. Animals demonstrated clinical signs over 2–12 months, with the principal signs being anemia and loss of condition and appetite. On autopsy, the kidneys were half the normal size and weight, and they were pale and mottled. In animals that were anemic, the hearts were enlarged ([McIntosh, 1972](#)).

In South Africa, mesems of the Aizoaceae are widely distributed in the western, semidesert areas, and although they are known to contain toxic quantities of oxalates ([Steyn, 1934](#)), they are so widely utilized that stock (especially sheep and goats) consume them in small quantities as part of their daily diet and frank toxicity, as in Western Australia, is not seen.

## Cattle

Burrows and Tyrl (2001) reported that the clinical signs in cattle are similar to those in sheep but less acute. Signs include incoordination, apprehension, belligerence, excess salivation, recumbency, coma, bloat, cyanosis, and death. Many of the clinical signs are associated with hypocalcemia (serum calcium as low as 1.4 mg/dL (0.35 mmol/L)), during which time blood magnesium and phosphorus may double. Subacute locomotor disturbances are mainly evident when animals are forced to move, and this begins with the forelimbs. In calves, however, more severe signs of hypersensitivity to stimulation and seizures are possible.

Lincoln and Black (1980) reported acute *H. glomeratus* poisoning in 16 of 680 range cattle during and following a trail drive. Signs of toxicosis included ataxia, recumbency, coma, and death. Histopathology revealed abundant, refractile calcium oxalate crystals in renal tubules. They suggested that although the plant is generally unpalatable for cattle, the toxicosis was precipitated by a preceding period of food deprivation. In cattle, oxalate toxicity induces catarrhal abomasitis, enteritis, pale edematous kidneys, and congested lungs (Dickie *et al.*, 1978). According to Walthall and McKenzie (1976), affected cattle on oxalate-containing pasture grasses (probably ammonium oxalate), much like sheep, tend to show signs of depression, anorexia, and diarrhea. On autopsy, the kidneys are pale and firm. On cut surface, the renal medulla is thin, and the calyces are dilated (confirmed histopathologically). Cortical and medullary tubules are distended with crystalline casts. The crystals displayed typical birefringence under polarized light and were specifically identified with Pizzolato's technique (peroxide-silver staining). In one incident, reported by Kellerman *et al.* (2005), 4 of 40 nursing beef cows developed acute flaccid paralysis 24 h after introduction to a harvested wheat land heavily infested with *Chenopodium album* (white goosefoot). The paralysis was so marked that the investigating veterinarian suspected botulism. The plants contained 16% oxalate (total) on dry matter basis.

Gopal *et al.* (1978) suggested that oxalates may also play a role in abortions and possibly teratogenicity. However, in their sequential sacrificing experiments (*vide supra*), Shupe and James (1967) found no crystalline deposits in the tissues of fetuses of ewes that had been pregnant during exposure to *Halogeton*.

Why ruminants do not "classically" develop chronic hypocalcemia and secondary nutritional hyperparathyroidism, as horses do, is not immediately obvious. Marias *et al.* (1997) estimate that at least 95% of the calcium in kikuyu grass is bound to oxalate and would be poorly available to ruminants. It is possible that when this "sequestered" calcium passes through the

abomasum, a sufficient amount is solubilized to cope with the dietary needs – calcium oxalate being three times more soluble (although still relatively insoluble) at gastric pH than at neutral pH.

## Horses

Both acute and chronic toxicity can occur in horses. However, chronic toxicosis is by far the more common naturally occurring form and is usually due to grazing pasture that is relatively high in oxalates, especially *Setaria* spp. (Jones and Ford, 1972).

Chronic poisoning following 2–8 months of exposure to oxalate-containing grasses resulted in nutritional secondary hyperparathyroidism, causing *Osteodystrophia fibrosa*. Clinical signs observed in these animals were lameness, ill thrift (harsh coats and loss of condition), and, in some animals, swelling of the osseous structure of the head. Mildly affected horses showed a decreased ability to work, whereas the more severely affected animals became cachectic and even died. The swelling to the head was bilateral and involved the nasal bones or the maxillae. Histopathologically, a decrease in osseous tissue could be confirmed. Fibrous tissue surrounded small fragments of old bone in which sites of osteoclastic activity were detected (Walthall and McKenzie, 1976). Although, in general, *Panicum* spp. grasses have considerably lower oxalate content than *Setaria* and *Cenchrus*, there may be local conditions leading to sufficiently high oxalate levels in this species to cause equine *Osteodystrophia fibrosa* (Curcio *et al.*, 2010).

For experimental acute toxicity to occur, animals need to be exposed to a very high dose of 454 g of sodium, potassium, or ammonium oxalate. This toxicity is characterized by hypocalcemia and will result in muscle rigidity and a stiff gait (Laan *et al.*, 2000). It is interesting, however, that there are no described instances of horses being poisoned by accidental ingestion of high-oxalate plants. Certain grasses can develop high enough oxalate levels to inflict acute toxicity in horses, with the attendant hypocalcemia and oxalate nephrosis. Nonfatal toxicity occurs when animals are exposed to 200 g of oxalic acid/day for 8 days (Andrews, 1971). In foals, exposure to *Rumex* spp. resulted in signs of hypocalcemia (Laan *et al.*, 2000).

Renal failure, as a subchronic and chronic presentation, has also been reported. The clinical signs are anorexia and gradual weight loss. Although the kidney appeared normal, on histopathology the renal cortex contained dilated tubules lined with flattened or degenerated epithelial cells. Tubular structures were displaced by fibrous tissue, whereas the glomeruli had undergone various degrees of degeneration. Crystals were present in the tubules, particularly the proximal convoluted

tubule, and were yellowish brown and aggregated into rosettes having radial symmetry. The crystals were anisotropic under polarized light (Andrews, 1971).

### Other hindgut fermenters

A 12-month-old black rhinoceros calf (*Diceros bicornis*) was reported by Wood *et al.* (1997) to have chewed half a leaf of an ornamental *Xanthosoma mafaffa* (elephant's ear or new cocoyam). The calf promptly spat it out, accompanied by severe salivation, flicking her tongue, and rubbing her mouth in mud for an extended period. She tried to browse after a while but spat out the food. These signs lasted for 3 or 4 h, and then she made an uneventful recovery.

Pigs have a strongly acidic gastric pH (like horses), but only one incident of oxalate poisoning is on record, following the consumption of beet. However, there is uncertainty because beet also contains nitrates and a "brown discoloration of the blood" was reported (Rupprecht, 1932). One would expect more reports of intoxication in this exceptionally widely farmed commodity and species (especially where they are farmed free-range) if oxalosis was indeed a problem in swine. Baxter (1956) described fodder beet poisoning in pigs on the basis that Gregor reported finding oxalic acid in toxic amounts in sugar beet tops (Gregor, 1953), but the signs were not typical. Beasley (1999) stated that convulsions may also occur in oxalate toxicosis in pigs.

### Dogs and cats

The predominant form of acute oxalate-associated pathology in dogs is due to consumption of ethylene glycol (antifreeze), discussed elsewhere in this book (Chapter 60). However, accidental ingestion of some high-oxalate plant material (*Dieffenbachia* and *Philodendron*) has been described, and the clinical presentation is typically of the peracute type with severe erosive/ulcerative glossitis, stomatitis, and oropharyngeal edema leading to dyspnea and airway obstruction in dogs (Loretto *et al.*, 2003; Peterson *et al.*, 2009) and extensive gastric ulceration and hematemesis in cats (Müller *et al.*, 1998).

#### *A growing problem: canine and feline oxalate urolithiasis. Is it chronic oxalate toxicosis?*

Despite the occasional reports of canine and feline dietary "indiscretion" leading to peracute and acute toxicoses, it would be reasonable to assume that the carnivores, in general, would have a very low intake of oxalates (assuming that dietary oxalate is invariably of plant origin). Consequently, oxalate urolithiasis

(the subchronic form of oxalate poisoning) should be of minor significance. However, based on reviews of a number of substantial uroliths databases of the University of Minnesota (451,891 stones, 1981–2007) (Osborne *et al.*, 2009), University of California at Davis (25,499 stones, 1985–2006) (Low *et al.*, 2010), and the University of Guelph (>50,000 stones, 1998–2008), we have been made aware of a significant and growing problem of feline and canine oxalate urolithiasis. In dogs, oxalate urolithiasis has increased from 5% of all stones examined in 1981 to 50% in 2008. In cats, the 1981 starting point was 2% and it peaked at 55% in 2002, declining to just under 50% in 2008. By contrast, cattle (1.8%) and sheep (0.9%), the known consumers of plant oxalates, appear to have a very low oxalate uroliths incidence (similar to the 1981 cat and dog prevalence) (Osborne *et al.*, 2009).

Two substantial epidemiologic studies evaluating dietary factors/contributions were conducted on cats (Lekcharoensuk *et al.*, 2001) and dogs (Lekcharoensuk *et al.*, 2000). Although these studies clearly identified a number of diet-related factors, it seems counterintuitive that the source of the oxalate was not considered an issue. In the pet food industry, corn gluten meal has been a commonly used protein source in combination with soy products (de Godoy *et al.*, 2009). Bran has a relatively high oxalate content, and soy has a high oxalate content (Massey *et al.*, 2001). From the medical literature, it appears that human "stone formers" are advised to adjust their diets to reduce oxalate intake (Grentz and Massey, 2002).

This topic was reviewed by Dijkster *et al.* (2011). It appears that in dogs, the little evidence that exists regarding the contribution of dietary oxalate to oxalate urolithiasis points to a complex, inconsistent interaction between food oxalate and calcium, with a high food calcium:oxalate ratio being protective. In cats, however, there are no such studies, and the authors suggest that the situation may be similar to that in dogs. In addition, the authors propose that in cats, endogenous production of oxalate from glyoxylate (from carbohydrate/amino acid metabolism) may play an important role but emphasize that the relative contribution of dietary oxalate is unknown.

### Poultry

Commercially produced chickens are unlikely to be exposed to oxalate poisoning. However, in an investigation of the contribution of a mixture of miserotoxin, nitrates, and oxalate involved in a particular syndrome, Williams and Olsen (1992) established the LD<sub>50</sub> of sodium oxalate for 1-week-old chicks to be 984 mg/kg.

## TREATMENT

Animals suffering from hypocalcemia have been treated with intravenous calcium (Laan *et al.*, 2000; Kellerman *et al.*, 2005). Following the development of acute clinical signs, oral dosing with lime water/milk or calcium lactate followed later by an emetic (in appropriate species) may be helpful. The rationale is to bind the unabsorbed oxalates to calcium in the gastrointestinal tract and remove it from the system. Activated charcoal may also be used. In animals already convulsing, the use of emetics (where applicable) is not recommended. In these animals, the plasma calcium levels should be monitored and treatment with calcium instituted. Calcium borogluconate is the standard treatment for most oxalate plant intoxications (Kellerman *et al.*, 2005), but in *Halogeton* poisoning in sheep, it may delay death but not necessarily result in survival. Van Kampen and James (1969) postulated that intracellular inactivation of Ca- and Mg-dependent enzyme systems may be significant in causing death.

## PROPHYLAXIS/ADAPTATION

In ruminants, dicalcium phosphate has been recommended to reduce the likelihood of *Halogeton* toxicity when mixed into the ration at a ratio of 1:3 with salt. Alternatively, 5% dicalcium phosphate-containing alfalfa pellets have been fed at a rate of 100 g to 2 kg (3–5 lb) per sheep per day (Beasley, 1999). The purpose of this is to have all the soluble oxalates precipitated in the rumen.

It has been shown that rumen microorganisms such as *O. formigenes* can metabolize oxalates. However, their numbers in the rumen appear to be dependent on the period of exposure. A study in goats indicated that artificial exposure of ruminants to oxalates can create adequate microorganism adaptation to allow an animal to cope on high oxalate-containing plants. The same may be achieved by gradually exposing animals artificially to the plants that contain oxalates (Frutos *et al.*, 1998). With *Halogeton*, James (1972a,b) experimentally determined that sheep were 5–10 times more resistant after 8–25 days of feeding, and they advised an adaptation period of 10 days prior to known field exposure that would increase the lethal dose by approximately 30%.

## CONCLUSIONS

The toxicity of oxalate-containing plants is difficult to assess and predict on the basis of the oxalate

concentration in the plant material alone. A number of additional factors interact and play a significant role in the eventual expression of a broad spectrum of clinical presentations. These are the pH of the plant material and the ionic form of the oxalate (which largely determine the solubility and availability), the feeding habits of the exposed animals, the availability of alternate/additional food sources, the total dose consumed, gastrointestinal conformation/anatomy (monogastric, ruminant, and hindgut fermenter), dietary divalent cation content, and endogenous production of oxalate from carbohydrate and amino acid metabolism. There is a paucity of published data on the role of these factors and their interactions in the various animal species. Thus, there is an urgent need for well-designed investigations to facilitate evidence-based diagnostic approaches to cases of suspected poisoning and provide safe food for domesticated animals as well as wild animals in captivity.

## ACKNOWLEDGMENTS

We thank the following individuals and organizations because the completion of this chapter is greatly attributed to them: Faan Naude, Merensky Branch, and Antoinette Lourens of the Onderstepoort Branch of the University of Pretoria (UP) Libraries for outstanding services; Dr. Moira Bode, CSIR, South Africa; Prof. Z. Apostolides, Department of Wild Life and Agricultural Sciences, UP; and colleagues of various departments at the Faculty of Veterinary Science, UP, particularly those of the Department of Paraclinical Sciences, where TWN spent much time.

# Mushroom toxins

Birgit Puschner

## INTRODUCTION

Management of mushroom poisonings of humans and animals can demand extensive effort from clinicians and toxicologists and often involves emotion and publicity. The public expects the toxicology profession to provide guidance and a coherent approach regarding these cases. Although it is estimated that very few species are lethal, it is not clear how many of the mushrooms worldwide contain potentially toxic compounds. New species are being discovered continuously, and for many species, toxicity data are unavailable. It is very difficult to establish a confirmed diagnosis of mushroom poisoning in animals; thus, clinical reports of mushroom poisoning are uncommon. In fact, because animals are at much greater risk of exposure to toxic mushrooms than are humans, mushroom poisonings in animals are most likely underreported.

## BACKGROUND

The reported frequency of mushroom poisonings in veterinary medicine is low because routine diagnostic methods to confirm exposure are lacking. Most cases are diagnosed by positive identification of the suspect mushroom along with the occurrence of consistent clinical signs and clinicopathological changes. Animals are often left unattended, and a history of mushroom ingestion is not available. An estimated 200–300 calls related to mushroom ingestions have been registered by U.S. animal poison control centers each year. California accounts for more than 10% of these cases, the highest

among all states. California also leads the United States in the number of reported cases of mushroom ingestions in humans; 894 cases were reported in 2008. Many factors influence the toxicity of mushroom toxins, such as genus and species of mushroom, geographic location where the mushroom is grown, preparation of mushroom prior to ingestion, and the individual's susceptibility. Although not inclusive of all mushroom toxins, this chapter is organized by the various types of toxins, providing detailed information on their toxic mechanisms, toxicokinetics, and diagnostic and therapeutic approaches, with a focus on veterinary medicine.

## HEPATOTOXIC CYCLOPEPTIDES

Worldwide, most fatalities are caused by exposure to cyclopeptides. Three genera – *Amanita*, *Galerina*, and *Lepiota* (Lincoff and Mitchel, 1977a) – are known to contain hepatotoxic cyclopeptides, with *Amanita phalloides*, the ubiquitous death cap or death angel, and *Galerina sulphurescens* being considered the most toxic worldwide. *Amanita phalloides* (Figure 84.1) is found throughout North America, commonly in association with oaks, birch, and pine, and it is the species most frequently resulting in fatalities in humans (Mitchel, 1980; Barbato, 1993) and probably dogs. It can also be found in open pastures. *Amanita phalloides* is particularly common in the San Francisco Bay area, the Pacific Northwest, and the northeast, and it is most abundant in warm, wet years. The large fruiting bodies appear in the late summer and fall, and they have several characteristics: a smooth, yellowish-green to yellowish-brown cap; white gills; a

FIGURE 84.1 *Amanita phalloides* (courtesy of Dr. R. Michael Davis, University of California at Davis).

FIGURE 84.2 *Amanita ocreata* (courtesy of Dr. R. Michael Davis, University of California at Davis).

white ring around the upper part of the stem (veil); and a white cuplike structure (volva) around the base of the stem. *Amanita ocreata* (Figure 84.2) is commonly known as western North American destroying angel and grows from Baja California, Mexico, along the Pacific Coast to Washington. *Amanita ocreata* is most commonly found in sandy soils under oak or pine and has caused fatalities in dogs (B. Puschner, unpublished data). The fruiting bodies are usually found in late winter and spring. *Amanita ocreata* has a white or cream-colored cap; white, short gills; a white stem with a white, thin, broken, partial veil (annulus); and a white, thin volva. *Amanita bisporigera*, *Galerina autumnalis*, and *Lepiota josserandii* have also been attributed to animal and human deaths in North America (Beug, 2009). In eastern Europe, *Galerina sulphurea* is considered the species most commonly associated with human fatalities, followed by *A. phalloides* (Klan, 1993). There are three groups of cyclopeptides – the amatoxins, phallotoxins, and virotoxins. Amatoxins are bicyclic octapeptides and include the amanitins ( $\alpha$ -,  $\beta$ -,  $\gamma$ -, and  $\epsilon$ -amanitins), amanin, amanullin, and proamanullin (Vetter, 1998). Severe poisonings and lethality are mainly attributable to the amanitins. The bicyclic heptapeptides phallotoxins were once thought to be the cause of gastrointestinal clinical signs; however, they are no longer believed to exert any acute toxicity. Although research is limited, bicyclic heptapeptides virotoxins are not considered to have toxic effects after oral exposure. Therefore, phallotoxins and virotoxins are not discussed further.

### Pharmacokinetics/toxicokinetics

Exact data on the bioavailability for amanitins are lacking, although there are known species differences

(Faulstich and Fauser, 1980). The bioavailability of amanitins appears to be much greater in humans than in rodents, dogs, and rabbits. Within animal species, the absorption rate of amanitins is estimated to be much greater in dogs than in mice and rabbits, and rats appear resistant to the toxic effects of amanitins.  $\alpha$ -Amanitin is taken up by cells in the gastrointestinal tract, where the first damaging effects are seen (Gundala et al., 2004). Following systemic absorption,  $\alpha$ -amanitin is taken up by hepatocytes via OATP1B3, an organic anion-transporting polypeptide (Letschert et al., 2006). The  $\alpha$ -amanitin has a low volume of distribution. Renal clearance is high and similar to the creatinine clearance (Faulstich et al., 1985). Following intravenous (i.v.) administration in dogs, it was shown that plasma half-life of amanitins is short, ranging from 25 to 50 min, and that amanitins are not detectable in plasma after 4–6 h. There is no known metabolism or plasma protein binding of the  $\alpha$ -amanitin. Between 80 and 90% of the administered dose of amanitins is eliminated in urine, and up to 7% is eliminated in bile (Faulstich et al., 1985). After oral ingestion of *A. phalloides* in humans,  $\alpha$ - and  $\beta$ -amanitins were detected in plasma up to 36 h after ingestion and in urine up to 72 h post-exposure (Jaeger et al., 1993). This may partly be due to slow intestinal absorption, enterohepatic circulation, and reduced renal elimination resulting from nephrotoxicity. Plasma and urine amanitin concentrations do not seem to correlate with the clinical severity or outcome.

Amanitins can be detected in serum and urine well before any clinical sign of poisoning, whereas routine laboratory tests such as complete blood count and serum chemistry profiles are unremarkable until liver or kidney damage has occurred. Early recognition of exposure is critical because survival rates are greatly improved with

timely therapeutic intervention. Amanitin concentrations in kidneys and livers of people ingesting *A. phalloides* have been detected up to 22 days post-ingestion. The kidneys contain higher concentrations than the liver, indicating that toxins are bound to renal tissue.

## Mechanism of action

Amanitins are of greatest significance because, unlike phalloidins, they are heat stable and are not degraded by the acid environment of the stomach or by freezing (Himmelmann *et al.*, 2001). Therefore, amanitins are toxic by ingestion, whereas phalloidins have only been shown to be toxic when experimentally administered by parenteral routes. Amanitins exert their toxicity by inhibiting nuclear RNA polymerase II (Lindell *et al.*, 1970; Wieland, 1983). The decrease in mRNA and associated decrease in protein synthesis result in hepatocyte necrosis. Cells with a high metabolic rate, such as hepatocytes, crypt cells, and proximal convoluted tubules of the kidneys are most commonly affected. Although this mechanism is well established, research has confirmed additional cellular effects that contribute to pathogenesis. In mice and cultured dog hepatocytes, apoptosis contributed to amanitin-induced liver failure (Leist *et al.*, 1997; Magdalan *et al.*, 2010b), and in pancreatic rat islets  $\alpha$ -amanitin resulted in a dose-dependent insulin-releasing and a  $\beta$ -cytotoxic effect (De Carlo *et al.*, 2003). Acute tubular necrosis in the kidneys is believed to be a result of reabsorption of amanitins by renal tubules after glomerular filtration.

The clinical course is divided into four phases, with the initial phase being the latency period of approximately 6–12h. The second phase is characterized by severe gastrointestinal signs, such as nausea, vomiting, bloody diarrhea, and severe abdominal pain. In dogs, the onset of clinical signs is generally 6–24h after mushroom ingestion. Beagles experimentally given an oral sublethal dose of amanitins developed vomiting and diarrhea at 16h. Gastrointestinal signs improved after 60h (Vogel *et al.*, 1984). The gastroenteric phase is often followed by a lag period of several hours to a few days during which the human or animal will appear to have recovered. During this third phase, close monitoring of liver and kidney function is essential in order to prevent misdiagnosis. The final stage begins approximately 36–84h after exposure to amanitins. In this stage, fulminant hepatic failure with subsequent coagulation disorders, encephalopathy, and renal failure may occur. In dogs, significant elevations in serum of aspartate aminotransferase (AST), alanine aminotransferase (ALT), alkaline phosphatase, and bilirubin are commonly observed (Vogel *et al.*, 1984; Kallet *et al.*, 1988). In humans, a combination

of the prothrombin index along with serum creatinine concentrations determined between 3 and 10 days after ingestion was most useful as a predictor of death (Ganzert *et al.*, 2005). Although no controlled study exists in dogs, prothrombin (PT) and partial thromboplastin (PTT) may provide critical information for case assessment (Tegzes and Puschner, 2002). Clinical signs of renal failure include polyuria, polydipsia, vomiting, and anorexia. Severe hypoglycemia can occur in dogs after the gastrointestinal phase, and it is associated with the breakdown of liver glycogen (Puschner *et al.*, 2007). In a study in which dogs were given lethal doses of amanitin toxins or pieces of *A. phalloides*, 50% of dogs died from hypoglycemia 1 or 2 days after exposure (Faulstich and Fauser, 1980). In clinical cases, dogs must be monitored closely for hypoglycemia, and treatment may be necessary. Clinical signs of hypoglycemia in dogs and cats include seizures, coma, and death. Finally, it is important to note that not all cases present with the classic four stages. In cases of large exposure to amanitins, or ingestion by puppies, the animal may die within 24h (Cole, 1993).

## Toxicity

Amanitins are extremely toxic, and poisonings have been confirmed in dogs, horses (Beug, 2009), and cattle (B. Puschner, unpublished data). The i.v. LD<sub>50</sub> of  $\alpha$ -amanitin in dogs is 0.1mg/kg body weight (Faulstich *et al.*, 1985). Based on an oral dosing study in dogs, the oral LD<sub>50</sub> for methyl- $\gamma$ -amanitin was estimated to be 0.5mg/kg body weight. In mice and rats, the i.v. LD<sub>50</sub> of  $\alpha$ -amanitin is 0.35 and 3 or 4mg/kg body weight, respectively, illustrating significant species differences. Guinea pigs and rabbits are considered to be approximately equally sensitive as dogs to amanitins, with i.v. LD<sub>50</sub>s of  $\alpha$ -amanitin of 0.1 and 0.2mg/kg, respectively. In humans, the estimated oral LD<sub>50</sub> of  $\alpha$ -amanitin is 0.1mg/kg body weight. Considering the average concentration of amanitins per mushroom, one *A. phalloides* has the potential to kill a dog or horse.

## Treatment

No specific antidote for amanitins exists, and thus there is wide variability in treatment and overall response rate. Prompt measures, including decontamination and supportive care, are required to improve prognosis. Even with supportive measures, the reported mortality rate from *Amanita* poisoning in humans is 15–20%, and it is often higher in children (Enjalbert *et al.*, 2002). In humans with amanitin poisoning, silibinin, penicillin, and *N*-acetylcysteine are most commonly recommended,

although clinical efficacy data are ambiguous. Similar treatment approaches have been used with variable success rates in dogs suffering from amanitin poisoning (Tegzes and Puschner, 2002).

Silibinin and penicillin reduce the uptake of amanitins into hepatocytes. Silibinin (also known as silybin) is the main component of silymarin, which is extracted from the common milk thistle (*Silybum marianum*). Silibinin is also a free radical scavenger, and it has immunostimulatory and iron binding properties (Mayer *et al.*, 2005). In Europe, a silibinin-contained product (Legalon-Sil) is a well-established and approved treatment for amanitin poisonings in humans. Treatment consists of a 5mg/kg loading dose i.v. followed by 20mg/kg/day via continuous infusion (Karlson-Stiber and Persson, 2003) until coagulopathy is no longer present and liver function tests have returned significantly toward normal. In 2009, an open clinical trial was sanctioned by the U.S. Food and Drug Administration and is currently being conducted in northern California (<http://clinicaltrials.gov/ct2/show/NCT00915681>). In dogs, silibinin was shown to be effective when given twice at a dose of 50mg/kg i.v. 5 and 24h after exposure to *A. phalloides* (Vogel *et al.*, 1984). Dosed dogs had better indices of liver function as assessed by serum elevations of AST, ALT, bilirubin, and prolonged prothrombin time. On histopathology, no hepatic lesions were found. Side effects of silibinin administration are rare but include anaphylactic reactions, mild laxative effects, and interactions with certain phase I and phase II metabolism enzymes (Venkataramanan *et al.*, 2000). Oral administration of milk thistle preparations is not recommended because they are poorly absorbed.

Penicillin G was shown to protect against amanitin-induced cell damage in cultured human hepatocytes (Magdalan *et al.*, 2010a). Mice given 1000mg/kg of penicillin G intraperitoneally 8h after exposure to a lethal dose 95 (LD<sub>95</sub>) of amanitin had less morbidity and mortality than did control mice (Floersheim, 1972). In dogs, i.v. administration of 1000mg/kg of penicillin G at 5h post *A. phalloides* exposure was considered an effective treatment (Floersheim, 1978).

The benefits of several antioxidants in amanitin intoxications have been evaluated in humans. Most information is available for *N*-acetylcysteine (NAC), which was shown to be as effective as silibinin in reducing mortality (Enjalbert *et al.*, 2002) and protecting against cell damage (Magdalan *et al.*, 2010a). In mice, NAC administration was not effective (Schneider *et al.*, 1992). Although efficacy data of NAC administration in dogs with amanitin poisoning are lacking, there is no reason not to include the glutathione precursor in the treatment regimen. Ascorbic acid may also be of benefit when managing amanitin poisoning in dogs, but specific data are not available. In contrast, cimetidine, thiocetic acid, and

steroids are no longer recommended because of poor clinical efficacy.

With the identification of OATP1B3 as the primary hepatic uptake transporter for amatoxins in humans, high-affinity substrates and inhibitors of OATP1B3 provide excellent candidates for antidotes (Letschert *et al.*, 2006). Silibinin and penicillin G are in this category, but rifampicin, cyclosporine A, and montelukast must be further evaluated because they may be superior in preventing amanitin uptake into hepatocytes.

Hemodialysis, hemoperfusion, activated charcoal, plasmapheresis, forced diuresis, and nasoduodenal suctioning have been used to treat amanitin poisonings. Controversy remains with regard to the efficacy of decontamination procedures because specific efficacy data do not exist. However, there is general agreement that activated charcoal is beneficial. In dogs, multidose activated charcoal is given every 2–6h until 2 or 3 days post-ingestion. Close monitoring, fluid replacement, and supportive care are essential for treatment. Intravenous fluids, correction of hypoglycemia and electrolyte imbalances, vitamin K<sub>1</sub>, and plasma transfusions should be considered. In humans, liver transplantation has been used successfully in patients with fulminant liver failure. Currently, liver transplantation is not an option for animals poisoned with amanitins.

Diagnosis of amanitin toxicosis is aided by identification of amanitin-containing mushrooms in the environment of the animal. Mushroom pieces found in gastric contents can confirm exposure. Accurate mushroom identification will require consultation with an experienced mycologist. Detection of amanitins in biological specimens is confirmatory, but these tests are not routinely available at diagnostic laboratories. A liquid chromatography–mass spectrometry method was developed and successfully applied to confirm amanitin poisonings in animals and humans (Filigenzi *et al.*, 2007). A competitive enzyme-linked immunosorbent assay was constructed that allows for the detection of  $\beta$ -amanitin in human serum and urine, but this assay is not available in clinical settings (Abuknesha and Maraghkou, 2004). Rapid confirmation of amanitins in suspect exposures assists in the early recognition of exposure, whereas a negative result can prevent unnecessary hospitalization. The well-known reported newspaper test of Wieland or the Meixner test should not be used alone to identify amanitin-containing mushrooms (Beuhler *et al.*, 2004). In suspect cases of amanitin poisoning, serum and urine samples should be collected at various time points beginning as early after exposure as possible. In postmortem presentations, liver and kidney samples are suitable for testing to confirm exposure. The suspect mushroom or vomited gastrointestinal contents should also be saved for further analysis.

Differential diagnoses in dogs and cats with a clinical presentation that involves gastroenteritis and hepatic failure include other toxic ingestions, such as microcystins, cocklebur, cycad palm, aflatoxin, xylitol, ricin, abrin, gyromitrin, and acetaminophen overdose. The history and geographic environment of the animal can help to eliminate most of the toxicant differentials on the list.

## HYDRAZINES

*Gyromitra* species are members of the false morel family, and *Helvellaceae* are usually found under conifers, aspens, and sometimes around melting snowbanks. The species most commonly associated with poisoning and studied in most detail is *G. esculenta*, but the toxins have been found in other species of *Helvellaceae* (Viernstein *et al.*, 1980), including *G. gigas*, *G. fastigiata*, *G. infula*, *Helvella crispa*, and *H. lacunose*. The toxins associated with false morel poisoning are hydrazine analogs. The toxins are heat labile, volatile, and water soluble (Michelot and Toth, 1991). The process of boiling and drying decreases, but does not completely eliminate, the toxin concentrations (Pyysalo, 1976). People who eat only a few of the cooked mushrooms may ingest sufficiently detoxified amounts so as to remain symptom free. This has caused misunderstandings among people with regard to the potential lethality of these mushrooms. Animals generally eat raw mushrooms; therefore, any exposure to these mushrooms may result in serious morbidity and mortality. Poisoning by some species of *Helvella*, *Verpa*, *Morchella*, *Peziza*, *Disciotis*, and *Sarcosphaera* closely resembles the syndrome caused by gyromitrin. It has been speculated that these mushrooms also contain hydrazines, although analysis has yet to confirm the presence of these toxins (Lincoff and Mitchel, 1977b).

### Pharmacokinetics/toxicokinetics

There is very limited information available. Toxicosis can result after oral and inhalation exposure. Ingestion of gyromitrin (acetaldehyde *N*-methyl *N*-formylhydrazine)-containing mushrooms results in the hydrolysis of gyromitrin to *N*-methyl-*N*-formylhydrazine, which is further metabolized to monomethylhydrazine. The degree of hydrolysis is dependent on the pH in the stomach, but it is not complete (Wright *et al.*, 1978). Inhalation of the fumes during the cooking process can also result in poisoning. Once hydrazines reach the liver, they are further metabolized to reactive intermediates, such as methyl cations and free methyl radicals (Gannett *et al.*, 1991).

### Mechanism of action

Gyromitrin is considered a gastrointestinal irritant leading to vomiting, abdominal pain, and diarrhea 6–12 h after ingestion (Coulet and Guillot, 1982). The principal toxin responsible for convulsions seen in severe cases is monomethylhydrazine, which inhibits pyridoxal phosphokinase resulting in decreased pyridoxal 5-phosphate concentrations (Lheureux *et al.*, 2005). Depletion of pyridoxal 5-phosphate leads to decreased  $\gamma$ -aminobutyric acid (GABA) synthesis and an increase in glutamic acid concentrations. Based on a study of mice in which GABA concentrations in the brain were not significantly decreased after methylhydrazine exposure (Maynert and Kaji, 1962), other mechanisms have been proposed. In addition to the gastrointestinal irritation and neurotoxicity, liver and renal failure as well as hemolysis have been described. *N*-methyl-*N*-formylhydrazine inhibits cytochrome P450 and glutathione-metabolizing enzymes (Braun *et al.*, 1979), and it can cause liver necrosis. However, the highly reactive metabolites, such as methyl cations, generated in the liver may significantly contribute to the hepatic injury. Furthermore, the hydrazine analogs present in false morels are carcinogenic in laboratory animals (Toth and Gannett, 1994). Only one case report exists in the veterinary literature. A 10-week-old dog vomited 2 or 3 h after chewing on a mushroom later identified as *G. esculenta* (Bernard, 1979). Six hours post-ingestion, the dog was lethargic, became comatose, and died 30 min later. Histopathological findings included renal tubulonephrosis, periascinar hepatic degeneration, and erythrophagocytosis.

### Toxicity

In humans, there seems to be great individual variability with regard to the toxicity of false morel. In mice, the oral LD<sub>50</sub>s of gyromitrin, *N*-methyl-*N*-formylhydrazine, and monomethylhydrazine are 344, 118, and 33 mg/kg, respectively (Wright *et al.*, 1978). In humans, the estimated lethal dose of gyromitrin is 20–50 mg/kg for adults and 10–30 mg/kg for children (Schmidlin-Meszaros, 1974). Toxicity information for dogs or cats does not exist. Gyromitrin concentrations in fresh *G. esculenta* are estimated to be 0.12–0.16%.

### Treatment

Most humans only develop mild gastrointestinal symptoms and recover fully within several days after exposure. Management is principally supportive. Early decontamination is often not possible because of the delayed onset of clinical signs. Administration of

activated charcoal has been recommended, although efficacy data do not exist. Correction of fluid and electrolytes is an important measure along with the administration of pyridoxine. The recommended dose in humans is 25 mg/kg i.v. over 15–30 min. The dosing can be repeated but should not exceed more than 20 g/day. Although pyridoxine can successfully control seizure activity, it has no benefit in preventing liver injury. In dogs, pyridoxine has been used successfully for non-mushroom toxin-induced seizure activity. It can be used alone or in combination with diazepam, but combination therapy has better efficacy than pyridoxine alone (Villar *et al.*, 1995). The dose for dogs is 75–150 mg/kg body weight, given i.v., during acute phases of seizure activity. Diazepam is given to dogs and cats at 0.5–1.0 mg/kg i.v. to effect. Phenobarbital is not recommended for seizure control because of its cytochrome P450-inducing capability. Administration of folinic acid has been recommended in humans, but controlled studies have not been performed. *N*-acetylcysteine can be considered. The dosing is the same as that given in acetaminophen-induced hepatic injury. Hemodialysis has been reported in the literature, but its role in removing gyromitrin or its toxic metabolites is not known.

Diagnosis of gyromitrin toxicosis is aided by identification of gyromitrin-containing mushrooms in the environment of the animal. Identification by a mycologist is important to distinguish between the true and the false morels. Detection of gyromitrin, hydrazine analogs, or metabolites in mushrooms or biological specimens is not routinely available (Arshadi *et al.*, 2006). Diagnosis is mainly based on clinical and clinicopathological findings and also mushroom identification.

## MUSCARINIC AGENTS

*Inocybe* and *Clitocybe* spp. contain the highest concentrations of muscarine, but lower concentrations are found in many other genera, including *Entoloma* and *Mycena* (Young, 1994). Muscarine was first discovered and characterized in *A. muscaria*, but concentrations of muscarine are only approximately 0.0003% (Eugster and Schleusener, 1969). In comparison, *Inocybe* and *Clitocybe* species have muscarine concentrations between 0.1 and 0.33%. *Inocybe* and *Clitocybe* species have worldwide distributions and are relatively common. *Inocybe* species grow in association with either conifers or broad-leaved trees. *Clitocybe* species grow on forest litter or grassland humus. The risk of poisoning remains after cooking because of the heat stability of muscarine. There is one published report of *Inocybe phaeocomis* poisoning in a dog (Yam *et al.*, 1993) and reported death of a dog presumably from *Inocybe* sp. exposure (Beug, 2009).

## Pharmacokinetics/toxicokinetics

Limited data are available. The naturally occurring form of muscarine is the (L)+ form. In general, quarternary ammonium compounds are poorly absorbed after oral exposure. Once absorbed, muscarine is quickly distributed throughout the body, and clinical signs develop within 30 min to 2 h. Because of its quaternary configuration, muscarine does not cross the blood–brain barrier, and its cholinergic effects are entirely peripheral. A portion of the ingested muscarine is eliminated unchanged in urine, but detailed toxicokinetic studies have not been performed.

## Mechanism of action

Muscarine acts in the peripheral nervous system, where it competes with acetylcholine at its receptor binding sites. The muscarinic cholinergic receptors are found in the heart in both its nodes and its muscle fibers, in smooth muscles, and in glands. They do not occur in skeletal muscles. Once bound to the receptor, muscarine mimics the effect of acetylcholine. Muscarine is not susceptible to inactivation by acetylcholinesterase (Young *et al.*, 1994), and uncontrolled overstimulation of receptors occurs. Clinical signs appear within a few hours and include salivation, lacrimation, vomiting, diarrhea, abdominal pain, miosis, and bradycardia (Lurie *et al.*, 2009). Clinical signs in the dog eating *I. phaeocomis* were observed 3 h after exposure and included salivation, diarrhea, vomiting, depression, and collapse (Yam *et al.*, 1993).

## Toxicity

The i.v. LD<sub>50</sub> of muscarine in mice is 0.23 mg/kg (Waser, 1961). The lethal dose of muscarine in humans is estimated to be between 180 and 300 mg. Ingestion of a single mushroom containing 0.33% muscarine on a dry weight basis can be lethal (Bresinsky and Besl, 1990a).

## Treatment

Treatment includes early decontamination, administration of activated charcoal, and fluid rehydration. If life-threatening clinical signs are present, atropine should be administered. After giving a test dose to determine its efficacy, atropine can be given repeatedly until symptoms are abolished or until cessation of salivation. Doses in dogs and cats are 0.2–2.0 mg/kg, where one-fourth of the dose is given i.v. and the remainder is given either subcutaneously or intramuscularly. Other criteria for therapeutic endpoint with atropine include ease of

respiration and lack of respiratory secretions. Mydriasis is not an indicator of its effectiveness. Because atropine also competes with acetylcholine at the receptors, ongoing treatment must be carefully monitored for its anticholinergic effects, including tachycardia, gastrointestinal stasis, severe behavioral changes (e.g., delirium), and hyperthermia. The dose of atropine should be reduced or discontinued with these adverse effects.

## ISOXAZOLES

Poisoning in this group is attributed to the heat-stable isoxazoles derivatives, ibotenic acid and muscimol. *Amanita pantherina* (panther cap or panther agaric) and *A. muscaria* (fly agaric) are most commonly associated with poisonings in humans in this group (Hall and Hall, 1994). The mushrooms grow from summer to autumn in coniferous and deciduous forests, and they are abundant in the Pacific Northwest, where they are often found under Douglas fir trees. Other species containing these toxins include *A. gemmata*, *A. smithiana*, *A. strobiliformis*, and *Tricholoma muscarium* (Lincoff and Mitchel, 1977c). There are a few reports of poisoning in dogs (Naude and Berry, 1997; Beug, 2009) and cats (Ridgway, 1978) after ingesting *A. pantherina*. Ingestion of *A. muscaria* presumably resulted in clinical signs in a horse (Beug, 2009).

### Pharmacokinetics/toxicokinetics

Definitive data on the toxicokinetics of muscimol and ibotenic acid have not been established. Based on the rapid onset of clinical signs after oral exposure, rapid absorption of toxins is suspected. Once absorbed, muscimol and ibotenic acid appear to cross the blood-brain barrier by an active transport system. Ibotenic acid decarboxylates to form muscimol in the stomach, liver, and brain (Nielsen *et al.*, 1985). Muscimol and ibotenic acid can be detected in urine within 1 h of exposure (Ott *et al.*, 1975; Merova *et al.*, 2008).

### Mechanism of action

The major toxins are muscimol and ibotenic acid, but other active substances have been identified, although with minor pharmacological activities. Ibotenic acid is known to act on glutamic acid receptors in the central nervous system (CNS) and produces an excitatory action (Cleland, 1996), whereas muscimol acts on GABA<sub>A</sub> receptors and has a depressant action (Chebib and Johnston, 1999). Although both muscimol and

ibotenic acid are present in mushrooms, muscimol is further derived from ibotenic acid by spontaneous decarboxylation that can occur during dehydration of the mushroom, during digestion in the stomach, or after absorption in a variety of tissues. Therefore, muscimol is likely the major toxin resulting in clinical signs. On activation by muscimol, the membrane permeability for anions increases, usually resulting in a slight, short-lasting hyperpolarization and associated decreased excitability of the receptive neuron. Effects on the CNS are similar to those produced by therapeutic doses of diazepam.

Clinical signs of muscimol toxicosis begin within 30 min to 2 h after ingestion and have been termed the “pantherine-muscaria” syndrome in humans, which is characterized by mydriasis, dryness of mouth, ataxia, confusion, euphoria, dizziness, and tiredness. Gastrointestinal signs are not consistently seen in cases of isoxazole poisoning. Full recovery is expected within 1 or 2 days. In cats, clinical signs have been observed within 15–30 min after ingestion of *A. pantherina* (Ridgway, 1978). After a brief period of sedation, cats experienced a 4-h-long state of excitement with pronounced muscle spasms, followed by a deep sleep. Cats are expected to fully recover within 24 h after ingestion, especially if decontamination measures are taken. In dogs, clinical signs observed after ingestion of *A. pantherina* include disorientation, opisthotonus, paresis, seizures, paddling, chewing movements, miosis, vestibular signs, respiratory depression, coma, and death (Hunt and Funk, 1977; Naude and Berry, 1997). Recoveries are recorded within 12–24 h after aggressive supportive care measures, including mechanical ventilation during periods of respiratory depression; however, death was reported in several dogs. Similar clinical signs were reported in a dog that survived *A. muscaria* poisoning (Martin, 1956).

### Toxicity

In mice, the oral LD<sub>50</sub> is 22 mg/kg for muscimol and 38 mg/kg for ibotenic acid (Hall and Hall, 1994). In rats, the oral LD<sub>50</sub> is 45 mg/kg for muscimol and 129 mg/kg for ibotenic acid. The intraperitoneal LD<sub>50</sub> of muscimol is 2.5 mg/kg in mice and 3.5 mg/kg in rats. In humans, the toxic threshold is estimated to be 6 mg of muscimol and 30–60 mg of ibotenic acid (Halpern, 2004). The concentration of ibotenic acid in *A. muscaria* was estimated at 100 mg/kg fresh weight, whereas the concentration of muscimol was less than 3 mg/kg fresh weight. Thus, an average-sized fruit body of *A. muscaria* weighing 60–70 g can contain a toxic concentration. Toxicity data for dogs are not available. However, postmortem examination of puppies indicated that the ingestion of a single *A. pantherina* can be lethal (Hunt and Funk, 1977).

## Treatment

Treatment of exposed animals is mainly symptomatic and supportive. Decontamination measures should be considered in recent exposures, although emetics are only recommended in animals that are not at risk for developing aspiration pneumonia. Specific measures to control seizures are not without complication. Benzodiazepines, as GABA agonists, may potentiate any CNS depression. Therefore, when diazepam is used, CNS and respiratory depression may be severe and prolonged, necessitating the use of mechanical ventilation. As long as ventilation is maintained adequately, the prognosis for recovery is good. Diazepam can be given to dogs and cats at 0.5mg/kg i.v. to effect and can be repeated as needed every 10min for up to three doses. Other drugs used to control seizures include phenobarbital and pentobarbital. Phenobarbital is dosed at 6mg/kg i.v. Pentobarbital is given at 5–15mg/kg i.v. to effect to dogs and cats. These, too, are agonists at the GABA receptors, and they can potentiate CNS and respiratory depression. Careful monitoring of the animal's oxygenation status is vital until the animal is fully awake and alert. Supplemental oxygen can be used if necessary. General supportive measures of unconscious animals include maintaining hydration with i.v. fluids, maintaining the airway free of respiratory secretions, and frequent position changes to prevent decubitus skin ulcerations. In humans, the use of atropine is contraindicated because of the atropine-like clinical presentation in poisonings.

## PSILOPIN AND PSILOCYBIN

Mushrooms that contain psilocybin are commonly referred to as hallucinogenic or magic mushrooms. *Psilocybe*, *Panaeolus*, *Conocybe*, and *Gymnopilus* are the four genera in North America that contain psilocybin (Smolinske, 1994). Many of these mushrooms are coprophilic and grow in fields and animal pastures, particularly in the northwestern and southeastern United States. The majority of mushrooms contain only psilocybin, but some, such as *Psilocybe cyanescens*, contain both psilocybin and psilocin. The concentrations of psilocybin and psilocin are influenced by growth conditions, geographic location, storage conditions, and species. Species commonly found in the Pacific Northwest contain between 1.2 and 16.8mg/kg psilocybin on a dry weight basis. If psilocin is present, concentrations may reach up to 9.6mg/kg on a dry weight basis (Smolinske, 1994). Psilocin and psilocybin are sensitive to heat. Some mushrooms in this group also

contain other pharmacologically active substances, such as serotonin and tryptophan. There is only one published report of hallucinogenic mushroom ingestion in a dog (Kirwan, 1990).

## Pharmacokinetics/toxicokinetics

Psilocybin is a prodrug and is rapidly dephosphorylated to psilocin. Dephosphorylation can take place in a variety of tissues, but high activity has been identified in kidney and liver of rodents (Horita and Weber, 1961) and in plasma of humans (Grieshaber *et al.*, 2001). However, the general assumption is that complete conversion of psilocybin to psilocin occurs prior to absorption into the systemic circulation (Laatsch, 1996). In humans, the absolute bioavailability of psilocin liberated from orally administered psilocybin was estimated to be  $52.7 \pm 20\%$  (Hasler *et al.*, 1997). Once absorbed, psilocin is further metabolized in plasma to 4-hydroxytryptophole (4HT) and 4-hydroxyindole-3-acetic acid (4HIAA). Psilocin crosses the blood-brain barrier and concentrates in brain tissue (Horita and Weber, 1961). Psilocin is excreted unchanged or as psilocin-glucuronide in urine and to some extent unchanged via the bile (Hasler *et al.*, 2002).

## Mechanism of action

Psilocin is the pharmacologically active metabolite of psilocybin. Because of its structural similarity to serotonin, psilocin stimulates serotonin receptors in the CNS (McKenna *et al.*, 1990). Psilocin has affinity for 5-HT<sub>1A</sub>, 5-HT<sub>2A</sub>, and 5-HT<sub>2C</sub> receptors (Halberstadt *et al.*, 2010). Activation of 5-HT<sub>2A</sub> receptors leads to increased cortical activity via glutamatergic excitatory postsynaptic potentials (Aghajanian and Marek, 1997). Activation of 5-HT<sub>1A</sub> receptors results in the inhibition of pyramidal cell activity (Puig *et al.*, 2005). In addition, psilocin may have peripheral effects that involve serotonergic receptors. In humans, psilocin's psychoactive effects are similar to those produced by LSD, are observed within 20–30 min of ingestion, and include visual hallucinations, intensified hearing, and incoordination. Other autonomic-mediated effects include increased heart rate, increased blood pressure, mydriasis, tremors, and increased temperature. The effects can last up to 8 h, but hallucinogenic activity rarely exceeds 1 h. Clinical signs in dogs include ataxia, vocalization, overt aggression, nystagmus, and increased body temperature (Kirwan, 1990). In contrast to the CNS effects after exposure to isoxazoles, there is no subsequent coma. Sedation may be necessary until behavioral signs resolve.

## Toxicity

In many countries (e.g., the United States, Great Britain, and Germany), psilocybin and psilocin are classified as controlled substances. In humans, oral exposure to 10–20 mg of psilocybin can cause mood changes and hallucinations. Information regarding lethal doses in animals is not found in the literature.

## Treatment

The management of hallucinogenic mushroom poisonings is primarily supportive, and in most cases treatment is not necessary. Gastric emptying procedures have not proven beneficial and are not recommended. The effect of activated charcoal in poisonings is not known, but activated charcoal administration can be considered. If severe neurologic signs such as seizures occur, diazepam is considered the first-line medication. Diazepam can be given to effect to dogs and cats at 0.5–1.0 mg/kg i.v. in increments of 5–10 mg. If diazepam is unsuccessful, subsequent seizures can be controlled with phenobarbital at 6 mg/kg to effect. In addition, control of body temperature is an important factor in symptomatic care.

Diagnosis of psilocybin exposure is confirmed by the detection of psilocin and psilocin-glucuronide in urine, serum, and blood. A number of methodologies are available and are routinely used in forensic investigations (Kamata *et al.*, 2003; Albers *et al.*, 2004; Laussmann and Meier-Giebing, 2010). Because of the infrequent presentation of hallucinogenic mushroom poisoning in animals, these methodologies are not routinely available at veterinary diagnostic laboratories.

## GASTROINTESTINAL IRRITANTS

This group includes mushrooms that result in gastroenteritis as the primary clinical sign. There are very few reports in the veterinary literature. Genera included are *Agaricus*, *Boletus*, *Chlorophyllum*, *Entoloma*, *Lactarius*, *Omphalotus*, *Rhodophyllum*, *Scleroderma*, and *Tricholoma*. The specific toxins in most have not been identified (Spoerke, 1994).

One of the mushrooms in this group commonly reported to cause poisoning is *Chlorophyllum molybdites*. This mushroom is commonly found in the United States except in the colder, northern areas, and the principal toxin has not been clearly identified. Clinical signs of nausea, vomiting, and diarrhea appear 1–6 h after ingestion in humans, and there is complete recovery within 24–48 h (Blayney *et al.*, 1980). A dog with *C. molybdites* poisoning had clinical signs of drooling and diarrhea,

whereas a horse that had presumably eaten several bites of *C. molybdites* died (Beug, 2009). *Omphalotus olearius*, *Omphalotus subilludens*, and *Lampteromyces japonicus* contain illudin S (Bresinsky and Besl, 1990b).

Illudin S is a sesquiterpene with a unique chemical structure. In humans, vomiting and diarrhea occur 1–2.5 h after ingestion (French and Garrettson, 1988). In a pot-bellied pig, death was reported 5 h after it ingested a fruiting body of *Scleroderma citrinum* (Galey *et al.*, 1990). The pig vomited and collapsed 20 min after exposure and remained weak and recumbent until death. The toxins in *S. citrinum* have not been characterized. In *Boletus satanas*, lectins may contribute to serious gastroenteritis in humans. Lectins, which are storage proteins that may play a role in plant defense, are widely distributed in many species of mushrooms (Wang *et al.*, 1998).

Poisonings by mushrooms of this group are rarely fatal; hence, they are likely to be underreported by owners and rarely recorded in the literature. After a usually short latent period of 15 min to 2 h after ingestion, an animal may present with vomiting, diarrhea, and abdominal pain. Usually, these clinical signs resolve spontaneously within a few hours, but they may last 1 or 2 days. The clinical signs may resemble any other common cause of gastroenteritis in small or large animals, including bacterial and viral infections, sudden diet changes or eating spoiled foods, and inflammatory mediated syndromes such as acute pancreatitis. The diagnostic challenge is that many of the more toxic mushrooms cause initial gastrointestinal signs. Cyclopeptides cause vomiting and diarrhea after a lag period similar to that seen with the gastrointestinal irritants. Therefore, any animal presenting with gastrointestinal signs after a known history of mushroom ingestion must be carefully assessed.

Treatment is entirely nonspecific and supportive. Vomiting is a hallmark of poisoning by gastrointestinal irritant mushrooms. Thus, in most cases, the stomach has already been emptied, and emetics are not necessary. Activated charcoal is thought to adsorb most of the toxins in this group and should be administered orally unless there is protracted vomiting. There are no specific antidotes for the toxins in this group. Treatment is aimed at rehydration and correction of serum electrolyte abnormalities.

## RENAL TOXIC MUSHROOMS

Several cyclopeptide-containing mushrooms cause renal failure without any hepatic insult. Mushrooms of the genus *Cortinarius* contain the cyclopeptide orellanine (Frank *et al.*, 2009). In North America, there are only a

few reported cases in humans, but poisonings occur with much greater frequency in western and central Europe. In humans, symptoms may not appear for 2–20 days after ingestion. In general, gastrointestinal signs occur a few days after exposure, and renal failure develops 4–15 days after ingestion. Hemodialysis may be necessary until renal function gradually improves. There are no reports of orellanine poisoning in animals.

*Amanita smithiana* has resulted in delayed renal failure in humans without evidence of hepatic dysfunction (West *et al.*, 2009). The toxin is allenic norleucine. Key clinical features are vomiting and abdominal pain with little or no diarrhea within a few hours of ingestion. Renal failure develops 1–4 days after exposure and may require several weeks of hemodialysis before recovery. There are no reports of *A. smithiana* poisoning in animals, but it is a common mushroom in the Pacific Northwest.

## RAMARIA FLAVO-BRUNNESCENS

This mushroom is found in North America, Australia, China, Brazil, and Uruguay and has caused poisoning in cattle and sheep (Kommers and Santos, 1995). *Ramaria flavo-brunnescens* is exclusively found in eucalyptus woods, and thus the poisoning has been termed “eucalyptus sickness.” Clinical signs have been observed as early as 3 days after exposure but may be delayed until 6 days post-exposure. Typically, animals develop anorexia, salivation, diarrhea, and recumbency. This is followed by alteration in keratinization, which becomes apparent by loss of hair and hooves, similar to what is seen in chronic selenosis. The toxins have not been identified but are most likely volatile and interfere with the incorporation of sulfur-containing amino acids.

## CONCLUDING REMARKS AND FUTURE DIRECTIONS

Overall, the number of reported mushroom poisonings in animals is low, although this is likely a result of the lack of methods to confirm exposure. In humans, most cases are diagnosed by positive identification of the suspect mushroom, which is often impossible in veterinary medicine. The chances of obtaining an intact and representative mushroom are slim because animals are often left unattended and a history of ingestion is not available. The development of new analytical techniques to identify mushroom toxins in biological samples of poisoned animals will provide insight into the true frequency of mushroom poisonings. Currently, therapeutic

measures are primarily based on both mechanisms of toxicity and clinical signs. Rapid toxin identification would allow for a confirmed, early diagnosis, which is especially important in cases in which intensive care is indicated. To develop analytical techniques for specific mushroom toxins, further research is necessary in the area of toxin characterization and toxicokinetics. Although thousands of mushrooms exist worldwide, only a few have been researched in-depth. It is also important to improve our knowledge of the efficacy of commonly recommended, but poorly evaluated, therapeutic procedures.

## *Datura* species and related plants

Vinny Naidoo

### INTRODUCTION

The family Solanaceae contains several genera that are toxic due to the presence of the alkaloids hyoscyamine, scopolamine (hyoscine), nicotine, and solanine. Of these, hyoscyamine and scopolamine, the toxic tropane alkaloids, are found within the genera *Atropa* (belladonna), *Hyoscyamus* (henbane), *Brugmansia* (angel's trumpet), and *Datura* (jimsonweed). Although all of these genera are of toxicological importance, only the genus *Datura* appears to be of veterinary significance because the others are uncommonly associated with accidental poisoning. Within the *Datura* genera, the species of concern are *D. stramonium*, *D. ferox*, *D. inoxia*, *D. quercifolia*, *D. wrightii*, and *D. metel* (Knight and Walter, 2003; Molyneux and Panter, 2009), with the first two being of most significance. *Datura stramonium* L. (jimsonweed, common thorn apple, or Jamestown weed) (Figure 85.1) and *D. ferox* L. (large thorn apple) (Figure 85.2) both enjoy a cosmopolitan distribution worldwide and are annual pioneer weeds on wastelands. They are particularly troublesome, serious invaders on fertilized soil with annual crops (Anderson and Henderson, 1966; Williams, 1980).

The *Datura* spp. are very similar morphologically and are characterized by their malodorous leaves (leading to one of their common names of stink leaf) and spiny fruit capsules that are erect and ovoid. Although the two main species *D. ferox* and *D. stramonium* look very similar, they can be differentiated by the fruit capsule because *D. ferox* has the longer spines between the two. The flowers of the plants are erect, funnel shaped, and white for the *D. ferox* and white, mauve, or purplish for *D. stramonium*. The stems are green, except a purple-stemmed variety

**FIGURE 85.1** *Datura stramonium* L. (jimsonweed, common thorn apple). (Courtesy of the South African National Biodiversity Research Institute (SANBRI), Pretoria, South Africa.)

can occur with the latter. The seeds of the two species are also identical in shape and are flattened black kidney shaped with characteristic pitted exterior (Anderson and Henderson, 1966). Although the seeds

FIGURE 85.2 *Datura ferox* L. (large thorn apple). (Courtesy of SANBRI, Pretoria, South Africa.)

are identical morphologically, the seeds of *D. ferox* are larger at 14.1 versus 6.6 mg. A third species, *D. innoxia* Mill. subspecies *innoxia* (downy thorn apple or moon-flower; Figure 85.3), is primarily an invader of waste areas and sandy riverbanks, and occasionally it can also be an invader of crops. Although it also produces large tubular white flowers, in contrast to the two previous species, the flower is softly gray velvety on all parts. In addition, the fruit capsule is densely covered in small spines, with the seeds being brown and of a similar shape and size as those of *D. ferox*.

*Datura stramonium* can be further divided into four varieties: *D. stramonium* var. *stramonium*, *D. stramonium* var. *tatula*, *D. stramonium* var. *inermis*, and *D. stramonium* var. *godroni*. There is minimal morphological difference between the four species; for example, *D. stramonium* var. *stramonium* has white flowers, whereas *D. stramonium* var. *inermis* has purple flowers, the latter being a dominant purple gene effect, and *D. stramonium* var. *inermis* has a smooth capsule due to a recessive gene for the characteristic (Berkov *et al.*, 2006). However, the four strains do differ in their toxin content.

## CHEMISTRY

The toxins that occur within the plant are known as the tropane alkaloids. These alkaloids basically consist of a bicyclic seven-member tropane alkaloid ring esterified through its hydroxyl group at C-3 with the carboxyl group of L-tropic acid (Figure 85.4). The toxic L-hyoscyamine predominates over scopolamine in *D. stramonium*, whereas *D. ferox* contains predominantly scopolamine (Ketchum and Sidell, 1997). L-Hyoscyamine racemizes in extraction to form a mixture of DL-hyoscyamine (known as atropine), which is only 50% active because the D-isomer is devoid of activity (Molyneux and Panter, 2009). Chemically, the toxins are produced in the roots and are translocated via the xylem to the aerial parts, where they are stored in vacuoles (Wink, 2009).

**FIGURE 85.4** (I) Structures of hyoscyamine (conventional (a) and stereo-specific (b)) and (II) scopolamine (conventional).

**TABLE 85.1** Concentration and percentage recovery of atropine and scopolamine from wheat flour before and after baking in bread

Material	Atropine		Scopolamine	
	mg/g mixed flour	% recovery	mg/g mixed flour	% recovery
Wheat flour + 12% jimsonweed seed	0.406	100	0.115	100
Bread crumbs	0.304	75	0.1	87
Bread crust	0.335	82	0.083	72

From Friedman and Levin (1999).

The scopolamine and atropine toxins within the plant are very stable and are not destroyed by normal processing methods. List and Spencer (1979) demonstrated that processing contaminated soybean meal cake resulted in approximately 90% of the available atropine and scopolamine remaining in the soybean cake. The remaining toxins were found in the oil. However, the atropine and scopolamine in the oil were reduced by 93% through the caustic refining process. The authors concluded that this was an expected finding because the tropane alkaloids were known to hydrolyze at alkaloid pH (List and Spencer, 1979). It was also demonstrated by Friedman and Levin (1999) that baking contaminated flour did not reduce the toxin levels to any substantial concentration (Table 85.1).

## TOXICITY AS RELATED TO THE PLANT PART

Although the entire plant is toxic (Table 85.2), the toxicity is most commonly associated with the ingestion of

**TABLE 85.2** Alkaloid content ( $\mu\text{g}/\text{mg}$ ) in *Datura stramonium*

Samples	Young plant		Adult plant	
	Atropine	Scopolamine	Atropine	Scopolamine
Small leaves	0.156	0.073	0.165	0.016
Medium leaves	0.831	0.047	0.15	0.022
Large leaves	0.228	0.035	0.134	0.044
Stems	0.915	0.129	0.001	—

Seeds	0.17	0.012	0.387	0.089

From Miraldi *et al.* (2001).

Flowers: represent buds for young plants and open flower for adults; fruits: immature fruits for young plants and mature fruits for adults.

seeds as a contaminant of commercial grain crops. This is due to their rapid growth when fields are invaded, which results in concurrent harvesting of the seed with the corn. The real problem with toxicity lies with the seeds, which have the same specific gravity as the corn and are thus not easily separated unless shifted in different layers. The latter is the reason why many countries have legislation controlling the number of seeds allowable in a particular crop (corn, sorghum, soybeans, and linseed). The plant itself is very rarely directly toxic to animals because it is not consumed due to poor palatability (Ralphs, 2002). Toxicity usually only results when animals are forced to eat the plant when exposed to poor grazing on pastures or, alternatively, when the dried plant parts contaminate the hay of intensively fed animals.

Nonetheless, despite toxicity being possible irrespective of the plant part consumed, the content of scopolamine (hyoscyne) and hyoscyamine does differ per plant part (Rhodehamel and Stuart, 1921; Miraldi *et al.*, 2001). The highest concentrations are found in the leaves, flowers, and seeds of the mature plant (Table 85.2). The reason for this distribution most likely rests in a need for these structures to be protected from consumption by both herbivorous mammals and insects. Being an annual plant, it does not store resources that could be used to reestablish biomass after consumption, with the result that the plant has developed a secondary mechanism to decrease foliage consumption (Valverde *et al.*, 2003).

In addition, the toxin content is related to the *Datura* plant species with *D. stramonium* containing hyoscyamine and scopolamine at approximately equal ratios, whereas *D. ferox* contains predominantly scopolamine at a ratio of 98:2.

## TOXICODYNAMICS AND TOXICOKINETICS OF TROPANE ALKALOIDS FROM *DATURA* SPP.

Both atropine and scopolamine function by being non-selective antagonists of the muscarinic receptors in the body, thus preventing acetylcholine esterase from having an effect. The muscarinic receptors affected are present on neuroeffector junctions supplying the smooth and cardiac muscle, glandular tissue, certain peripheral ganglia, and the central nervous system (Brown and Taylor, 2001); that is, the clinical effects are always multisystemic due to the distribution of the specific receptor.

The pharmacokinetics of atropine and scopolamine have not been elucidated from the plant itself (i.e., the rate of release). The pharmacokinetics of the individual toxins, such as atropine and scopolamine, have been characterized in people. In an anesthetic study by Saarnivaara *et al.* (1985), children were treated with atropine at 0.03 mg/kg to determine the onset of the effect of the orally administered atropine. The atropine was characterized by a  $C_{\max}$  of 6.7 nmol/L, with a corresponding  $T_{\max}$  of 2 h. The clinical onset of satisfactory antispasmodic effect occurred within 70 min of administration (Saarnivaara *et al.*, 1985). Elimination half-life is reported to be 4 h (Royal Pharmaceutical Society of Great Britain, 2010).

The pharmacokinetics and bioavailability of scopolamine were evaluated in six healthy male subjects receiving 0.4 mg of the drug by either oral or intravenous administration. Scopolamine was characterized by a  $C_{\max}$  of  $528.6 \pm 109.4$  pg/mL, and the half-life of elimination was  $4.5 \pm 1.7$  h. The oral absolute bioavailability, however, was low at 10.7–48.2% (Kanto and Klotz, 1988).

Although both scopolamine and atropine are equally effective in inducing clinical signs associated with the peripheral nervous system (tachycardia, colic, drying up of secretion, and urinary retention), only scopolamine is responsible for the neurological symptoms of the plant. The reason for this lies in the toxicokinetics of the two molecules because atropine, the more water soluble of the two molecules, fails to reach adequate concentrations within the brain, whereas the more lipid-soluble scopolamine easily crosses the blood–brain barrier to achieve clinically effective concentrations within the central nervous system.

## CLINICAL SIGNS OF POISONING

Although the susceptibility of people to toxicity is unquestionable, there seems to be debate as to which

domestic species is the most susceptible. Piva and Piva (2006) stated that pigs were the most susceptible species, followed by cattle, horses, and chickens. However, based on evaluation of the literature, it appears that the order of susceptibility may realistically be horses > pigs > cattle > poultry based on susceptibility and chance of exposure. Sheep and rabbits are not normally susceptible due to the presence of an esterase enzyme system that rapidly breaks down the alkaloids (Piva and Piva, 2006).

### Equines

In general, toxicity from the ingestion of the growing plant in the grazing animal is not a problem because the plant is often avoided due to its offensive smell. *Datura* poisoning in horses is therefore usually accidental and results from the ingestion of the seed as a contaminant in the grain or the plant as a contaminant of the hay. The latter tends to result from both the inability of the animal to select its food and the loss of the offensive smell as the plant dries.

Toxicity in horses results soon after ingestion. In field outbreaks, clinical signs are reported to occur within 6–24 h of exposure to seeds in the feed (Salyi and Abonyi, 1994). In a more controlled study by Galey *et al.* (1996), four adult mares exposed to air-dried *D. innoxia*, containing 550 mg scopolamine and 740 mg atropine at levels of 0.0125, 0.025, 0.1, and 0.5 g of plant material per kilogram, developed clinical signs consistent with toxicity (gastrointestinal atony, tachycardia, sweating, and colic) 2 h after dosing. Clinical signs failed to resolve by 72 h post-dosing. The alkaloid concentrations peaked within 1 or 2 h after dosing, and the half-life of elimination was determined to be 1.7 and 2.3 h for scopolamine and atropine, respectively, for the lowest dose. An interesting finding was the lack of a relationship between the duration of the clinical signs in relation to the half-life (72 vs. 2.3 h). Although this result was never explained, two plausible explanations are that the effect on the muscarinic receptor system is more prolonged, akin to irreversible antagonism, or, more likely, due to constant low-level absorption from the gastrointestinal tract (i.e., atropine and scopolamine are slowly released as the plant is digested).

A number of field outbreaks from the ingestion of contaminated grain have been reported (Barney and Wilson, 1963; Williams and Scott, 1984; Salyi and Abonyi, 1994; Schulman and Bolton, 1998), all with varied clinical signs. This suggests that toxicity is related to the amount ingested, the toxin concentration within the grain, and, to a degree, individual variation. In the first case, 15 of 34 animals were affected following exposure to cracked maize containing a large number of seeds (Barney and Wilson, 1963). The clinical signs recorded were anorexia,

hyperexcitability, staggers, muscular spasms, frequent urination, mydriasis, and impaired vision progressing to convulsions, seizures, rigor, coma, and death in 11 animals. In the second case, 2 horses fed a meal containing 0.5% *D. stramonium* seeds showed signs of depression, mydriasis, anorexia, tachycardia, polydypsia, polyuria, fever, and fetid diarrhea (Williams and Scott, 1984). In the third report, in which toxicity was assumed to have resulted from exposure to a combination of *D. stramonium* and *D. ferox* in 2 horses, is the first incidence of severe gastrointestinal signs being recorded as 1 horse died from acute gastric dilation and rupture and the other from an unresponsive paralytic ileus (Schulman and Bolton, 1998).

Toxicity via contamination of hay has also been reported (Naude *et al.*, 2005; Gerber *et al.*, 2006). In both cases, toxicity was confirmed by the presence of the toxic plant in the hay. In the first case, *D. stramonium* and *D. ferox* toxicity was suspected from the physical examination of the plant and high-performance liquid chromatography analysis, which demonstrated the presence of scopolamine and hyoscyamine (1600:1500 µg/g) in one of the dried plants and only scopolamine in the other (1100 µg/g). The second case confirmed toxicity by the presence of the plant in the hay and also by the presence of hyoscyamine and scopolamine at 18.5 and 1553 µg/g, respectively, in the urine (Gerber *et al.*, 2006). Clinical signs for both these cases were consistent with that for the seed exposure and included impaction, colic, and paralytic ileus.

The clinical pathological changes induced by *Datura* were evaluated by Binev *et al.* (2006a–c) following the exposure of horses to fresh maize with a high content of jimsonweed. The erythron revealed an erythrocytosis and increased hematocrit in the absence of changes in mean corpuscular hemoglobin concentration, mean corpuscular hemoglobin, and mean corpuscular volume, which suggested the induced changes were due to dehydration. The leukon was more revealing and showed an increase in the total leukocytes, metamyelocytes, and band and segmented neutrophil counts, whereas the lymphocyte count decreased. The specific change in the leukon was believed to have resulted from either direct irritation of the mucosa by the toxin or, more likely, the colic that developed. Binev *et al.* also suggested that a failure of the leukon to return to normal within 4 or 5 days of exposure may be a good indicator of an overall poorer prognosis.

The pathology that results from the ingestion of *D. stramonium* seeds appears to be nonspecific. Salyi and Abonyi (1994) reported clinical signs of restlessness, colic, dyspnea, tachycardia, peripheral circulatory insufficiency, constipation, tympany, ileus, dilated pupils, and drying of oral and nasal mucosa. On postmortem, seeds were always present in the stomach in combination with

other nonspecific changes, such as circulatory disturbances, pulmonary emphysema, cardiac dilation, constipation, and, occasionally, intestinal displacement. The nonspecific pathology was related more to the colic that developed rather than specific changes induced by the toxins; that is, congestion and pulmonary pathology are common complications of colic due to increased pressure on the diaphragm by parts of the distended gastrointestinal tract.

## Cattle

Few studies on the clinical signs of *Datura* intoxication are available for cattle. This probably results from the low levels of toxicity seen because animals do not readily consume the plant due to poor palatability; that is, poisonings only result when animals are forced to consume the plants in times of starvation. According to Naude (2007), fresh *Datura* posed little problem in cattle as animals were observed consuming the plants on well-fertilized pastures. Analysis of *D. ferox* revealed 149 and 988 µg/g of hyoscyamine and scopolamine, respectively, whereas *D. stramonium* contained 260 µg/g each of scopolamine and hyoscyamine, which are at the toxic levels. Therefore, this suggests that the rumen is capable of deactivating the ingested tropane alkaloids when given time to habituate.

The clinical signs of hyoscyamine and scopolamine exposure, however, were elucidated in a controlled study in cattle. Nelson *et al.* (1982) exposed heifers to a diet containing 0, 8.8, 880, and 4410 of *D. stramonium* seeds/kg of feed for 14 days. The seeds were shown to contain 0.26% atropine and 0.55% scopolamine, which worked out to a total exposure of 2.49 g atropine and 0.5 g scopolamine/kg/day for the high-dose group. The main clinical sign of anorexia was evident in only the high-dose group and resolved completely within 2 or 3 days. It was speculated that the toxins induced rumen atony that subsequently presented as anorexia. With the induced anorexia, the animal stopped consuming the toxic material and as a result was allowed sufficient time for toxin washout and return to normal health. Other clinical signs seen in the high-dose group were spells of bloat, dry muzzle, miosis, and tenesmus (Nelson *et al.*, 1982).

## Sheep and goats

According to Naude (2007), sheep are very resilient to the effects of *D. stramonium*. In an unpublished study, sheep were dosed by fistula with 50 g/kg of the seeds with a known alkaloid concentration of 0.2% without the development of any clinical signs. The same study also

demonstrated that purified atropine was more effective when given intravenously than orally. The oral dose of 50 mg/kg induced only a marginal increase in papillary dilatation, whereas the intravenous dose of 33 mg/kg induced a marked papillary dilatation and tachycardia. This again supports the information available for cattle that suggests that the rumen does offer protection against orally ingested toxins. Other literature indicates that the protection appears to be from the aromatase enzyme system (Piva and Piva, 2006).

The finding of Naude (2007) does not appear to be a universal finding for this species because a controlled study by El Dirdiri *et al.* (1981) showed a different result. In this study, male desert sheep and Nubian goats were dosed daily with fresh leaves or fruit until death resulted. The sheep ( $n = 2$ ) were dosed with fruit or leaves at 10 g/kg for the fruit and 1 g/kg for the leaves for an intended 61 days. Clinical signs were evident 2–6 days after dosing and continued until death at 12–38 days for fruit, whereas signs were slower to develop in the leaf group, with initiation at 35 and 45 days and continuing until death of the first animal on day 45 or until scheduled death for the second. This trend was evident in the goats ( $n = 4$ ), which were similarly dosed with leaves or fruit at 10 g/kg/day or fruit at 2.5 g/kg/day for a longer period of 136 days. Clinical signs were evident 2–101 days after dosing and continued until death at 30–136 days for the leaf group, whereas signs were slower to develop for the seed group, with initiation at 36–110 days and continuing until the death of the first animal on day 30 or until scheduled death for the remaining animals. The signs noted in both species were reduced water intake, anorexia, intermittent hyperesthesia, tremors, drowsiness, and recumbence. Histological evaluation revealed focal necrosis and fatty vacuolation of centrilobular hepatocytes and renal tubular degeneration.

## Springbok

Lideque and Scheepers (1992) reported that a group of Springbok (*Antidorcas marsupialis*) in the northern Namibian desert area were forced to graze almost exclusively on dense stands of the alien invader *D. inoxia*. Two adult male animals from this group exhibited abnormal behavior, having an unsteady gait and a delayed response to visual and auditory stimuli allowing the observer's vehicle to approach to a quarter of the distance at which these antelope usually fled.

## Pigs

As hindgut fermenters, it is not surprising that pigs are susceptible to tropane alkaloid toxicity because the toxin is preferentially absorbed from the upper gastrointestinal

tract. It is also not surprising that pigs are commonly involved in toxicity because their diets are intensive and consist typically of maize in the ration. Clinical signs in pigs are also muscarinic associated. Reported signs include ataxia, lethargy, docility, drowsiness, papillary dilatation, and possible even gas distention of the gastrointestinal tract (Keeler, 1975).

In the 1970s, it was speculated that *D. stramonium* could be teratogenic and induce arthrogryposis in piglets after the abnormal occurrence of this clinical sign in piglets born to sows exposed to *D. stramonium* (the sows did demonstrate classical signs of *Datura* exposure) (Leipold *et al.*, 1973). The deduction was later shown to be incorrect by Keeler (1984), who dosed pregnant sows with dried *D. stramonium*. For this study, animals were dosed for 40 ( $n = 5$ ) and 10 ( $n = 5$ ) days at 1.2–1.7 g/kg/day, which approximates to 1.8–2.6 mg/kg of tropane alkaloid. The study recorded one fatality at the highest dose, which indicates that the exposure concentration was sufficiently high (Keeler, 1984).

Worthington *et al.* (1981) fed two groups ( $n = 4$ ) with ground *Datura* seed in ration at the alkaloid level of 1, 4, and 2.2 mg/kg/day for 4 days without any signs of toxicity being evident. However, the pigs did find the ration rather unpalatable. The latter observation was confirmed by Janssens and de Wilde (1989), who demonstrated decreased weight gains as a result of lower feed intake following exposure to linseed oil cake contaminated with *D. ferox* at a scopolamine level of 2 mg/kg.

It is also possible that the exposure to *Datura* induces neurological clinical signs. In a clinical case of poisoning, Spencer *et al.* (2000) reported head pushing against the pen bars in animals suspected to have been exposed to *D. stramonium*-contaminated maize; head pushing ceased on withdrawal of the feed. It was speculated that the clinical signs may have been due to hallucinations induced by scopolamine content of the plant. However, another plausible reason for the head pushing may be more behavioral than psychological effect. The muscarinic effect of the plant could easily have induced gastrointestinal stasis and subsequent colic, which would manifest as head pushing – a well-recognized sign of pain in animals.

The clinical and pathological changes induced by *Datura* are poorly documented for pigs. In a controlled study, pure scopolamine and atropine (98:2) were fed to 40 growing pigs at a concentration of 0, 1.5, 15, 75, and 150 mg/kg of feed for either 14 or 76 days (Piva *et al.*, 1997). Again, the major changes evident in all the treatment groups were decreased weight in comparison to the control. The two high doses also showed an increase in total plasma cholesterol, triglycerides, and total lipids, which the authors interpreted as increased fat mobilization. All animals also demonstrated an increase in plasma urea and uric acid, which suggests muscle

catabolism. The most prominent finding histologically was lymphocytic infiltration of the gastrointestinal tract mucosa with loss of epithelium and concurrent villus necrosis and dystrophic regeneration.

## Chickens

Similar to pigs, chickens are exposed to *Datura* due to the intensive diets they are fed. However, unlike pigs, chickens appear to be less susceptible to toxicity. In a study in which pure scopolamine and atropine (98:2) were included in a simulation of *D. ferox* exposure, five groups of broilers ( $N = 20$ ; 16 females and 4 males) were exposed to concentrations of 0, 1.5, 15, 75, and 150 mg/kg of feed, with no signs of muscarinic blockage. The only toxic effect was a reduction in weight gain for the higher dose group (Kovatsis *et al.*, 1993).

In a subacute study, Day and Dilworth (1984) fed milled *D. stramonium* seeds (unspecified toxic levels) to 1-day-old chicks at a concentration of 0, 1, 3, and 6% of the admixture of their diet. At 3 weeks, the two higher dose groups showed only lower weight gain. In a study by Flunker *et al.* (1987), milled *D. stramonium* was fed at 0.5 and 3% to six groups ( $n = 24$ ) of 1-day-old chicks for different time intervals or at concentrations of 1, 2, and 3% for 14 days to adult white leghorn hens ( $n = 5$ ). No deleterious effect on growth in the chicks or egg production was reported, with the exception of decreased feed intake (3%) in the high-dose hen group. In a subchronic study, Kovatsis *et al.* (1994) dosed pure scopolamine and atropine (98:2) at a concentration of 1.5, 15, 75, or 150 mg/kg to 100 egg-laying hens for 3 months. The high-dose group showed reduced egg production for the first 5 or 6 weeks, whereas lower doses had no effect. No changes in shell thickness, body weight, plasma aspartate aminotransferase, alanine aminotransferase, alkaline phosphatase, leucine aminopeptidase, and necropsy results were evident (Kovatsis *et al.*, 1994). As a result, it was concluded that broilers and layers could tolerate up to 3% of seeds in the diet for 14–21 days without adverse effects being evident. Long-term exposure, however, could decrease feed intake and interfere with performance (Damron, 1998).

## Other species

Cases of toxicities have been reported in dogs and cats following the accidental ingestion (through playing) of ornamental house plants. Unfortunately, the reporting publication did not mention the clinical signs seen in these animals (Berny *et al.*, 2010). A single case of a poodle dying has also been reported. The animal demonstrated

clinical signs of agitation, aggression, ambulatory delirium, tachycardia, tachypnea, mydriasis, and seizures that progressed to coma and death following exposure. At necropsy, the organs were congested, with lung edema, cardiac dilatation, and multiple pericardial petechiae; histopathology revealed hepatic necrosis, renal tubular degeneration, and widespread congestion and hemorrhage of the central nervous system (Tostes, 2002).

## TREATMENT

Treatment in most instances is supportive and symptomatic. Withdrawal of the contaminated feed or removal of animals from contaminated pastures should be the first step. For more severe cases, usually horses, more intensive management of the resulting colic is required. Treatment for the latter usually entails the infusion of crystalloid fluids, analgesic support, and, in cases of impaction, oral fluid administration and cathartics such as magnesium sulfate or mineral oil. In more severe cases, animals may require trocharization to relieve the gas distention and possibly even surgical intervention. The use of physostigmine as an antidote in animals appears to be ineffective, especially in horses presenting with clinical signs.

## CONCLUSIONS AND FUTURE DIRECTIONS

*Datura* poisoning is commonly reported in both people and animals. In the former, toxicity results mainly from the ingestion of the seeds, whereas in the latter, toxicity results from the contamination of the feed with either the plant or seeds. The clinical signs associated with toxicity are characteristic of the central and peripheral muscarinic inhibitory mechanism of the contained hyoscyamine and/or scopolamine toxins. Although the clinical signs are easily discernible, the clinical pathological and necropsy changes induced by the toxin are usually nonspecific. Toxicity is clearly species specific, with the susceptible domestic species being horses, pigs, cattle, and poultry. In addition, toxicity is related to the concentration of the toxic principles within the plant and the degree of adaptation of the animal. Treatment of toxicity is mainly supportive, with removal of the source of the toxin being imperative. Although the plant and its seed can pose major problems in animal production, these can be limited by proper feed management and screening.

## Ruminants

The available literature for cattle is scant and confusing to such an extent that some publications report cattle as being very susceptible, whereas others report them as being rather resistant. This suggests that rumen adaptation plays an important role in the development of toxicity. As such, it would be interesting to determine how much time is required for rumen adaptation and the degree of protection this offers to animals. It would also be interesting to ascertain if subclinical changes occur in these animals despite rumen adaptation.

## Toxicokinetics

Although a fair amount of literature is available on the toxicity of tropane alkaloids in animal species, there is a paucity of information on the general and interspecies toxicokinetics of the two toxins concerned. It would therefore be interesting to ascertain if the toxicokinetic parameters, such as absorption and metabolism, in the various domestic animals could be established. It would also be interesting to determine the importance of the first-pass effect in toxicity as well as the physiological protection offered by the blood-brain barrier of the different domestic species (i.e., whether atropine and scopolamine follow the same distribution patterns in all species). Another feature of toxicity that is poorly discussed is whether the release and absorption of the toxins is rapid (rapid and immediate release from the plant or a more slow and gradual release over time) and whether the liberated hyoscyamine isomerizes on absorption (i.e., whether studies that use pure hyoscyamine essentially only simulate 50% exposure to the toxic component of the plant).

## Cottonseed toxicity

Steven S. Nicholson

### INTRODUCTION

Whole cottonseeds are a product of cotton (*Gossypium*) production. They are approximately 18% oil and 24% protein and contain polyphenolic pigments, one of which is the toxic component gossypol ( $C_{30}H_{30}O_8$ ; molecular weight, 518.55). The structural formula of gossypol is shown in Figure 86.1. Gossypol is a yellow liquid located within the pigment or oil glands in the cotton plant. In cottonseed, these glands appear as brown to black specks within the white matrix of the seed. The content of gossypol in whole cottonseed is free and unbound and ranges from 0.02 to 6.64%, and it is thought to provide resistance to insects (Price *et al.*, 1993). Free gossypol is not bound to protein and is available for absorption from the digestive tract in monogastric animals. In ruminants, some of the ingested free gossypol becomes bound to protein and is not absorbed. Gossypol is recognized for its toxic effect on cardiac, hepatic, pulmonary, and reproductive systems. Whole cottonseed, cottonseed meal, and cottonseed hulls are important feedstuffs. Variation of free gossypol levels in cottonseed meal is due to different processing methods used to extract oil as well as some natural variation in cotton varieties and an influence of growing factors (Cherry *et al.*, 1978). Cottonseed meal is a 36–41% protein supplement used in beef and dairy rations in the United States. Cottonseed hulls are used as a fiber source in cattle rations. The risk of gossypol toxicosis limits the amount of cottonseed meal in the diet of swine, poultry, dogs, and other monogastric animals as well as preruminant calves and preruminant lambs. The literature does not describe clinical cases in equids. Adverse effects of

FIGURE 86.1 Structural formula of gossypol.

gossypol on reproduction in humans and animals may occur in certain situations.

### BACKGROUND

Free, unbound gossypol is one of several polyphenolic compounds found in the pigment glands of whole cottonseed. Cottonseed cake remains after oil is extracted from the seeds. Removal of the oil by commercial processors leaves cottonseed meal containing gossypol in two forms – free, which is the toxic form, and bound. Methods of extraction of the oil include mechanically extracted cottonseed meal containing 0.06% free gossypol and the expander solvent method cottonseed meal containing 0.14% free gossypol (NCPA, 2005). A solvent-only method of extraction produced cottonseed meal

with free gossypol content up to 0.6%. Bound gossypol is bound to amino acids in the meal and is considered unavailable for digestion. Some bound gossypol may be digested and absorbed by ruminants.

## PHARMACOKINETICS/ TOXICOKINETICS

Intake of free gossypol at a toxic level for a period of days or weeks by susceptible animals leads to the appearance of toxic effects. Gossypol tends to accumulate in the liver and kidneys. Little or no gossypol was detected in milk from cows fed cottonseed products (Lindsey *et al.*, 1980). The half-life of gossypol in three dairy cows ranged from 40.7 to 67.5 h (Lin *et al.*, 1991). Low dietary iron leads to increased gossypol absorption, and iron added to the diet can reduce absorption (Haschek *et al.*, 1989). Tissue concentrations in swine from highest to lowest were found in muscle, liver, fat, and red blood cells. In swine, gossypol is metabolized in the liver to various compounds, conjugated as glucuronides and sulfates, and excreted in the feces (Abou-Donia, 1989). In poultry, gossypol reacts with iron in egg yolks to produce an olive-green color. Cyclopropenoid fatty acids in cottonseed meal causes egg whites to become pink.

## MECHANISM OF ACTION

Gossypol seems to produce poisoning by more than one mechanism. Considerable evidence points to oxidative stress, formation of reactive oxygen species, and DNA scission – characteristics of redox cycling by electron transport in biosystems (Kovacic, 2003). Myocardial necrosis, congestive heart failure, and secondary hepatic changes and anemia due to complexing of gossypol with iron account for clinical signs and course of the toxicosis. Death may occur suddenly and unexpectedly in some cases due to cardiac failure.

## TOXICITY

Toxic levels of free gossypol in the diet produce cardiac necrosis and congestive heart failure in swine, dogs, goats, cattle, preruminant calves, and preruminant lambs. Dairy cows are susceptible to gossypol toxicosis.

Cottonseed products are seldom fed to horses. Horses appear to be fairly resistant to gossypol toxicity because

this problem has not been reported on a clinical basis in horses consuming cottonseed meal. However, because of problems with other species of livestock, possible gossypol toxicity should be noted as a concern. Precautions for feeding yearling horses cottonseed meal include the fact that it is low in lysine and to feed meal containing less than 0.2% gossypol. No effect on the health of young horses was reported when gossypol was fed to yearling horses at 115 ppm of the diet (Potter, 1981). Weanling-age and suckling foals showed no toxic effect at 348 ppm (McCall, 1982).

High mortality was seen in dairy calves fed cottonseed meal with 250–380 ppm gossypol during the first 10 weeks of life (Holmberg *et al.*, 1988). Holstein calves may develop ascites, diarrhea, and weakness after consuming toxic levels of gossypol in a diet containing cottonseed meal for 70 to approximately 180 days. In the author's experience (unpublished data), a typical case of gossypol poisoning presents as follows. Holstein calves 3–8 months of age were confined to dry lot and fed up to 3.6–4.5 kg per day of lactating cow ration for 4 months with little or no hay available. The feed contained 600 lb (272 kg) cottonseed meal per ton. The free gossypol content of the cottonseed meal was determined to be 0.6%. Two calves died approximately 1 day apart from what was thought to be pneumonia because of cough, dyspnea, and blood-tinged nasal discharge. Two calves were sick at the time of the farm visit. One had diarrhea, ascites, dyspnea, anemia, and weakness. At necropsy, ascites was marked and the liver was swollen, the intestinal tract was edematous, the heart had pale areas within the myocardium that were later confirmed as areas of necrosis, and the lungs were edematous. Other causes of myocardial necrosis, including the plant oleander (*Nerium oleander*), ionophores, excess selenium injection, *Senna* (formerly *Cassia*) myopathy, and white muscle disease, were ruled out. In a published incident, 24 of 57 calves fed a diet containing 33% cottonseed meal died at between 7 and 15 weeks of age. Initial deaths were not accompanied by premonitory signs, but after cottonseed meal withdrawal, most calves developed rough coats, anorexia, weakness, ascites, and subcutaneous edema. Those that died had large volumes of serous fluid in the body cavity, firm liver of "nutmeg" appearance, and pulmonary congestion. Histopathology revealed periportal hepatic necrosis in acute cases and periportal fibrosis in chronic cases. Lungs from several calves had edema, hemosiderosis, and fibrosis in some pulmonary vessels. Atrophy of myocardial fibers was present in most cases. The concentration of free gossypol in the diet was 100–220 ppm. Antemortem and postmortem findings supported a diagnosis of gossypol poisoning. The deaths continued for 4 weeks after withdrawal of cottonseed meal from the diet (Zelski *et al.*, 1995).

Gossypol poisoning in mature cattle is uncommon, but dairy cows can be at risk because they may be fed both

cottonseed and cottonseed meal during lactation. Dairy cows consuming high levels of cottonseed meal may be at risk of cardiac failure (Jimenez, 1979; Lindsey *et al.*, 1980; Smalley and Bicknell, 1982). High environmental temperature and humidity seem to enhance the risk. Dairy cows tolerated up to 6.2mg/kg body weight free gossypol per day for 100 days, but 8.8mg/kg caused red cell fragility, depressed hemoglobin levels, and increased respiratory rate in response to elevated ambient temperatures (Lindsey *et al.*, 1980). Erythrocyte fragility on days 28 and 56 and elevated serum alkaline phosphatase were noted, but adverse reproductive effects were not seen in crossbred heifers fed a diet of 30% cottonseed (Calhoun *et al.*, 1991). Consumption of a high-gossypol diet for 170 days had no effect on the health of lactating dairy cows, but it increased plasma gossypol concentrations and impaired reproductive performance (Santos *et al.*, 2003). Ammoniation of cottonseed meal to reduce aflatoxin content was thought to have enhanced the toxic effects of gossypol in dairy cattle fed 6–9lb of cottonseed meal per day (Smalley and Bicknell, 1982).

Rogers and Moore (1995) reported that it was safe to feed higher levels of free gossypol in the diet when the source of free gossypol was whole cottonseed instead of cottonseed meal. For example, for mature cows and bulls, the recommended safe levels of free gossypol in the diet were 900 and 1200ppm, respectively, when whole cottonseed was fed compared with 200 and 600ppm, respectively, when the source of free gossypol was cottonseed meal. The higher levels of free gossypol recommended for diets containing cottonseed reflect the fact that free gossypol in unprocessed whole cottonseed is extensively bound during digestion in the rumen and is less available than free gossypol in cottonseed meal (Calhoun, 1995).

Lambs fed a diet containing 900ppm free gossypol for 3 or 4 weeks died suddenly or after exhibiting signs of cardiac failure (Morgan *et al.*, 1988). Clinical signs included sudden death and/or chronic dyspnea syndromes. Serum chemistry alterations in the lambs included high serum total lactate dehydrogenase and lactate dehydrogenase liver-specific isoenzyme activities. Serum total creatine kinase activity decreased markedly in lambs of all groups treated with gossypol at 45, 136, or 409mg per day. All lambs given 409mg of gossypol per day died before the end of the 30-day study.

Gossypol in the diet at 250–300mg of free gossypol per day for several months apparently caused congestive heart failure in adult goats (East *et al.*, 1989).

In swine, dietary levels of 200–300ppm free gossypol result in cardiac insufficiency and respiratory distress with mortality rates exceeding 50% (Haschek *et al.*, 1989). A level of 100ppm free gossypol in the diet of swine is considered safe.

In dogs, cardiotoxicity associated with prolonged gossypol intake is similar to that in other species. Four

dogs died, with lesions compatible with those described in experimental gossypol poisoning, after eating food sprinkled with cottonseed meal over a period of months. The amount of free gossypol fed was approximately 5.4–5.7mg/kg body weight per day for an unknown duration (Patton *et al.*, 1985). Six dogs died after accidental ingestion of cottonseed bedding, but clinical signs of illness were not seen. At necropsy, the lungs were congested and edematous, and the liver was firm, congested, and had a marked reticular pattern. Moderate ascites was noted. Histopathology revealed multifocal myocardial degeneration and necrosis, severe pulmonary edema, and chronic passive congestion of the lungs, heart, liver, and kidneys. Transmission electron microscopy of the myocardium revealed disruption of myofibrils, chromatin condensation, and disrupted and swollen mitochondria. The cottonseed bedding contained 1600mg/kg of free gossypol, a concentration considered toxic for monogastric animals. The stomach content revealed the presence of gossypol. Gossypol poisoning in dogs is extremely rare and had not previously been associated with cottonseed bedding (Uzal *et al.*, 2005).

Rabbits and guinea pigs are susceptible to gossypol toxicosis.

Severe cases of perivascular lymphoid aggregate formation, biliary hyperplasia, and hepatic cholestasis were observed in chicks fed 800 and 1600mg/kg of purified gossypol in feed (Henry *et al.*, 2001b). Gossypol was added to broiler feed at 0, 100, 200, and 400mg/kg of feed in experiment 1 and at 0, 800, and 1600mg/kg of feed in experiment 2. Feed conversion ratios of chicks fed 800 and 1600mg/kg gossypol were significantly higher than those of chicks fed control diets (1.383 vs. 1.564 vs. 1.745 for 0, 800, and 1600mg/kg gossypol, respectively). Enlarged gallbladder was the only gross pathologic lesion associated with gossypol levels. Severe cases of perivascular lymphoid aggregate formation, biliary hyperplasia, and hepatic cholestasis were observed in chicks fed 800 and 1600mg/kg of gossypol in feed. No gossypol-related changes were observed in kidney tissues of chicks. These results show that gossypol is toxic to broiler chicks at high levels. This study also shows that histopathology changes in liver due to gossypol also occur at levels lower than those that affect body weight (Henry *et al.*, 2001b). In another experiment, broiler chicks were fed diets containing 20% feed-grade or extruded cottonseed meal and compared with control chicks fed corn and soybean meal-based broiler rations. Weight gain, feed intake, and feed conversion ratio of broilers at 21 days were significantly affected by the diets. Feeding feed-grade and extruded cottonseed meal resulted in decreased body weight gain, increased feed intake, and inefficient feed utilization. When 2% lysine was added to feed-grade or extruded meal, body weight gains of chicks were not significantly

## TREATMENT

different from those fed the control diet. The extrusion process reduced the free gossypol in the meal, but the total gossypol level was not changed and chick performance was not improved. The authors concluded that with adequate supplemental lysine, cottonseed meal can be used in broiler diets without a reduction in performance (Henry *et al.*, 2001a).

In fish, the pathological effects of gossypol in tilapia (*Oreochromis* sp.) were a decline in body weight, low hemoglobin and hematocrit levels, an abundance of immature red blood cells, and abnormal spleen morphology (Garcia-Abiado *et al.*, 2004). In rainbow trout, feeding diets containing cottonseed meal during a period of 10 months did not result in differences in growth and mortality compared to the control group ( $P > 0.05$ ). Gossypol was transferred to the eggs, and embryo survival increased linearly as gossypol content in the diet was increased (Blom *et al.*, 2001). In channel catfish fed cottonseed meal, there was no toxic effect of free gossypol noted at 900 ppm (Dorsa *et al.*, 1982).

In summary, the signs and lesions of gossypol toxicosis include myocardial necrosis, congestive heart failure, centrilobular necrosis of the liver, pulmonary edema, and perhaps mild hemoglobinuria caused by red blood cell fragility. Mild to moderate anemia may be present. Ascites, diarrhea, and edema of the intestinal tract secondary to congestive heart failure may be seen. Dairy cows and lambs may die suddenly with minimal lesions. Death caused by heart failure may occur several weeks after last consumption of toxic levels of gossypol.

The diagnosis of toxicosis includes history of prolonged dietary exposure, clinical signs and lesions compatible with acute or chronic heart failure, and elimination of other potential causes.

Adverse male reproductive effects are of concern because studies have found a decrease in testicular steroidogenesis and spermatogenesis in pubescent rams and bulls (Lin *et al.*, 1981; Kramer *et al.*, 1991). Reversible male infertility has been reported for some animal species and humans (Abou-Donia, 1989). In peripubertal bulls, gossypol (8 mg/kg per day for 56 days) increased sperm abnormalities. The number of sperm with proximal droplets was significantly higher in the gossypol-treated bulls, suggesting testicular degeneration, but the effects were reversible (Hassan *et al.*, 2004). Extensive damage to the germinal epithelium has been shown in both rams and bulls that were fed diets containing gossypol, and this is of concern (Randel *et al.* 1992). Its use in the diet of prepubertal bulls may be a concern. However, cottonseed meal has been and remains an important winter feeding supplement for beef cattle herds in the southwestern United States. The generally cited recommendation for limiting cottonseed meal in the diet for young developing bulls is based on a maximum of 150 ppm free gossypol in the diet.

Gossypol sources in the diet should be removed. Treatment of food animals affected by gossypol toxicosis is impractical. Adding ferrous sulfate to the diet has a protective effect. Generally, ferrous sulfate added to the diet in amounts equal to free gossypol inactivates gossypol and thereby reduces its toxicity (Barraza *et al.*, 1991). Feed supplemented with high protein levels can also provide a protective effect by reducing free gossypol. Dogs may benefit from therapy designed to strengthen heart function in congestive heart failure.

## CONCLUDING REMARKS

Pelleting reduced free gossypol by as much as 70% in whole cottonseed and by 48% in cottonseed meal (Barraza *et al.*, 1991). Pelleting represents a mechanism to decrease the toxicity of gossypol in cottonseed. Preruminant calves, early weaned lambs, pigs, and poultry can safely be fed diets containing up to 100 ppm free gossypol without fear of gossypol toxicity.

## Fescue toxicosis

Tim J. Evans, Dennis J. Blodgett and George E. Rottinghaus

### INTRODUCTION

“Fescue toxicosis” is one of the most economically costly grass-related intoxications of livestock in the United States, as well as other regions of the world. Historically, there were portions of the United States where particularly unpredictable weather conditions resulted in less than desirable pasture development for grazing livestock. A hardy tall fescue grass, which has undergone a series of changes in nomenclature during the past 40 years (currently *Lolium arundinaceum* [Shreb.] Darbysh., *Schedonorus arundinaceus* [Schreb.] Dumort., or *Schedonorus phoenix* [Scop.] Holub; formerly *Festuca arundinacea* Schreb. var. *arundinacea* Schreb. or *Festuca elatior* L.), was obtained from a Kentucky farm in 1931 and was first marketed commercially in 1943 (Ball, 1984; Burrows and Tyrl, 2001; Strickland *et al.*, 2011). Today, this variety of tall fescue, Kentucky 31, occupies more than 20 million ha in the United States and represents an important grazing grass, especially within the southeastern and southern mid-western regions of the United States (Evans *et al.*, 2004b; Stuedemann and Seman, 2005), as well as internationally. It is a cool-season grass that grows well in the fall, producing substantial forage for the winter months. By 1948, a disease syndrome referred to as “fescue foot” had been described in New Zealand, and in 1950, the same syndrome was reported in the United States (Bacon, 1995). In 1973, it was noticed that cattle on a Kentucky 31 pasture were very unthrifty compared to cattle on an adjoining nonfescue pasture (Schmidt and Osborn, 1993). This observation initiated an investigation that revealed a fungus growing within the plant (endo = within; phyte = plant) (Bacon *et al.*, 1977). Today, it is believed that

greater than 95% of tall fescue pastures containing mostly the Kentucky 31 variety are infected by the endophyte, *Neotyphodium coenophialum* (Yates and Powell, 1988). Endophyte-infected (E+) fescue is estimated to cause more than \$1 billion in lost livestock production in the United States each year (Oliver, 1997).

### BACKGROUND

#### Endophyte name

Endophytes are not uncommon in a number of forage grasses and other pasture plants, and unlike other fungal infections, such as those associated with species of *Claviceps*, they are not visible to the naked eye because they grow “within” the plant (Evans *et al.*, 2004a, 2004b). Bacon *et al.* (1977) initially discovered the endophyte and based on earlier morphologic research classified it as *Epichloë typhina*. This endophyte was later renamed *Acremonium coenophialum* (Morgan-Jones and Gams, 1982). Further molecular phylogenetic evaluation has generated the latest name for the tall fescue endophyte, *N. coenophialum* (Morgan-Jones and Gams, 1982; Glenn *et al.*, 1996), and a similar endophyte, *Neotyphodium lolii*, is found in perennial ryegrass.

#### Mutualism (symbiosis) and endophyte survival

The tall fescue plant and its endophyte enjoy a mutualistic or symbiotic relationship (Thompson *et al.*, 2001). Each benefits from the survival of the other. The plant

supplies a comforting and safe internal environment for the endophyte along with all the required nutrients. In return, the endophyte lives in intercellular spaces in the plant without disrupting cells of the plant. The endophyte generates multiple toxins that are distributed throughout the plant. The toxins make the plant more resistant to drought, insects, parasitic nematodes, fungi, and herbivores. The endophyte invades seed heads of the plant and is able to continue its relationship with the next generation of fescue through its contamination of the seed. Unlike ergotized (*Claviceps purpurea*-infected) tall fescue, endophyte infections cannot be transferred naturally to a non-endophyte-infected variety of tall fescue (Evans *et al.*, 2004a). However, E+ varieties of fescue are more hardy and persistent. They produce more forage and seeds than non-endophyte fescue plants and, thereby, may eventually take over a pasture.

## Endophytic toxins

Multiple classes of toxins are produced by *N. coenophialum*, including ergot alkaloids, loline alkaloids, and peramine (Porter, 1995). Loline alkaloids and peramine are primarily insect deterrents. Loline alkaloids belong to an aminopyrrolizidine group of alkaloids but are not known to cause hepatic problems similar to the pyrrolizidine alkaloids in other plant species. The loline alkaloids found in fescue include loline, *N*-acetyl loline, *N*-formyl loline, *N*-acetyl norloline, and *N*-methyl loline (Porter, 1994). Several of these compounds, particularly *N*-acetyl norloline, have been associated with equine fescue edema syndrome involving a genetically modified form of *N. coenophialum* in the Mediterranean variety of tall fescue (Bourke *et al.*, 2009).

## Ergot alkaloids

### General classification and toxicity

The ergot alkaloids are a large class of compounds, for which the nomenclature can sometimes be confusing. Ergot alkaloids found in fescue include the lysergic acid amides (e.g., ergonovine), sometimes also referred to as ergoline alkaloids; the clavine alkaloids; and the peptide or peptine alkaloids (Porter, 1995; Evans *et al.*, 2004b; Strickland *et al.*, 2011). Ergovaline is a peptide or ergopeptide (i.e., peptine or ergopeptine) alkaloid with a lysergic acid structure combined with three amino acids. It differs in structure from ergotamine by one amino acid. Among the ergot alkaloids found in tall fescue, ergovaline is by far the most prevalent ergopeptide (Porter, 1995). It accounts for approximately 90% of the ergopeptide alkaloid content of tall fescue (Lyons *et al.*, 1986). The

concentrations of ergovaline in the stems and leaves of tall fescue usually range between 200 and 600 ppb and in the seed heads from 2000 to 4000 ppb (Evans *et al.*, 2004b). Estimates of the minimum threshold toxic concentrations of ergovaline in fescue, which have the potential to cause clinical problems in livestock, range from 50 to 500 ppb (Moubarak *et al.*, 1993; Tor-Agbidye *et al.*, 2001; Aldrich-Markham *et al.*, 2003; Evans *et al.*, 2004b). These minimal threshold concentrations depend on the species affected, the type of syndrome being considered, and environmental temperatures, and they will most likely vary with geographical location. Species susceptibility from most to least susceptible is as follows: horses (i.e., late-gestational mares) > cattle > sheep > camelids (Aldrich-Markham *et al.*, 2003; Evans *et al.*, 2004b). In general, total dietary ergovaline concentrations greater than 100–200 ppb on a dry weight basis are potentially toxic for cattle and horses, depending on other contributing factors (Rottinghaus *et al.*, 1991; Blodgett, 2001; Evans *et al.*, 2004b). The clinical signs observed following animal exposure to ergopeptide alkaloids are dependent on animal species and physiological state, environmental conditions, relative toxicities of and interactions between different ergopeptide alkaloids, and the level as well as duration of ergopeptide alkaloid exposure (Evans *et al.*, 2004b). For example, dietary concentrations of ergovaline as low as 50 ppb have been associated with clinical cases of agalactia in mares.

### Role of ergovaline in fescue toxicosis

The ergopeptide alkaloids are believed by many to be the major toxins responsible for the multiple fescue toxicosis syndromes observed in animal species (Porter and Thompson, 1992; Evans *et al.*, 2004b). Because ergovaline is the most prominent ergopeptide alkaloid, it probably either dictates the likelihood of a toxicosis occurring or, at least, is a reliable biomarker for toxicity. Ergovaline has traditionally been difficult to purify and synthesize, and therefore little research has been done with pure ergovaline to prove that it is the primary toxin in fescue. Although subject to some debate, there are multiple reasons to believe that ergovaline is the primary toxin or, minimally, at least serves as a biomarker for the content of ultimate toxicant in E+ fescue. An experiment with synthetic ergovaline in sheep reproduced most clinical signs of the summer slump syndrome seen in cattle (Gadberry *et al.*, 2003). Ergovaline injected intraperitoneally into cattle for 3 days produced increased rectal temperatures and respiratory rates observed with summer slump (Spiers *et al.*, 2005a,b). Other ergopeptide alkaloids, including ergotamine and bromocryptine, are also able to reproduce fescue toxicosis syndromes (Evans *et al.*, 1999, 2004b; Blodgett, 2001). Ergovaline is a very potent vasoconstrictor in *in vitro* models (Oliver *et al.*, 1998). In addition, ergovaline is also a strong prolactin

inhibitor, whereas ergonovine, a lysergic acid amide in E+ fescue, is unable to produce typical signs of fescue toxicosis or lower prolactin concentrations in cattle (Oliver *et al.*, 1994). Antibodies against ergot alkaloids, including – to some extent – the ergopeptine alkaloids, are able to ameliorate some clinical features of fescue toxicosis in cattle and mice (Hill *et al.*, 1994; Rice *et al.*, 1998). New, novel endophyte varieties of fescue that lack ergovaline, but not other types of fescue endophytic toxins, do not cause fescue toxicosis (Roberts and Andrae, 2004). Syndromes similar to fescue toxicosis are seen when ergotized grains infected by *C. purpurea* are ingested by livestock (Thompson *et al.*, 2001; Evans *et al.*, 2004a). Finally, it has been shown that D<sub>2</sub> dopamine antagonists, which stimulate prolactin secretion, are able to alleviate most of the toxic effects of fescue (Lipham *et al.*, 1989; Cross, 1997; Evans *et al.*, 1999). With improved analytical capabilities, it might be possible in the future to discern more accurately the exact roles of specific ergot alkaloids and their various isomers in the pathogenesis of fescue toxicosis (Strickland *et al.*, 2011).

#### Seasonal variation

The concentration of ergot alkaloids in fescue pastures varies with the season, with ergovaline concentrations reported to be low in the spring (300–500ppb) and reaching peak concentrations in seed heads (up to 1000–5000ppb) during the summer months (Rottinghaus *et al.*, 1991). Concentrations of ergovaline decrease somewhat during the early fall and rebound with fall regrowth. Seed heads consistently contain the highest concentration of ergovaline. Stockpiled fescue pasture has more ergot alkaloids early in the winter than late in the winter (Roberts and Andrae, 2004). Drought and rainy conditions tend to increase ergovaline concentrations (Arechavaleta *et al.*, 1992; Aldrich-Markham *et al.*, 2003). Fertilization of fescue pastures with nitrogen- and phosphorus-based fertilizers or poultry litter also increases ergot alkaloid concentrations (Stuedemann and Seman, 2005). Because ergovaline is a mycotoxin and mycotoxin production and persistence are dependent on multiple seasonal and environmental conditions, it is not surprising that concentrations of ergovaline in tall fescue would be expected to vary from season to season and year to year (Lyons *et al.*, 1986).

#### Interactions with *Claviceps purpurea*

Although ergotism in livestock is sometimes considered a historical problem, instances of clinical disease associated with the ingestion of ergotized small grains or pasture grasses, including E+ and non-endophyte-infected tall fescue, continue to occur in the United States (Evans,

*et al.*, 2004a,b). This is especially true when grain or grass screenings (fines) are used in feedstuffs. Because of the much higher concentrations of ergopeptine alkaloids present in ergot sclerotia, compared to endophytic mycelia, it is important to evaluate the potential for ergotism in instances in which the typical clinical signs of fescue toxicosis appear to be less dependent on environmental temperature or there is no history or evidence of exposure to E+ fescue (Evans *et al.*, 2004a).

## PHARMACOKINETICS/ TOXICOKINETICS

### Absorption

Although relatively little research has been devoted to *in vivo* absorption of ergot alkaloids in livestock species, a growing body of literature involving the pharmacokinetics/toxicokinetics of ergot alkaloids provides at least some additional insight into how ergot alkaloids are handled by the body following oral exposure (Strickland *et al.*, 2011). The rumen and small intestine are most likely the principal sites of ergot alkaloid uptake, which, depending on pH, animal species, and physiological state, can involve both passive and active processes. After cannulation of ruminal, gastric, and mesenteric veins of sheep consuming E+ fescue, ergot alkaloids were detected only in ruminal veins (Hill, 2005). However, *in vitro* tissue specimens of rumen, reticulum, and omasum are all capable of ergot alkaloid transport. It is currently thought that most of the gastrointestinal absorption of the ergopeptine alkaloids takes place in the small intestine (Strickland *et al.*, 2011). Ergovaline is difficult to detect in rumen fluid and is metabolized by rumen microbes to lysergic acid. Other researchers have found that although 50–60% of ingested ergovaline is in the abomasal contents, minimal amounts of ergovaline remain in the ileal contents or feces (Oliver, 1997).

### Distribution/metabolism

Ergovaline is present only in parts per billion or low parts per million concentrations in E+ tall fescue, so the dilution factor in the body and sensitivity of various methods make evaluation of the concentration in any organ extremely difficult. Therefore, relatively little is known about the distribution of ergovaline and other ergot alkaloids in the body. Intravenous injection of several ergopeptides in calves documented a distribution and tissue equilibrium phase in serum lasting approximately 1 h (Moubarak *et al.*, 1996). This was followed by

an elimination phase with a half-life of approximately 20–30 min. It is known that multiple systems in the body may show some effects of ergot alkaloid consumption, including the cardiovascular system, central nervous system, and abdominal fat. There is evidence that ergopeptine alkaloids accumulate in adipose tissue, but experimental results have not been entirely consistent (Strickland *et al.*, 2011). In ruminants, ergovaline undergoes microbial breakdown to lysergic acid and related compounds. Ergovaline is believed to be metabolized in the liver by the cytochrome P450 3A subfamily of enzymes (Moubarak and Rosenkrans, 2000; Moubarak *et al.*, 2003; Settivari *et al.*, 2008; Strickland *et al.*, 2011). Cytochrome P450 3A4 is responsible for adding one or two hydroxyl groups to the peptide ergoline ring to make it more hydrophilic for excretion (Moubarak and Rosenkrans, 2000). Interestingly, this enzyme family is inducible in rats treated with dexamethasone but is not induced in rats with prior ergot alkaloid exposure (Moubarak *et al.*, 2003). However, CYP450 induction has been shown in *in vitro* studies (Settivari *et al.*, 2008), and sheep fed E+ fescue had increased hepatic activity of mixed function oxidases (Zanzalari *et al.*, 1989). The indole ring of ergopeptine alkaloids may also undergo eventual oxidation (Moubarak and Rosenkrans, 2000). Whether or not other groups of enzymes are involved in metabolizing or conjugating ergovaline is not known.

## Excretion

Urine, bile, feces, and, to a much lesser extent, milk are the primary routes of elimination and excretion for ergot alkaloids (Strickland *et al.*, 2011). Metabolites of ergot alkaloids have been measured indirectly with lysergol antibodies in bile and urine of cattle (Stuedemann *et al.*, 1998). Ninety-six percent of the metabolites in cattle are found in urine. Ergot alkaloids are detected in urine within 12 h of exposure to E+ fescue and are maximal within 24 h. After removal from a fescue pasture, ergot metabolites are gone within 48 h from the urine of cattle. Similarly, when removed from pastures containing E+ fescue, post-term mares may show signs of mammary development and impending parturition within 48 h of removal from pasture (Schmidt and Osborn, 1993).

## MECHANISMS OF ACTION

### D<sub>1</sub> dopaminergic antagonist

Activation of D<sub>1</sub> dopamine receptors has been reported to be associated with vasodilation, and antagonism of

these receptors has been reported in conjunction with ergot alkaloids (Cross *et al.*, 1995). The precise role of this mechanism in the gangrene of the extremities described later has not been determined.

### D<sub>2</sub> dopaminergic agonist

#### *Prolactin inhibition*

Ergovaline is a dopamine D<sub>2</sub> receptor agonist (Oliver, 1997). Ergopeptine alkaloids have a 10-fold greater affinity for dopamine D<sub>2</sub> receptor binding than do ergoline alkaloids (Larson, 1997). Dopamine agonists mimic the endogenous tonic inhibition of pituitary lactotropes by dopamine and inhibit prolactin secretion by the anterior pituitary. Prolactin inhibition is one of the most consistent problems observed in multiple species exposed experimentally to ergopeptine alkaloids and/or experiencing clinical fescue toxicosis. In essence, this effect of ergovaline and other ergot alkaloids is an exquisite, naturally occurring example of “endocrine disruption” and is a sensitive biomarker for exposure to these compounds.

#### *Lactation suppression*

One of the roles of prolactin is induction of mammary gland growth and milk production (i.e., lactogenesis). Hypoprolactinemia is often associated with agalactia at parturition in many species, especially the horse and pig. Ruminant species have a placental lactogen that can overcome this initial lack of prolactin stimulation of the mammary gland prior to and at birth (Cross, 1997). However, lower prolactin concentrations in dairy and beef cows consuming E+ fescue, as well as diminished feed intake associated with the ingestion of E+ fescue, can be reflected by decreased milk production (up to 50%) observed after the perinatal period (Schmidt and Osborn, 1993; Thompson *et al.*, 2001; Evans *et al.*, 2004b).

#### *Effect on other reproductive hormones*

Prolactin facilitates corpus luteal function and gonadotropin secretion (Porter and Thompson, 1992). Altered luteal function in heifers grazing E+ fescue can result in reduced progesterone. Consumption of E+ fescue and ergopeptide exposure have been associated with low progesterone production in both cows and horses, diminished progestagens in late-gestational mares (5 $\alpha$ -pregnanes rather than progesterone normally predominate the last two trimesters of equine pregnancy), suppressed relaxin associated with possible impaired placental function, and, somewhat more variable, alterations in estrogen concentrations in pregnant mares (Cross, 1997; Evans *et al.*, 1999; Thompson *et al.*, 2001; Evans, 2011). These imbalances of reproductive

hormones lead to early pregnancy problems in cattle and late pregnancy problems in horses. Ergopeptide potency for prolactin inhibition has been correlated with inhibition of ovum implantation in rats (Fluckiger *et al.*, 1976). Ergovaline is intermediate among the ergopeptides in its ability to inhibit implantation, but it is approximately twofold more potent than ergotamine.

#### *Effect on hypothalamic thermoregulatory center*

Another role of dopamine and/or prolactin is control of the thermoregulatory center in the hypothalamus (Strickland *et al.*, 1993). Diminished prolactin and/or dopamine receptor perturbation causes the thermoregulatory center to deregulate and contributes to the development of hyperthermia or hypothermia observed in exposed animals. Deregulation is more likely when environmental temperatures are outside of the thermoneutral range of the animal (Spiers *et al.*, 2005a,b). Fescue foot problems are more likely at temperatures less than 8°C (Tor-Agbidye *et al.*, 2001), whereas summer slump problems are more apparent when temperatures exceed 31°C (Schmidt and Osborn, 1993; Spiers *et al.*, 2005a,b).

#### *Effect on lipogenesis*

Prolactin also has a role in lipogenesis through control of metabolism of cholesterol and triglycerides by the liver (Strickland *et al.*, 1993). Cattle suffering from summer slump traditionally have low serum cholesterol and triglyceride concentrations (Oliver, 1997). Low serum cholesterol is also commonly found in cattle herds with abdominal fat necrosis (Schmidt and Osborn, 1993). Necrotic abdominal fat is lower in ether-extractable material, but it has a much higher cholesterol content of the ether-extractable fraction. Lipolysis in cattle experiencing fescue toxicosis is decreased (Thompson *et al.*, 2001). Metoclopramide, a dopamine antagonist and prolactin enhancer, increases serum cholesterol levels in steers grazing E+ fescue pastures (Lipham *et al.*, 1989). Serum triglycerides and cholesterol are also reduced by  $\alpha_1$  adrenergic receptor antagonists and  $\alpha_2$  adrenergic agonists, which are both physiologic effects of ergot alkaloids (Oliver, 1997).

#### *Effect on winter hair loss*

Change in photoperiod with the end of winter and the start of spring normally will increase prolactin production and stimulate shedding of long winter hair in favor of new spring hair coat growth (Thompson *et al.*, 2001). Associated with a decrease in prolactin, cattle experiencing fescue toxicosis often fail to shed some or all of their long winter hair. This long hair may become bleached out by the summer sun and contributes to an unthrifty appearance. In addition, fescue toxicosis has

been associated with alterations in copper homeostasis (probably associated with decreased feed intake), which most likely also contributes to the discolored appearance of the hair coat in animals on E+ fescue pasture.

#### *Effect on immunity*

Prolactin is considered an immunomodulator (Strickland *et al.*, 1993). Impaired immune function from E+ fescue seed was noted in mice and rats, whereas cattle were not affected. However, numerous other E+ fescue studies in cattle cite decreased antibody response, reduced globulins, or increased morbidity and mortality (Thompson *et al.*, 2001). In contrast, Rice *et al.* (1997) noted increased humoral immunity in cattle fed E+ fescue.

#### *Miscellaneous neurologic effects*

Other miscellaneous neurologic effects include a consistently negative effect of dopamine agonists on feed intake, which can have a major impact on consumption of both macro- and micronutrients. Ergopeptide alkaloids may also interfere with gastrointestinal motility, and there evidence that at least motility of the reticulo-rumen compartment is inhibited by these compounds (Strickland *et al.*, 2011). Use of a dopamine antagonist, metoclopramide, increased feed intake in lambs fed E+ fescue without an effect on body temperature (Thompson *et al.*, 2001). Nervous behavior in cattle fed E+ fescue might be related to the ability of ergopeptide alkaloids to release dopamine in *in vitro* synaptosomal preparations (Larson, 1997).

### $\alpha_1$ Adrenergic antagonist

Ergopeptide alkaloids are  $\alpha_1$  adrenergic receptor antagonists as well as  $\alpha_2$  receptor agonists (Oliver, 1997). Many of the most characteristic clinical effects of ergopeptide alkaloids are easily described in terms of  $\alpha_2$  receptor agonism (discussed later). The assessment of the net effects of interactions between ergot alkaloids and adrenergic receptors in the animal requires that the antagonistic effects of these compounds on  $\alpha_1$  receptors be interpreted in light of the endophytic toxins' agonistic effects on  $\alpha_2$  receptors.

### $\alpha_2$ Adrenergic agonist

#### *Vasoconstriction*

#### *Gangrene of extremities*

Ergovaline acts as a potent  $\alpha_2$  adrenergic agonist on blood vessels, especially arterioles (Oliver, 1997). The persistent vasoconstriction of peripheral arterioles in

the back legs of cattle consuming fescue is believed to be responsible for thickening of the smooth muscle wall of the arterioles seen with fescue foot problems (Thompson *et al.*, 2001; Strickland *et al.*, 2011). Chronic exposure of cattle to E+ fescue makes their  $\alpha_2$  adrenergic receptors more reactive to ergot alkaloids (Oliver, 1997).

#### *Decreased heat loss*

Constriction of blood vessels in the skin of cattle also contributes to hyperthermia during the summer months. In addition to the thermoregulatory effects of dopamine/prolactin on the hypothalamus, the decreased dissipation of heat through the skin of cattle is believed to contribute to the higher body temperature observed when summer temperatures are at or above 30°C (Thompson *et al.*, 2001).

#### *Serum enzyme decrease*

Multiple serum enzyme decreases in cattle have been associated with inhibition of adenylyl cyclase levels due to  $\alpha_2$  adrenergic activity of ergovaline (Oliver, 1997). Ergovaline inhibits cyclic AMP production via the  $\alpha_{2a}$  adrenergic receptor (Larson, 1997). In addition to the aforementioned decrease in serum cholesterol and triglycerides, there are also decreases in alkaline phosphatase,  $\gamma$ -glutamyltransferase, aspartate aminotransferase, alanine aminotransferase, creatinine kinase, lipase, and lactic dehydrogenase (Oliver, 1997). Potentially, the inhibition of ATPase in brain and kidney may be mediated by the same mechanism (Moubarak *et al.*, 1993).

#### *Oxidative stress*

A few studies have noted oxidative stress effects in cattle grazing E+ fescue pastures (Oliver, 1997).  $\alpha_2$  Adrenergic receptor agonists have the capability of depleting glutathione, a peptide integral in defending against oxidative stressors. Lakritz *et al.* (2002) noted reduced glutathione concentrations in whole blood samples from cattle exposed to heat stress and E+ fescue. Settivari *et al.* (2008) observed decreases in antioxidant proteins following exposure to endophytic toxins.

#### *Renal-related effects*

$\alpha_2$  Adrenergic receptor agonists decrease antidiuretic hormone release by the pituitary (Oliver, 1997). This causes an inability of cattle to concentrate their urine. Ergot alkaloids also block aldosterone production in the adrenals (Oliver, 1997). Decreased aldosterone and antidiuretic hormone promote diuresis, and cattle coming to feedlots from E+ fescue pastures have a reputation for producing a muddy wallow in their pens. Aldosterone action could also be compromised by lowered kidney

sodium/potassium-ATPase activity seen with ergot alkaloid exposure (Oliver, 1997).

### **Serotonergic agonist**

Ergot alkaloids also act on serotonergic<sub>2</sub> receptors (Oliver, 2005). Ergovaline is an agonist at serotonergic<sub>2</sub> receptors of uterine and umbilical arteries (Dyer, 1993). This serotonergic activity in blood vessels causes persistent vasoconstriction *in vitro*. Serotonergic activity of ergot alkaloids may also be important in the enhanced mitogenesis of vascular smooth muscle, hypothalamic thermoregulatory center effects, pulmonary vasoconstriction and bronchoconstriction, and, importantly, the appetite suppression seen with fescue toxicosis (Oliver, 1997, 2005).

## **TOXICITY**

### **Seasonal variation and effects of decreased feed intake**

#### *Cattle*

##### *Summer slump*

Summer slump or summer syndrome is the most common and costly syndrome seen in cattle with fescue toxicosis. Although it is most dramatic during the summer when environmental temperatures reach above 31°C, the problem has been reported to occur during other times of the year as well, but the possibility of concurrent exposure to ergot was not ruled out in these instances (Schmidt and Osborn, 1993; Stuedemann and Seman, 2005). Slump refers to the fact that cattle just “ain’t doing right.” Cattle have an unthrifty appearance with rough hair coats that often have not shed from the winter. The sun may bleach out the hair coats. Because of their high body temperatures, cattle spend more time in the shade or watering holes during the day and less time consuming forage. Beef cows consuming E+ fescue produce approximately 50% less milk for their calves, which results in lower weaning weights (Schmidt and Osborn, 1993). At weaning time, calves raised on E+ fescue pasture may be 30–40kg lighter than similar calves on endophyte-free forage (Schmidt and Osborn, 1993). Other potential clinical signs include nervousness, increased salivation, increased rate of respiration, delayed puberty, and reduced conception rates, possibly arising from adverse effects on the male as well as the female (Schmidt and Osborn, 1993; Looper *et al.*, 2009; Strickland *et al.*, 2011). The reduced conception rates are

thought to occur in cattle during the early embryonic period and are generally not associated with late-term abortions or stillborn calves (Thompson *et al.*, 2001). Although sudden deaths during hot summer months have been reported, negligible mortality is associated with summer slump arising from ingestion of endophytic toxins alone, without concurrent exposure to ergopeptine alkaloids produced by *C. purpurea*.

#### *Fescue foot*

Fescue foot refers to a syndrome seen in cattle during the late fall or winter months, which is reported to occur when dietary ergovaline concentrations exceed 400 ppb (Tor-Agbidye *et al.*, 2001). However, the minimum threshold concentrations of ergovaline necessary for the development of fescue foot are very likely temperature dependent and will vary with geographical region. Peripheral vasoconstriction arising from cold environmental temperatures is additive to the vasoconstrictive properties of ergot alkaloids. However, fescue foot is not as common as summer slump, and determinants other than environmental temperature probably exist that help predict whether fescue foot or summer slump is observed clinically. Differences in concentrations of ergovaline or other vasoconstrictive ergot alkaloids, as well as a host of other factors, probably play a role. Vasoconstriction tends to be more severe in rear legs than in the front legs. The switch of the tail and sometimes the tips of the ears are also affected. Vasoconstriction of the back legs is between the coronary band of the hooves and the fetlock area. Areas proximal to the vasoconstriction may be congested, and areas distal to the vasoconstriction undergo gangrenous necrosis, with hooves potentially being sloughed. Affected cattle have visibly swollen rear legs, with shifting rear leg lameness, muscle tremors, rough hair coats, knuckling of the pastern, arching of the back, and eventually, if severe enough, the inability to stand and ambulate (Spiers *et al.*, 2005a,b).

#### *Lipomatosis*

Lipomatosis is a syndrome of fat necrosis affecting abdominal fat stores in mature cattle (Burrows and Tyrl, 2001; Schmidt and Osborn, 1993). If mesenteric fat surrounding intestines is involved, scanty feces, bloat, or intestinal obstruction may result. Perirenal fat may also be affected with or without causing significant clinical problems. Fat in the pelvic canal may become necrotic and hardened and cause dystocia. Although the hardened fat may sometimes be detected by rectal palpation, the discovery is often made at necropsy as an additional finding unrelated to the animal's death. The incidence of fat necrosis in cowherds is highest in those herds with the lowest concentrations of serum cholesterol (Stuedemann and Seman, 2005).

#### *Small ruminants*

Sheep may be affected by fescue and have a syndrome very similar to summer slump in cattle. Ewes grazing fescue have decreased milk production and increased early embryonic mortality (Schmidt and Osborn, 1993; Thompson *et al.*, 2001). Weight gain and skin temperature in young lambs may be decreased (Gadberry *et al.*, 2003). Fescue foot problems are possible in sheep with threshold dietary concentrations of 500 ppb ergovaline at environmental temperatures equal to 7.8°C (Tor-Agbidye *et al.*, 2001). In addition, ergot alkaloids have also been associated with tongue necrosis, along with infertility problems, in sheep (Thompson *et al.*, 2001). There are also reports of goats and deer experiencing lipomatosis (Evans *et al.*, 2004b; Smith *et al.*, 2004).

#### *Horses*

##### *Gestational abnormalities*

Reproductive problems are the most common E+ fescue-related abnormalities noted in horses (Cross, 1997; Blodgett, 2001; Evans, 2011). Late-term abortion is possible but not common. Pregnant mares are most susceptible to adverse effects associated with ingestion of E+ fescue after day 300 of gestation ("average" gestational length of 335–345 days). Lack of prolactin in the late-gestational mare, along with decreased progestagens and higher or lower than normal estrogen concentrations, can cause problems in the mare and/or foal (Cross, 1997; Blodgett, 2001; Evans *et al.*, 2004b; Evans, 2011). Failure to remove mares from fescue pasture or hay during the last month of gestation (30 days prior to a mare's expected foaling date; approximately day 300 of pregnancy) might result in foal abnormalities, prolongation of pregnancy by 20–27 days or more, and/or, at least, agalactia (Cross, 1997; Blodgett, 2001; Evans *et al.*, 2004b). "Fescue foals" can be smaller than average or normally sized and are predisposed to dysmaturity (birth of dysmature or "dummy" foals). Especially in instances of endophytic toxin-induced prolonged gestation, foals can continue to grow and are likely to become "overmature." Overmature foals are similar to dummy foals (i.e., slow to stand and suckle, and predisposed to failure of passive transfer and septicemia), but they are generally larger than "normal"-sized foals, with prematurely erupted teeth and overgrown hooves. In situations involving larger than normal foals, which are often "not ready" for birth and postnatal survival, the mare frequently does not prepare well for parturition, and the incidence of dystocia increases dramatically, resulting in possible uterine, cervical, and/or vaginal trauma. In addition, the chorioallantois (i.e., the portion of the equine fetal membranes diffusely attaching to the uterus) might be thickened and edematous and not rupture at the cervical

star, as is normal. The chorioallantois might also detach prematurely and precede the foal through the birth canal, presenting as a “red bag.” If the foal is able to successfully break out of the edematous chorioallantois and/or amnion and not suffocate, it invariably faces an agalactic mare with minimal colostral antibodies for passive transfer (Cross, 1997; Blodgett, 2001). In these unfortunate circumstances, the mare and/or particularly the foal can die, and if the mare survives, she frequently experiences rebreeding problems. Retained fetal membranes are also more common with fescue toxicosis.

#### *Subfertility*

One study noted increased early equine embryonic mortality with exposure to E+ fescue (Brendemuehl *et al.*, 1994), and depressed endogenous catecholamine activity has been observed in mares exposed to E+ fescue early in gestation (Youngblood *et al.*, 2004). However, other studies have found no increased equine pregnancy loss up to day 300, despite lower progestagen concentrations between gestational days 90 and 120 (Brendemuehl *et al.*, 1996). In general, equine pregnancy rates are usually fairly good on E+ fescue pasture, as long as mares have progressed through the transitional phase in the early spring and are already cycling normally and they are not currently being exposed to ergotized grains or grasses (Evans *et al.*, 2004b). The adverse effects of E+ fescue toxins on stallion reproductive function remain to be demonstrated, although any observed hyperthermia has the potential to decrease semen quality.

#### *Laminitis*

Endophytic toxins can predispose horses to laminitis or painful inflammation of the dermal laminae within the hoof, a condition that can result in potentially life-threatening lameness (Rohrbach *et al.*, 1995).

#### *Camelids (llamas and alpacas)*

Little research has been done with respect to fescue toxicosis in camelid species. Llamas and alpacas can have hyperthermia problems during summer months. Because endophytic toxins can directly affect the thermoregulatory center in the hypothalamus and decrease dermal heat loss via vasoconstriction, E+ fescue should be considered a potential contributor to the heat “stroke” or stress syndrome sometimes seen in llamas and alpacas.

#### *Laboratory rodents*

Although rodents are most likely not naturally exposed to ergopeptine alkaloids, research performed with these species has facilitated initial research evaluating the genomic effects of these compounds (Settivari *et al.*, 2006). Like cattle, rats ingesting E+ rations

experience diminished dry matter intake, making them an appropriate and practical model to evaluate the physiological effects of endophytic toxins associated with summer slump, especially those related to restricted caloric intake (Spiers *et al.*, 2005a,b).

## TREATMENT

### **Nonspecific treatment/prevention for bovine fescue toxicosis**

Cattle experiencing summer slump toxicosis are generally unthrifty and are treated by removal from E+ fescue or by dilution of the ergovaline content of their overall diet. Dilution can be accomplished by feeding supplemental nonfescue forage or concentrates. Clovers or bermudagrass are often oversown into fescue pastures to aid in dilution for a few years (Thompson *et al.*, 2001). Ergot alkaloid concentrations decrease fairly rapidly in E+ fescue following cutting so that waiting at least 1 month after clipping E+ fescue to feed it to cattle is a practical way to control ergovaline exposure (Roberts *et al.*, 2009). Abnormal copper homeostasis related to decreased feed intake can be addressed by copper supplementation (Stewart *et al.*, 2010). Providing shade and water holes can help to cool hyperthermic animals. Some researchers have investigated the use of heat stress-resistant breeds or lineages of cattle to lessen the impact of summer slump. Gangrenous problems with fescue foot are treated with broad-spectrum antibiotics to diminish secondary infection, and the provision of windbreaks or shelter, in particularly cold climates, might be beneficial.

### **Specific treatment for fescue toxicosis in various species**

A D<sub>2</sub> dopamine antagonist that does not cross the blood-brain barrier and cause extrapyramidal side effects, as opposed to perphenazine and metoclopramide, has been developed to treat agalactia and prolonged gestation problems in mares (Cross, 1997). The generic name of the drug is domperidone, and it is marketed as an oral gel called Equidone. It is commonly given orally at 1.1 mg/kg once a day during the week before anticipated parturition if the mare shows no signs of milk production or at a point in time when it is determined that gestation is prolonged. The total dose or dosing regimen can be adjusted if the mare begins dripping colostrum. Agalactia in a mare that has already foaled can be treated once or twice a day with the same dosage mentioned previously until milk flow resumes. Experimentally, cattle

have been treated successfully with domperidone to relieve some of the adverse effects of E+ fescue on cattle production, and other forms of pharmacologic intervention have also been investigated (Jones *et al.*, 2003; Strickland *et al.*, 2011). Domperidone has also been given empirically to agalactic camelids at twice the equine dosage, but there are no peer-reviewed reports of the absorption of domperidone in these species or the efficacy of this treatment approach for agalactia. The Rauwolfian alkaloid reserpine (dose of 2.5–5.0 mg/450 kg horse, once a day), which depletes brain depots of dopamine, serotonin, and/or norepinephrine and causes mild sedation, can be used for the treatment of postparturient agalactia but not for less than anticipated mammary development prior to foaling or prolonged gestation associated with exposures to E+ fescue or other ergopeptine alkaloids (Evans *et al.*, 1999; Evans, 2011).

## PREVENTION

### Prevention of equine fescue toxicosis

#### *Breeding and foaling management*

Knowledge of breeding dates, confirmation of pregnancy, and monitoring of mammary gland development are critical steps in the prevention of equine fescue toxicosis. Removal of the mare from E+ fescue pasture and hay beginning on gestational day 300, during at least 30 days prior to the anticipated foaling date, will also generally prevent agalactia, prolonged gestation, and foaling problems associated with endophytic toxin exposure. Careful evaluation of mammary gland development, supervision of the mare during foaling (with assistance provided as necessary), and observation of the foal for normal postnatal behavior benchmarks, such as the ability to stand and suckle, as well as successful passive transfer, are also essential steps in ensuring that both the mare and the foal have not been exposed to or adversely affected by exposure to tall fescue endophytic ergopeptine alkaloids (Evans, 2011).

#### *D<sub>2</sub> dopamine receptor antagonists*

In some specific instances and geographical location, it is almost impossible to completely remove mares from any exposure to E+ fescue and/or hay. Domperidone can be given once a day to mares kept on fescue during the final 10–14 days before expected parturition (Cross, 1997). The dosage is the same as that for the treatment outlined previously. The D<sub>2</sub> dopamine receptor antagonist fluphenazine (25 mg administered intramuscularly in pony mares on day 320 of gestation) has

also been used to prevent decreases in relaxin related to ergopeptine alkaloid-induced placental dysfunction (Evans, 2011).

### Novel or non-endophyte-infected fescue

Endophyte-infected tall fescue pastures can be replanted with other grasses, such as non-endophyte fescue or new novel varieties of endophyte-infected fescue. Renovation requires a nonselective herbicide (e.g., paraquat and glyphosate) to kill off the pasture grasses and planting with a smother crop for a season before spraying again with a herbicide and replanting with another pasture grass (Roberts and Andrae, 2004). Estimated costs of renovation are approximately \$450/ha (Fribourg and Waller, 2005). Non-endophyte-infected fescue has been used to replace E+ fescue, but it is not very drought, insect, nematode, or herbivore resistant; therefore, stand persistence is not good. Novel endophyte varieties have been developed by infecting endophyte-free varieties of fescue with endophytic strains that produce the peramine of tall fescue but minimal or no ergot alkaloids (Roberts and Andrae, 2004; Fribourg and Waller, 2005). Several varieties have shown promise, including MaxQ and ARK Plus, with the novel varieties having insect and drought resistance without adversely affecting cattle, horses, or sheep. However, caution is warranted until more information is available, given the incidence of equine fescue edema syndrome in Australia. This newly reported syndrome occurred, following drought-like conditions, in horses grazing the Mediterranean variety of tall fescue infected with a novel endophyte (Bourke *et al.*, 2009).

### Ammoniation of hay

Ammoniation of hay will degrade the ergovaline content of hay and make it safe for livestock consumption (Thompson *et al.*, 2001). Ammoniation requires enclosing the hay in an airtight tent structure and pumping anhydrous ammonia gas into the tent for a period of time. Although extremely effective, this process is considered by some to be too time- and labor-intensive, as well as too costly, for routine use. However, there are regions of the United States, where cattle populations are large enough and E+ fescue pastures sufficiently extensive, which might warrant the investment of the labor, time, and money necessary for proper ammoniation E+ fescue hay (Evans *et al.*, 2004b; Roberts and Andrae, 2004).

### Feed supplements

Supplementing livestock with concentrates will decrease the overall dose of ergovaline from fescue. Several different

types of feed additives have also been investigated as ways to ameliorate fescue toxicosis. A glucomannan product (FEB-200) from yeast cell walls that is purported to bind ergovaline in the gastrointestinal tract and prevent its absorption improved cattle performance (Fribourg and Waller, 2005). Another feed supplement from seaweed, Tasco, has been reported to ameliorate some of the oxidative effects and immunosuppression associated with exposure of cattle to E+ fescue (Fike *et al.*, 2001; Saker *et al.*, 2001). Copper supplementation can be beneficial in cattle ingesting E+ fescue (Evans *et al.*, 2004b).

### Pasture considerations

Pastures might be made less toxic by dilution with other grasses or legumes such as bermudagrass or clover, cutting seed heads from the pasture during the most toxic time period of the summer, or increasing the grazing pressure during the summer to avoid seed heads (Stuedemann and Seman, 2005). Provision of plenty of shade, potable water to drink, and water holes in which to cool off or moving cattle to a nonfescue pasture during the warmest summer months are also reasonable management practices that take into consideration pasture circumstances.

## CONCLUDING REMARKS

Tall fescue toxicosis is the major grass-associated forage problem in the United States and is worldwide in its occurrence (Oliver, 1997). Because the toxic principles are actually mycotoxins (i.e., secondary metabolites of a fungus), fescue toxicosis is, in fact, a mycotoxicosis rather than a plant intoxication. The production of the ergopeptine alkaloid ergovaline, potentially the primary toxin responsible for clinical disease, by the endophyte *N. coenophialum* varies seasonally and from year to year. During some years, the ergovaline concentrations in a particular fescue pasture are very high, or there is an increased prevalence of ergotized grasses, including tall fescue. In these circumstances, livestock species, especially cattle and horses, can experience debilitating disease, which can be exacerbated by extremes in ambient temperature. During other years, lower ergovaline concentrations, combined with the nutrient value and hardiness of the endophyte-infected fescue, as well as milder climactic conditions, make its use as a pasture grass or source of hay very practical and, ultimately, extremely profitable. The major disease syndromes associated with fescue toxicosis arise from the prolactin-inhibiting and vasoconstrictive properties of endophytic ergot alkaloids.

Researchers are currently addressing fescue toxicosis in several different ways. One approach is to replace tall fescue with a novel endophyte-infected fescue that is not toxic for animals but is still drought and insect resistant. This has been accomplished, but the costs of pasture renovation are considerable, with some hilly terrain not suitable for renovation. There is also the potential for other, unanticipated toxicoses to be associated with the novel endophyte, under certain growth conditions (Bourke *et al.*, 2009). The other approach to fescue toxicosis has been to find an antidote or preventative for the fescue problem. Domperidone is a suitable treatment or preventative for pregnant mares, but residue concerns will likely prevent its use in the near future for food-producing animals. Other possible preventatives for food animals are still being investigated and include adsorbents, feed supplements, and even vaccines. In addition, newer analytical procedures are being developed, which might help elucidate the precise role of ergovaline, other ergot alkaloids, and their metabolites in the pathogenesis of fescue toxicosis in various livestock species (Strickland *et al.*, 2011).

# Aflatoxins

Robert W. Coppock, Ralph R.G. Christian and Barry J. Jacobsen

## INTRODUCTION

Aflatoxins (AFs) are considered the most important mycotoxins in human foods and animal feedstuffs on a worldwide scale (Diener *et al.*, 1987; Williams, *et al.*, 2004; Strosnider *et al.*, 2006). Aflatoxin-linked adverse health effects occur in companion animals, livestock, poultry, aquatic animals, humans and other species because aflatoxins are potent hepatotoxins, immunosuppressants, teratogens, mutagens, carcinogens, and are linked with stunted growth and reproductive dysfunctions (Clegg and Bryson, 1962; Allcroft and Lewis, 1963; Robens and Richard, 1992; Eaton and Gallagher, 1994; Bennett and Klich, 2003; Shuaib *et al.*, 2010a). Aflatoxins are the most potent naturally occurring hepatic carcinogens. Many authors are of the opinion that aflatoxicosis in domestic animals is considerably under-identified, and the short- and long-term effects on human health are underestimated. It was estimated by Williams *et al.* in 2004 that ~4.5 billion people have uncontrolled chronic exposure to aflatoxins, and other authors have increased the current estimate to >5 billion people (Khangwiset and Wu, 2010). Due to the potency of aflatoxins there are increasing concerns regarding animal and human exposures. Contamination causes economic losses of corn, cottonseed, peanuts, sorghum, wheat, rice, nuts and spices condiments and other commodities. Losses also occur when processed foods and finished feeds are considered unfit for human and animal consumption.

Worldwide, aflatoxins, because of their prevalence and toxicity, are important in public health with concerns

centering on both primary poisoning from aflatoxins in commodities, food and feedstuffs and relay poisoning from aflatoxins in milk and other animal products. Aflatoxicosis in the human population, especially in areas stricken by poverty, drought and other adverse growing conditions, is an important public health problem and may be increased by climate change (Williams *et al.*, 2004; Vineis and Xun, 2009; Wild and Gong, 2010). Another public health concern is that plant-source illicit drugs may contain aflatoxins, and the interactions between aflatoxins and infectious diseases can contribute to spread of disease in this population.

Many governmental jurisdictions regulate the levels of aflatoxins allowed in animal feedstuffs and human foods because of their toxicity. The allowable levels of aflatoxins in animal feedstuffs and human foods vary with governmental jurisdictions and the perceived risk. For example, the regulated level for aflatoxins in feedstuffs for dairy animals is lower than aflatoxins in feedstuffs fed to beef cattle. Commodities considered unsafe for human foodstuffs are often incorporated into animal feedstuffs (Coppock and Swanson, 1986), and most governments have regulations allowing this diversion. Grain and other seeds used for feeding wildlife can be high in aflatoxins (Henke *et al.*, 2001) and these feedstuffs are generally under-regulated. Regulatory information for aflatoxins is generally posted on government and WHO websites. Regulatory limits for aflatoxins and other mycotoxins have been summarized in the 2003 CAST publication (CAST, 2003).

BACKGROUND

History of aflatoxins

In the late 1950s and early 1960s, aflatoxins were identified as the cause of the mysterious turkey “X” disease in Great Britain (Clegg and Bryson, 1962; Allcroft and Lewis, 1963; Richard, 2008). In the U.S., studies incriminated AFs as the cause of epizootic hepatitis in dogs and as the cause of moldy corn poisoning in pigs (Newberne *et al.*, 1966a,b). Aflatoxins were identified as a potent carcinogen in rainbow trout (Newberne and Butler, 1969). Aflatoxin linkages to human liver disease were made in the 1960s (Robens and Richard, 1992). Since these early discoveries, intensive research has shown and continues to show that the risk of exposure to aflatoxins is a world-wide animal and human health issue. Many authors are of the opinion that other fungal metabolites produced by aflatoxigenic fungi contribute to the toxicology observed under field exposure conditions (Coppock and Jacobsen, 2009).

Aflatoxigenic fungi

Varga *et al.* (2009) have reviewed aflatoxigenic species. Three sections likely account for all the aflatoxigenic species of *Aspergillus*, namely *Flavi*, *Ochraceorosei* and *Nidulantes* (Table 88.1). The most commonly recognized aflatoxigenic fungi are *Aspergillus flavus*, *A. parasiticus* and *A. nomius*; other species of *Aspergillus* have been reported to produce aflatoxins and are given in Table 88.1. Aflatoxigenic species of *Aspergillus* commonly grow in plant-source debris on the soil and can also grow in feedlot manure (Hendrickson and Grant, 1971). Insects

and wind currents spread the spores of aflatoxigenic fungi to plants and these fungi commonly colonize areas of insect damage. Management of insect pests in the order Lepidoptera is a key to reducing aflatoxin contamination in corn, cotton and some tree nuts. In corn infection can take place via silks and the subterranean flowers of peanuts can also be infected without insect injury (Griffin and Garren, 1974; Jones *et al.*, 1980). In addition to plant residues, spores, mycelia, or sclerotia of aflatoxigenic fungi are commonly found in soil, storage areas, processing facilities and in the distribution systems for manufactured products. The production of aflatoxins is associated with spore production by species of *Aspergillus* (Calvo *et al.*, 2002). Strains of *A. flavus* can vary in aflatoxin capability from nontoxic to highly toxigenic and are more likely to produce more aflatoxin B<sub>1</sub> (AFB<sub>1</sub>) than aflatoxin AFG<sub>1</sub>. *A. flavus* and other species can also produce cyclopiazonic acid (CPA). Strains of *A. parasiticus* generally have less variation in toxigenicity and generally produce AFB<sub>1</sub> and varying amounts of AFB<sub>2</sub>, AFG<sub>1</sub> and AFG<sub>2</sub>. The aflatoxin profile produced by *A. nomius* is considered to be similar to *A. parasiticus*, and like *A. parasiticus*, *A. nomius* is not known to produce cyclopiazonic acid. Recent studies have shown that *A. nomius* is more important as a product of aflatoxins than previously suspected (Johnsson *et al.*, 2008). Aflatoxigenic strains of *Aspergillus* can also produce sterigmatocystin (ST) (Table 88.1).

Conditions for aflatoxin production

The fungi associated with AF production are *A. flavus*, *A. parasiticus* and *A. nomius*, and these fungi are common in most soils and are usually involved in decay

TABLE 88.1 Species of *Aspergillus* identified as producers of aflatoxins (adapted with permission from Varga *et al.*, 2009)

Species <sup>a</sup>	Country	Mycotoxins identified <sup>b</sup>
<i>A. bombycis</i> (F)	Japan, Indonesia	AFB, AFG, KA, A-acid
<i>A. flavus</i> (F)	Ubiquitous	AFB <sub>1</sub> , AFB <sub>2</sub> , KA, CPA, others
<i>A. nomius</i> (F)	U.S., Thailand, S. America	AFB, AFG, KA, others
<i>A. parasiticus</i> (F)	Likely ubiquitous	AFB, AFG, KA, others
<i>A. parvisclerotigenus</i> (F)	Africa	AFB, AFG, CPA, KA
<i>A. minisclerotigenes</i> (F)	U.S., Africa, Australia, S. America	AFB, AFG, KA, CPA, other
<i>A. arachidicola</i> (F)	S. America	AFB, AFG, KA, CPA, others
<i>A. pseudotamarii</i> (F)	Japan, S. America	AFB <sub>1</sub> , KA CPA
<i>A. ochraceoroseus</i> (O)	Africa	AFB <sub>1</sub> , AFB <sub>2</sub> , ST, others
<i>A. rambellii</i> (O)	Africa	AFB <sub>1</sub> , AFB <sub>2</sub> , ST, others
<i>E. stellata</i> (N)	S. America	AFB <sub>1</sub> , ST, others
<i>E. olivicola</i> (N)	S. Europe	AFB <sub>1</sub> , ST, others
<i>E. venezuelensis</i> (N)	S. America	AFB <sub>1</sub> , ST, others

of plant materials (Moss, 1991; Smith and Ross, 1991; Jacobsen *et al.*, 2007). The general growth conditions for aflatoxigenic species are described as requiring moisture contents in equilibrium with 80–85% or more and temperatures of 13 to 42°C with optimum growth at 25° to 37°C (Jacobsen *et al.*, 2007). For example, the critical moisture content for growth of *A. flavus* in starchy cereal grains is 17 to 18%, soybeans 17 to 17.5% and for peanuts is 9 to 10.5% (Sauer *et al.*, 1992). The upper limit of moisture for growth of *A. flavus* and AF production is about 30%. *Aspergillus flavus* will grow slowly below 13°C, and most rapidly at 37°C, but does not produce AFs at temperatures below 13°C or above 42°C. In addition to temperature and equilibrium relative humidity, other factors that influence aflatoxin production are carbon, nitrogen, plant metabolites and sugars in substrates. High maximum and high minimum temperatures with high net evaporation are more important triggers than temperature and humidity alone. High aflatoxin production generally occurs when the fungus grows in the seed embryo. Both epigenetic and genetic factors affect aflatoxin production and the interactions are not well understood (Bhatnagar *et al.*, 2006). Aflatoxigenic *A. flavus* isolates vary from 40 to >70% of the total *A. flavus* population (Campos *et al.*, 2008). This observation has led to the use of atoxigenic *A. flavus* strains to preemptively colonize infection sites such that toxigenic strains are prevented from infecting and growing (Atehnkeng *et al.*, 2008). The percent of aflatoxigenic isolates can vary between ingredients and finished feeds, and finished feeds that have spoiled can have high primary production of aflatoxins. Growth of aflatoxigenic fungi and aflatoxin production can rapidly occur especially in damaged high moisture seeds. Experimental study on maize with 57% damaged kernels had 25 ppm AFB<sub>1</sub> at 6.5 day (Seitz *et al.*, 1982). High levels of aflatoxin production can occur in maize before a 0.5% loss in dry matter occurs. High levels of aflatoxins in corn are not linked to the production of kojic acid (black light fluorescence).

### Moisture management of grain

The most common methods of preventing the growth of aflatoxigenic fungi in dry-stored commodities are by controlling the moisture level and temperature. Water available for aflatoxigenic fungi in stored grain is best indicated by equilibrium relative humidity or water activity ( $a_w$ ) in the air around the grain (Caddick, 2003). The  $a_w$  is equal to percent relative humidity/100. Temperature of the grain is important as the  $a_w$  increases with temperature. In cereal grains aflatoxigenic fungi generally cannot grow when the  $a_w$  is below 0.80. A lower  $a_w$  is required for protection of oilseeds. Oilseeds have more available water on the seed surface

because the seed absorbs less moisture. Increasing the oil fraction of the seed decreases the water that is absorbed into the seed. For most cereal grains, storage moisture of 12% is recommended for a wide range of grain temperatures, and for oilseeds the storage moisture from <8 to 9% is recommended for a wide range of temperatures inside the storage unit since other species of *Aspergillus* can grow in commodities at lower  $a_w$  than *A. flavus*. These fungi produce both heat and metabolic water as they grow and this can create a favorable moisture and temperature for *A. flavus* to grow (Sauer *et al.*, 1992).

Measuring moisture with a grain tester provides the average moisture of the kernels. This measurement can misinterpret the storability of grain. If the moisture is heterogeneously distributed among the seeds or pellets, hot spots can occur. This phenomenon occurs because a microbial microcosm exists around each high moisture seed and that microcosm can meet the requirements for fungal growth and mycotoxin production. This is the reason why high and low moisture grain should not be blended. In the microcosm with a favorable  $a_w$  level, growth of aflatoxigenic fungi can occur. The metabolism of microorganisms in the microcosms produce moisture and some microorganisms can also produce heat. Insects and other pests in grain also produce moisture and hot spots can form because of insect and other pests in stored grain. Monitoring multiple areas of a storage unit is essential for preventing the production of mycotoxins. Samples for aflatoxin analyses should be placed in moisture-proof bags to prevent desiccation. As soon as possible after sampling, the individual moisture content of at least 100 seeds or pellets should be determined to identify moisture distribution in the kernels or pellets. This test result provides valuable insights into the storability of the commodity.

### In vivo production of aflatoxins

*Aspergillus flavus* and *A. fumigatus* have also been identified as pathogens in animals and humans (Barton *et al.*, 1992; Drakos *et al.*, 1993; Pepelnjak *et al.*, 2004). Aflatoxins can be produced in tissues by toxigenic fungi. Assays of cultured *A. flavus* and *A. fumigatus* isolated from tissues have shown these fungi can produce AFs, and chemical analyses of infected tissues have shown aflatoxins to be present (Matsumura and Mori, 1998; Mori *et al.*, 1998; Pepelnjak *et al.*, 2004). Aflatoxins being produced in tissues have not been shown to cause liver lesions typical of aflatoxicosis. Typically, aflatoxigenic fungi infect animals and humans that are immunocompromised. Systemic aspergillosis by aflatoxigenic fungi was considered to contribute to immunosuppression (Mori *et al.*, 1998). *A. nomius* has been identified as an etiology of keratitis.

## PROVENANCE OF AFLATOXINS IN FEEDSTUFFS AND FOODS

### Sources and occurrences of aflatoxicosis

Almost any food or feedstuffs that can support the growth of aflatoxigenic fungi can contain aflatoxins. Aflatoxins and their metabolites can be relayed to edible animal products. Occurrences of contaminated cows', goats' and human milk (AFM<sub>1</sub>) for human consumption have been identified. Essentially all species of domestic animals have been poisoned with aflatoxins under field conditions. Outbreaks of aflatoxicosis in pet foods including birdseed have occurred and may be under-reported (Leung *et al.*, 2006; Boermans and Leung, 2007; Rumbelha and Morrison, 2010). Birdseed and other feedstuffs for wildlife have been reported to be high in aflatoxins (Thompson and Henke, 2000; Henke *et al.*, 2001). The sources of the aflatoxins in pet foods have been primarily maize and maize byproducts, rice, millet and peanut byproducts. Food garbage, moldy bread and other diverted foods can be a source of AFs. Tree nuts, peanuts, figs, oilseeds, tobacco, coconut, condiments and spices, cereal grains, eggs, cheese and many other commodities, feedstuffs and foodstuffs have been shown to contain aflatoxins.

All cereal crops and oilseeds can contain aflatoxins and the determinant is the growth of aflatoxigenic fungi. These fungi prefer minimum temperatures of >25°C, with the abiotic and biotic microclimate of a geographic region having major effects on the genera and species of aflatoxigenic *Aspergillus* present and on production of aflatoxins (Cotty and Jaime-Garcia, 2007). Aflatoxin contamination of commodities in the field can be divided into two distinct phases. Growth of aflatoxigenic fungi and mycotoxin production occurring preharvest in the developing crop and post-harvest mycotoxin production after the crop has matured and has been harvested. In the preharvest phase, wounds in the developing crop including those caused by insects, birds, mammals and hail provide entry points for aflatoxigenic fungi. The importance of Lepidopteran insect damage is demonstrated by reductions of aflatoxin content in maize and cotton where transgenic (Bt) maize and cotton are grown, or a reduction in peanuts where the lesser stalk borer numbers are reduced, or in almonds or pistachio nuts where insects such as the orange navel worm are controlled (Mahoney and Rodriguez, 1996; Cotty *et al.*, 1997; Schatzki and Ong, 2001; CAST, 2003; Wu, 2006). Excessive heat and drought may decrease the native resistance of plants to aflatoxigenic fungi by physiological and anatomical mechanisms. Insect damage to ears, bolls, pods or nuts has been shown to dramatically increase the risk of aflatoxin production in maize, cotton, peanuts, almonds and pistachios. The post-harvest fungal invasion and aflatoxin production can occur

from maturation in the field to the point of human and animal consumption. Post-harvest aflatoxin contamination can occur when the commodity is suitable for growth of aflatoxigenic fungi at harvest during transport, storage and manufacturing. Aflatoxin contamination in wheat is essentially a post-harvest phenomenon (Jacobsen, 2010) whereas maize contamination can be either preharvest or post-harvest (Payne, 1992). Delayed harvest due to wet conditions with sufficient heat to support growth of aflatoxigenic fungi can result in high levels of aflatoxins being produced. In some tree nuts such as walnut, almond and pistachio and in cotton a natural opening in the nut hull or boll combined with delayed harvest and warm, humid conditions can result in significant aflatoxin contamination. Delayed irrigation and resulting drought stress at silking can increase the risk for aflatoxin production in maize. Damage to kernels or nuts during harvest, cleaning and general grain handling weakens the mature seeds to fungal invasion. The suitability of grain for storage at harvest is adversely affected by moisture content, physical damage to the kernels and the extent to which fungi have invaded the seed before storage (Johansson *et al.*, 2006, 2008; Coppock and Jacobsen, 2009). Moisture level is a risk factor for mycotoxins in stored commodities (Sauer *et al.*, 1992; Frisvad, 1995; Wicklow, 1995; Jacobsen *et al.*, 2007; Dorner, 2008). Blending grain of high moisture levels (moisture considered too high for safe storage) with grain of lower moisture levels (safe for storage) can produce conditions in the grain mass that favor storage mold growth and mycotoxin production (Coppock and Christian, 2007; Coppock and Jacobsen, 2009). The migration of moisture from the high moisture seeds occurs at a slow rate. Moisture migration is dependent on moisture level in the air trapped between the seeds with seeds of lower moisture content taking up the moisture from the seeds with higher moisture content. The high moisture seeds provide a niche with a high water activity ( $a_w$ ) that is favorable for the growth of toxigenic and other fungi, which if allowed to grow, produces additional moisture and heat via microbial metabolic activity. The probability of fungal infection in seeds increases when the moisture content and temperature of the seed is increased. In nuts the acquired inoculum remains with the whole and shelled nut and the low water activity ( $a_w$ ) prevents fungal growth and mycotoxin production (Bayman *et al.*, 2002). Intensive cropping practices and decreased genetic diversity probably contributes to increased preharvest infections of commodities with fungi that produce aflatoxins (Lillehoj, 1992; Brown *et al.*, 1999).

### Rapid formation

Aflatoxin formation can rapidly occur (Coppock *et al.*, 1989). Lee *et al.* (1986) showed that maturing corn kernels

in the ear on the plant inoculated with *A. flavus* had 0.3 to 2 ppb aflatoxins present at 2 days after inoculation, 950 to 2800 ppb aflatoxins present at 4 days after inoculation and 3600 to 4500 ppb aflatoxins present at 7 days after inoculation. The *A. flavus* infection reduced the starch content of the kernel by 12%. Kojic acid was present at 2700 ppb 16 hours (h) after inoculation. High moisture corn and sorghum lightly inoculated with *A. flavus* was shown to produce ppm levels of aflatoxins within 48 h (Winn and Lane, 1978). Over-mature sweet corn was shown to contain 2.36 ppm AFB<sub>1</sub> and 0.21 mg of AFB<sub>2</sub> (Hall *et al.*, 1989). Sweet corn has been considered more hazardous than field corn because of its higher free sugar content.

## Oilseeds

Cottonseed can be a source of aflatoxins in animal diets. Preharvest contamination of cottonseed occurs (Jaimi-Garcia and Cotty, 2003). Insect damage, timing of irrigation or rain, relative humidity around the bolls, stage of maturity and variety of cotton can be factors in causing preharvest contamination of cottonseed with aflatoxins (Russell *et al.*, 1976; Lillehoj *et al.*, 1987). In stored cottonseed growth of aflatoxigenic fungi may occur when the average moisture level in stored cottonseed is greater than 7 to 8%. The lipids and protein in cottonseed enhances AF production (Mellon and Cotty, 1998; Mellon *et al.*, 2000). Peanut hay, peanuts and peanut byproducts are an important source of AFs (McKenzie *et al.*, 1981; Cullen and Newberne, 1994). Aflatoxins generally are the most concentrated in the seeds. The growth of aflatoxigenic fungi can occur in stored peanuts when moisture exceeds 8% and ambient temperature is above 25°C. Drought-stressed peanuts have decreased native resistance to infection by aflatoxigenic fungi (Wotton and Strange, 1987). Phytoalexin produced by the infected peanut seed increased and inhibited the growth of *A. flavus*, but levels of AFs continued to increase for an additional day. Drought-stressed peanut seeds have decreased production of phytoalexin, and aflatoxin production in drought-stressed peanut kernels is limited by available moisture. *A. flavus* can grow on soybeans at  $a_w$  of 0.77 (Trucksess *et al.*, 1988).

## Distiller's grains and commodity byproducts

Distiller's byproducts can be a source of aflatoxin (Hesseltine, 1984; Anom, 2006; Wilkinson and Abbas, 2008). Using aflatoxin-contaminated commodities for fuel alcohol production can salvage corn and other high starch commodities. Fermentation does not destroy AFs. On a dry matter basis, the concentration of AFs in the stillage, compared to AFs in the feedstock, is increased three- to four-fold due to the loss of starch.

Approximately 40% of the AFs are in the syrup (distiller's solubles) fraction and 60% are in the solids fraction. Aflatoxins generally are not found in the alcohol fraction. Depending on the processes, commodity byproducts can have AF levels that exceed the levels in the raw commodity (Bullerman and Bianchini, 2007).

## Chemistry

Aflatoxins have a difuranocoumarin chemical structure (Figure 88.1). Approximately 18 aflatoxins have been chemically characterized. Aflatoxins are in two chemical groups, the difurocoumarocyclopentenone series (includes AFB<sub>1</sub>, AFB<sub>2</sub>, AFB<sub>2A</sub>, AFM<sub>1</sub>, AFM<sub>2</sub>, AFM<sub>2A</sub> and aflatoxicol) and the difurocoumarolactone series (includes AFG<sub>1</sub> and AFG<sub>2</sub>). The "B" Group fluoresce blue in long wavelength ultraviolet light and the "G" Group fluoresce green. The primary aflatoxins of concern in feedstuffs are AFB<sub>1</sub>, AFB<sub>2</sub>, AFG<sub>1</sub> and AFG<sub>2</sub>. Analytical results for aflatoxins generally are the sum of the concentrations of these four toxins. AFB<sub>1</sub> is the most potent aflatoxin and this chemical form is generally the most abundant in feedstuffs and foods. The order of toxicity is AFB<sub>1</sub> > AFG<sub>1</sub> > AFB<sub>2</sub> > AFG<sub>2</sub>. Hydroxylated aflatoxin metabolites are excreted in milk and the important metabolites are AFM<sub>1</sub> and AFM<sub>2</sub> (Garrido *et al.*, 2003; Wu *et al.*, 2009). AFM<sub>1</sub> is the toxic metabolite of AFB<sub>1</sub> and AFM<sub>2</sub> is the hydroxylated form of AFB<sub>2</sub>. Although AFM<sub>1</sub> and AFM<sub>2</sub> are commonly associated with milk and other edible animal products, aflatoxigenic fungi can also produce these compounds. The regulated level of AFs generally is the total mass of AFB<sub>1</sub> + AFG<sub>1</sub> + AFB<sub>2</sub> + AFG<sub>2</sub>. Versicolorin A and sterigmatocystin mycotoxins are intermediates in the synthesis of aflatoxins. Cyclopiazonic acid is produced by aflatoxigenic strains of *A. flavus*. Other

FIGURE 88.1 Chemical structures of aflatoxins.

mycotoxins can be produced by aflatoxigenic strains of *Aspergillus* (Table 88.1) (Varga *et al.*, 2009).

## SAMPLING AND ANALYSIS

The majority of the variation observed in taking multiple samples from a shipping vessel or storage unit occurs with sampling (Whitaker, 2003). Aflatoxins in the bulk lot of feedstuffs are generally assumed to be the same as the mycotoxins identified in the sample. For this reason the samples obtained should be representative of the feedstuffs. A representative sample may be difficult to obtain because the distribution of aflatoxins in the suspect feedstuff or foodstuff can be highly heterogeneous. For this reason, a single random sample may not represent the aflatoxin levels in the feedstuffs sampled. A small percentage of the kernels in a lot of wheat, barley, corn, cottonseed, peanuts and other feedstuffs and foodstuffs may be contaminated with very high concentrations of aflatoxins. Sampling error can occur even with a well-designed sampling protocol. Interpretations of analytical findings should reflect the sampling procedure, and aflatoxicosis cannot be ruled out based on negative chemical analyses of feedstuffs. Another sampling problem is that the available feedstuff for laboratory testing may be limited because livestock or poultry has consumed the suspect feed. In these situations feed may be available from the edges of the feed trough, or clumps of feed retained in the feed handling equipment. Aflatoxin can be present in clumps of feedstuffs (Crockcroft, 1995). These clumps may contain high levels of aflatoxins and only a few animals may have consumed feed from this source, or the clumps were mixed with the feed and fed to a large number of animals. The toxicologist should know the sampling and analytical method(s) used and the limitations of these methods before interpreting analytical results. For the analytical results it is important to know the method(s) employed, the reference standards used including internal standards and an estimate of the percent extracted from the matrix. If this information is not available or is not known to the toxicologist, a risk exists in misinterpreting the qualitative and quantitative results.

## PHARMACOKINETICS/ TOXICOKINETICS

### Absorption

Aflatoxins are efficiently absorbed by passive diffusion from the gastrointestinal tract and are primarily

transferred from the intestine to the hepatic portal blood (Hsieh and Wong, 1994). Very few aflatoxins appear to be transferred into the lymphatic system (Kumagai, 1989). Young animals absorb AFs more efficiently than older animals. Rats at 2.5 weeks of age absorbed AFB<sub>1</sub> at a rate ~15 times greater than rats 4 to 5 weeks of age. Cattle were given a single oral dose of AFs from rice culture (42% AFB<sub>1</sub> and 27% AFB<sub>2</sub>) in gelatin capsules (Cook *et al.*, 1986). AFB<sub>1</sub> and AFM<sub>1</sub> were observed in venous blood (jugular vein) 30 minutes after dosing and reached maximal levels 4 to 8 hours after dosing. The maximal levels of AFM<sub>1</sub> occurred before AFB<sub>1</sub> and the maximal blood levels of AFB<sub>1</sub> generally were higher than AFM<sub>1</sub>. These findings suggest that AFs are rapidly absorbed from the rumen. Rats have been shown to absorb AFB<sub>1</sub> most efficiently from the duodenum and jejunum (Kumagai, 1989). The rate of absorption of AFB<sub>1</sub> in rats is dependent on concentration providing evidence that AFs are absorbed by passive diffusion. The rate of AFB<sub>1</sub> absorption from the duodenum of rats in diestrus was greater than the rate of absorption of AFB<sub>1</sub> from the duodenum in rats in mid-lactation. Aflatoxins can be bound to adsorbents in the gastrointestinal tract.

### Metabolism and excretion

Biotransformation is important in the toxicology of AFs. The most important organ for biotransformation is the liver, and biotransformation can also occur in the kidney and intestinal tract. The majority of research has focused on the biotransformation of AFB<sub>1</sub>. With the exception of the AFB<sub>1</sub>-8,9-epoxide, the biotransformation products are less toxic than AFB<sub>1</sub>. Cytochrome P450 (AFB<sub>1</sub> hydroxylase) has a key role in the biotransformation of AFB<sub>1</sub> to AFB<sub>1</sub>-8,9-epoxide. The formation of AFB<sub>1</sub>-8,9-epoxide is considered to be the most significant biotransformation pathway because the AFB<sub>1</sub>-8,9-epoxide forms adducts with DNA, RNA and proteins. Conjugation of AFB<sub>1</sub>-8,9-epoxide with glutathione (GSH) is considered to be an important detoxification pathway. Other biotransformation products of AFB<sub>1</sub> are AFQ<sub>1</sub> which can be metabolized to AFH<sub>1</sub>. AFB<sub>1</sub> is also metabolized to AFP<sub>1</sub>, AFM<sub>1</sub>, aflatoxicol and other metabolites. The AFP<sub>1</sub>, AFM<sub>1</sub>, AFQ<sub>1</sub> and aflatoxicol form glucuronide and sulfate conjugates.

Turkeys activate AFB<sub>1</sub> ~3.5 times more than chickens by homologs to human CYP1A2, CYP1A5 and other CYPs to form AFB<sub>1</sub>-8,9-epoxide (Yip and Coulombe, 2006; Rawal *et al.*, 2010). Younger birds activate AFB<sub>1</sub> at a greater rate than older birds. Conjugation of the AFB<sub>1</sub>-8,9-epoxide by GSH is considered by some authors to be the rate-limited determinant in species susceptibility to AFB<sub>1</sub> rather than the rate at which AFB<sub>1</sub>-8,9-epoxide is formed. It is likely that there are interactions

between the rate at which AFB<sub>1</sub>-8,9-epoxide is formed and detoxication by GSH. The affinity of the glutathione S-transferases for AFB<sub>1</sub>-8,9-epoxide is also important.

Cattle were given single oral doses (ranging from 0.2mg, 0.4mg, 0.6mg and 0.8mg/kg body weight) of AFs from rice culture (42% AFB<sub>1</sub> and 27% AFB<sub>2</sub>) in gelatin capsules (Cook *et al.*, 1986). AFM<sub>1</sub> was identified in rumen contents 2h after dosing. This observation suggests that AFM<sub>1</sub> is formed by the flora and fauna in the rumen. Urine from these cattle contained AFB<sub>1</sub> and AFM<sub>1</sub>. Kuilman *et al.* (1998, 2000) showed that bovine hepatocytes metabolized AFB<sub>1</sub> to AFM<sub>1</sub> (48% metabolized in 8h), AFB<sub>1</sub> dihydrodiol and minor levels of AFB<sub>1</sub> glutathione conjugate. Liver preparations from calves previously treated with  $\beta$ -naphthoflavone had increased *in vitro* transformation of AFB<sub>1</sub> to AFM<sub>1</sub> when compared to liver preparations from calves that had not been previously treated with  $\beta$ -naphthoflavone (Bodine *et al.*, 1982). Hatch *et al.* (1982) showed that hepatic damage by AFB<sub>1</sub> in goats was increased by pretreatment with phenylbutazone and benzoflavones. Hepatic Kupffer and endothelial cells in the rat have been shown to have up-regulated activity of AFB<sub>1</sub> hydroxylase, the enzyme that converts AFB<sub>1</sub> to AFM<sub>1</sub> (Gemechu-Hatewu *et al.*, 1996). The P450 inducers used were phenobarbital, isosafrole, Aroclor 1254 and 3-methylcholanthrene.

Aflatoxins are excreted in milk, eggs, urine, semen, bile and feces. Excretion of AFs in milk is discussed in the following sections (see Residues). Bingham *et al.* (2004) identified AFM<sub>1</sub> and AFP<sub>1</sub> in dog urine. AFB<sub>1</sub>, AFM<sub>1</sub> and aflatoxicol have been shown to be formed by hens and are transferred to the egg (Oliveira *et al.*, 2000, 2003). Dogs dosed with 100 $\mu$ g AFB<sub>1</sub>/kg body weight excreted AFM<sub>1</sub> in the urine and 90% of the AFM<sub>1</sub> excreted occurred within 12h after dosing (Bingham *et al.*, 2004). Humans exposed to dietary aflatoxins excrete ABM<sub>1</sub>, AFP<sub>1</sub> and AFB<sub>1</sub>-N<sup>7</sup>-Guanine in urine (Groopman *et al.*, 1985). Aflatoxins have been shown to be excreted in boar semen (Picha *et al.*, 1986). Rats excrete AFB<sub>1</sub> into the intestinal tract via bile and the intestinal mucosa also excretes aflatoxins (Kumagai, 1989).

## Residues

Residues of AFs, especially AFM<sub>1</sub>, can occur in edible animal products. The foodstuffs of greatest public health concern are milk, dairy products, especially those made from casein, and liver and kidney (Applebaum *et al.*, 1982). Aflatoxins can be present in meat. Most governmental jurisdictions regulate the permissible level of AFs in edible animal products. In addition to relay from feedstuffs to edible animal products, AFs can be formed in animal products that support or have supported the growth of aflatoxigenic fungi.

## Milk

Aflatoxins can be present in processed milk products. Issues regarding aflatoxin contamination of fluid milk generally increase when regional contamination of commodities (e.g., corn, sorghum, cottonseed) occurs before harvest (Applebaum *et al.*, 1982). Milk products such as cheese and dried milk also can become directly contaminated with AFs by fungal growth in these substrates. Aflatoxins appear in cows' milk within 12 to 48h after ingestion (Applebaum *et al.*, 1982; Frobish *et al.*, 1986). The amount of dietary AFs being excreted in milk varies with the high value being reported as 3% and the low value being reported as 0.17% (Applebaum *et al.*, 1982; Stubblefield *et al.*, 1983; Price *et al.*, 1985; Frobish *et al.*, 1986). To compare with other mammalian species, humans excrete 0.09 to 0.43% of dietary AF intake in breast milk, sheep excrete 0.26 to 0.33% of the dietary AFB<sub>1</sub> as AFM<sub>1</sub> in the milk, and AFs in sows' milk have been shown to be ~1000-fold less than the AFs in the diet (Zarba *et al.*, 1992; Silvotti *et al.*, 1997; Battacone *et al.*, 2005). The stage of lactation is important for excretion of aflatoxins (Veldman *et al.*, 1992). The percentage of AFs in milk has been reported to increase with increasing milk yields (Frobish *et al.*, 1986). Cows in early lactation can excrete from 3.8 to 6.2% of the dietary AFB<sub>1</sub> as AFM<sub>1</sub> in the milk, and cows in late lactation can excrete 1.8 to 2.5% of dietary AFB<sub>1</sub> as AFM<sub>1</sub>. This phenomenon is independent of the level of AFB<sub>1</sub> in the diet and appears to be linked to cows having up-regulation of AFB<sub>1</sub> metabolism during early lactation. The phenomenon of excreting more AFM<sub>1</sub> in milk during early lactation must be considered in calculating safe dietary levels of aflatoxins for dairy cattle, and may be of importance in calculating the rations for other milk-producing animals. Herd-specific analytical data can be used to calculate the dietary:milk ratio for AFs. Our experience has shown that this approach is accurate to predict aflatoxins in milk after changes have been made to reduce dietary aflatoxins. The dietary threshold for aflatoxin excretion in cows' milk appears to be ~15ppb dietary level or 230 $\mu$ g AFB<sub>1</sub>/cow/day. Aflatoxins in milk generally disappear within 24 to 72h after all the aflatoxins have been removed from the diet.

Sheep and swine excrete AFs in milk. Residues of AFM<sub>1</sub> in milk have been studied in dairy sheep (Battacone *et al.*, 2003, 2005, 2009). The ratio of AFB<sub>1</sub> in the diet to AFM<sub>1</sub> in milk was not affected by the dose of aflatoxins. Sheep receiving a single dose of AFB<sub>1</sub> excreted 0.26 to 0.33% of the dose as AFM<sub>1</sub> in milk. Aflatoxin level in curds was two times higher than milk. Aflatoxins are excreted in sows' milk (Silvotti *et al.*, 1997). The levels of aflatoxins in sows' milk increased over a 25-day lactation period. The sows were fed diets containing 800ppb AFB<sub>1</sub> or a diet containing 400ppb AFB<sub>1</sub> + 400ppb AFG<sub>1</sub> for the entire gestation and

TABLE 88.2 Levels in ng/g or ng/ml of AFs in tissues after steers were fed a diet containing 800ppb AFs for 17.5 weeks (Richards *et al.*, 1983)

Toxin	Liver	Kidney	Muscle	Heart	Lung	Rumen
AFB <sub>1</sub>	0.37	0.09	0.002	0.004	0.014	13.05
AFM <sub>1</sub>	1.07	4.82	0.115	0.14	0.29	1.66

lactation period. The average ratio of aflatoxins in the diet to aflatoxins in milk was ~1000:1. Sows fed diets containing 800ppb AFB<sub>1</sub> or 400ppb AFB<sub>1</sub> + 400ppb AFG<sub>1</sub> excreted AFB<sub>1</sub> or AFB<sub>1</sub> + AFG<sub>1</sub>, respectively. Sows fed AFB<sub>1</sub> excreted AFM<sub>1</sub> and sows fed AFB<sub>1</sub> + AFG<sub>1</sub> excreted AFM<sub>1</sub> + AFM<sub>2</sub> metabolites.

The general consensus in the scientific literature is that aflatoxins are stable in milk, and are primarily associated with milk protein. Aflatoxins in raw milk slowly decrease by 11 to 25% in 1 to 3 days of storage at 5°C. Approximately 75% of aflatoxins in milk are found in the casein (protein) fraction and 25% in the whey fraction of milk. Aflatoxins are also found in butter and the division is ~84% in butter milk and ~16% in butter. Aflatoxins are concentrated in cheese, and the concentration factor varies with the type of cheese and cheese-making procedures. AFM<sub>1</sub> is decreased during yogurt manufacturing and decreasing the pH of yogurt decreases the levels of AFM<sub>1</sub> (Govaris *et al.*, 2002).

### Residues in meat

Aflatoxins generally are found in liver, kidney and edible parts of the gastrointestinal tract. Aflatoxins are not known to accumulate in the body fat. Two-week-old turkey poults were fed diets containing 50 and 150ppb AFB<sub>1</sub> (Richard *et al.*, 1986). The poults were killed at 11 weeks, 13 weeks and 1 week or 2 weeks after being fed the 50 and 150ppb diets for 11 weeks (1 or 2 weeks on aflatoxin-free diet). At 50ppb feeding level for 11 weeks AFB<sub>1</sub> was found in liver (0.02 to 0.09ng/g), kidney (0.01 to 0.02ng/g) and gizzard (0.043 to 0.162ng/g), and AFM<sub>1</sub> was not shown to be in liver, kidney and gizzard. Feeding 50ppb aflatoxins for 13 weeks increased the residues of AFB<sub>1</sub> and AFM<sub>1</sub>; for AFB<sub>1</sub> liver contained 0.02 to 0.13ng/g, kidney contained 0.01 to 0.34ng/g and gizzard at trace to 0.113ng/g; AFM<sub>1</sub> in liver was 0.11 to 0.14ng/g and kidney contained 0.01 to 0.07ng/g. At the 150ppb feed level, fed for 11 weeks, AFB<sub>1</sub> in liver was 0.08 to 0.13ng/g, kidney was 0.025 to 0.08ng/g and gizzard trace to 0.22ng/g; AFM<sub>1</sub> was 0.03 to 0.10ng/g in liver and 0.09 to 0.13ng/g in kidney. Aflatoxin M<sub>1</sub> was not shown to be present in the gizzard. Breast and thigh muscles did not contain AFs. Birds on the 150ppm diet for 11 weeks and the control diet (no aflatoxins) for 2 weeks essentially had cleared the aflatoxins from the liver, kidney and gizzard. Chickens

fed a diet containing rice culture that had supported growth of *A. parasiticus* only produced AFB<sub>1</sub> (Pandey and Chauhan, 2007). At 2 weeks of age groups of birds were placed on diets containing minimum levels of 0.0ppm, 2.5ppm, 3.13ppm and 3.91ppm AFB<sub>1</sub>, respectively. These diets were fed for 40 weeks. Tissues and eggs were collected on day 40 for aflatoxin analyses. AFB<sub>1</sub> in eggs increased with feed levels, the mean levels were 1.43ppb, 1.39ppb and 1.63ppb, respectively, for the different treatment groups. Levels in breast meat were 18ppb, 26ppb and 26ppb, respectively, for the chickens in the different treatment groups. The levels of aflatoxin metabolites were not reported, and renal and liver histopathology was reported. Young birds have higher levels of AFs and require longer to clear AFs (Hussain *et al.*, 2010). The translocation of AFB<sub>1</sub> from diet to eggs was studied in 12-week-old hens given diets containing 0, 100, 300 or 500ppb AFB<sub>1</sub> (Oliveira *et al.*, 2000). AFB<sub>1</sub> was only detected at levels from 0.05 to 0.16ppb (mean 10ppb) in the eggs from hens on the 500ppb diet. In this study the transfer rate was 5000:1 diet to egg ratio.

The translocation of AFs into edible tissues of pigs has been studied. Jacobson *et al.* (1978) fed feeder pigs (54 to 72kg body mass) diets containing pure AFB<sub>1</sub> at 100, 2000 and 400ppb. The basal diet contained 0.1ppb AFB<sub>1</sub> and 0.1ppb AFB<sub>2</sub>. The diets were fed for 4 weeks. Liver, kidney and skeletal muscle contained levels of AFB<sub>1</sub> that were correlated with the feeding level. In decreasing dietary level, AFB<sub>1</sub> levels in liver were 1.5, ~0.5 and ~0.2ppb; levels in skeletal muscle were ~1, ~0.5 and ~0.2ppm; and levels in kidney were 4.4, ~0.7 and ~0.2ppb.

Steers fed a diet containing 800ppb aflatoxins for 15 weeks and then placed on an aflatoxin-free diet for 2.5 weeks did not have residues of aflatoxin in heart, skeletal muscle, liver and kidney (Richard *et al.*, 1983). Steers fed a diet containing 800ppb aflatoxins for 17.5 weeks did have residues of aflatoxins (Table 88.2).

## TOXICODYNAMICS

### Mechanisms of action

The metabolism of aflatoxins, unlike many other mycotoxins, is closely linked with toxicity (Eaton and Gallagher, 1994). AFB<sub>1</sub> is metabolized in a P450-dependent

reaction to AFB<sub>1</sub>-8,9-epoxide which forms adducts with macromolecules in the cell. The affinity of AFB<sub>1</sub>-8,9-epoxide in decreasing order for macromolecules is DNA > RNA > protein. The formation of these adducts is considered important in the toxicity of aflatoxins. The DNA adduct is formed with N<sup>7</sup>-guanine and this adduct is relatively resistant to DNA repair processes. Up-regulation of the P450 system increases the toxicity of aflatoxins. Species sensitivity to aflatoxins is linked to the rate of bioactivation and the rate of detoxification. AFB<sub>1</sub>-8,9-epoxide is primarily detoxified by Phase II synthetic reactions by GSH. In mammals glutathione S-transferase mediated conjugation is an important detoxification pathway, and species differences in enzyme activity in part account for differences in species susceptibility. Other Phase II pathways that decrease the toxicity of aflatoxins include formation of glucuronide and sulfates.

### Immunotoxic effects

The immunotoxic effects of aflatoxins are of public health and economic importance. The native resistance to disease is reduced and vaccine protection is also impaired. The apparent clinical signs of aflatoxicosis may be limited to increased occurrences of infectious disease. Recovery from infectious disease may be prolonged and require additional treatments. A clue to immune dysfunction is often infections caused by organisms that generally are not considered to be pathogens. Studies have shown that the immunotoxicity of AFs could be a teratogenic effect of prenatal or pre-hatching exposure to aflatoxins. As a general summary, AFB<sub>1</sub> lowers lymphoid cell populations especially circulating activated lymphocytes, suppresses lymphoblastogenesis and decreases both cutaneous delayed-type hypersensitivity (DTH) and graft versus host reaction (Meissonnier *et al.*, 2008). AFB<sub>1</sub> reduces natural killer cytotoxicity and macrophage functions including phagocytic activity and production of oxidative radicals. A brief literature review is provided for the immunotoxic effects of aflatoxins in different species.

The immunotoxic effects of aflatoxins have been studied in pigs. Treatment with AFB<sub>1</sub> has been shown to shorten the incubation period of *Serpulina* (*Treponema*) *hyodysenteriae* in pigs (Joens *et al.*, 1981). Pigs given AFB<sub>1</sub> and infected with *S. hyodysenteriae* also had a longer period of diarrhea. Feeding weanling piglets a diet containing 140 or 280 ppb AFs (~70% AFB<sub>1</sub>) for 4 weeks caused an increase in serum  $\gamma$ -globulin (Marin *et al.*, 2002). At the 280 ppb level, a reduced immune response to *Mycoplasma agalactiae* was observed. There were indications that interleukin-1 $\beta$  and tissue necrosis factor- $\alpha$  expression was decreased by exposure at the 280 ppb level. Sows were fed diets containing 800 ppb AFB<sub>1</sub> or

a diet containing 400 ppb AFB<sub>1</sub> + 400 ppb AFG<sub>1</sub> for the entire gestation and lactation period (Silvotti *et al.*, 1997). At 25 days of age the piglets born to the sows were found to have decreased immune functions in lymphoproliferative response to mitogens, monocyte-derived macrophages failed to have induced oxygen bursts and granulocytes had reduced chemotactic response. There is some evidence that *in utero* exposure of piglets to AFB<sub>1</sub> interferes with zinc metabolism and low plasma zinc decreases cell-mediated immunity because of a decrease in a zinc-dependent thymic hormone (Mocchegiani *et al.*, 1998).

Aflatoxins have been shown to be immunotoxic in ruminants. Feeding a diet containing 2 ppm AFs (83.4% AFB<sub>1</sub>, 12.3% AFB<sub>2</sub> and AFG<sub>1</sub> and AFG<sub>2</sub>) to lambs for 37 days increased serum  $\gamma$ -globulin, decreased bacteriostatic activity in serum and decreased cellular immunity (Fernandez *et al.*, 2000). Studies done *in vitro* have shown that aflatoxin inhibits thymidine uptake by phytohemagglutinin-stimulated lymphocytes (Bodine *et al.*, 1984). Holstein steers (183 kg) fed a diet containing ~375 ppb aflatoxin for 17.5 weeks were observed to have a decrease in delayed cutaneous hypersensitivity (Richard *et al.*, 1983). Changes were not observed in antibody production (*Brucella abortus* antigen) and lymphoblastogenesis. Cattle were administered 0.3 mg of AFB<sub>1</sub> equivalent/kg body weight for 12 to 14 days (Brown *et al.*, 1981). Before administration of aflatoxins, the cows were previously infected intramammary with *Streptococcus agalactiae*, *Staphylococcus aureus* and *Staphylococcus hyicus*. Clinical evidence of mastitis was not observed, but three of four cows had increased bacteria in the milk. The California mastitis test scores increased after the last dose of aflatoxins were given. Steers were administered a single oral dose of 0.6 or 0.8 mg AFB<sub>1</sub>/kg body weight (Thurston *et al.*, 1986). Complement activity and bacteriostatic activity of serum decreased for 48 to 72 h and then returned to baseline at 7 days. In the same study cattle were administered 0.25 mg AFB<sub>1</sub>/kg body weight/day for 14 days. The bacteriostatic activity of serum decreased until day 11 and then remained decreased for 29 days.

The immunotoxic effects of aflatoxins have been studied in poultry. Immunotoxic effects in poultry are lymphocytopenia, reduced T cell counts and reduced native resistance to disease (Pier and Heddleston, 1970). Two-week-old turkey poults were placed on a diet containing 50 and 150 ppb aflatoxins for 11 weeks (Richard *et al.*, 1986). The poults were vaccinated with sheep red blood cells (SRBC) or *Pasteurella multocida* at 4 weeks and the vaccinations repeated at 8 weeks. Poults in the 150 ppb group had an increase in humoral response to *P. multocida* at 4 weeks and a decreased response to SRBC at 8 weeks. Three-week-old chicks were injected intramuscularly with 0.250 mg AFB<sub>1</sub> every 2 days for

four administrations of AFB<sub>1</sub> (Otim *et al.*, 2005). At 3 and 6 weeks of age the chicks were vaccinated with Newcastle virus vaccines. Hemagglutination reaction to Newcastle disease virus was reduced. The immunosuppression of aflatoxins (from cultures of *A. flavus* NRRL 5518) were found to be additive with fowl adenovirus serotype-4 (Shivachandra *et al.*, 2003). The response to dinitrochlorobenzene hypersensitization was also reduced by AFB<sub>1</sub>. Hens were fed diets containing 0.2, 1.0 and 5.0 ppm AFB<sub>1</sub> and fertile eggs were collected (Qureshi *et al.*, 1998). All chicks from hens given aflatoxins had reduced macrophage phagocytic activity and reactive oxygen burst. Antibody titers to SRBC were not changed on the primary vaccination, but the secondary response was depressed in chicks from hens given the diet containing AFB<sub>1</sub>. A study by Sur and Celik (2003) showed that decreased development of the bursa of Fabricius was observed in chicks after the egg was injected with 10 µg AFB<sub>1</sub> at day 7 of incubation.

## Reproductive and teratogenic effects

The reproductive effects of aflatoxins are best described as aflatoxin-linked deviation from the expected reproductive outcome. Two recent reviews have been published (Shuaib *et al.*, 2010a; Gupta, 2011). The reproductive effects in poultry have been described (Ortatli *et al.*, 2002). Feeding AFs, which had been previously produced in wheat using *A. parasiticus*, to mature roosters at 0, 2.5, 10 and 20 ppm AFs for 8 weeks caused testicular degeneration and a reduction in plasma testosterone. It is important to point out that toxicants that target spermatogenesis and spermiogenesis may not be apparent for 3 to 6 weeks, dependent on the species, due to the time required for spermiogenesis. A study in chickens using aflatoxins produced in rice by *A. parasiticus* showed that aflatoxins fed at 0, 10 and 20 ppm led to a reduction in testicular mass at 122 weeks of age and a reduction in plasma luteinizing hormone (Clarke and Ottinger, 1987). This effect of aflatoxins appears to be a reduction in pituitary response to luteinizing hormone-releasing hormone (LHRH) (Clarke and Ottinger, 1987). The effects of aflatoxin on egg production, fertility, hatchability and progeny performance were investigated in mature chicken hens by feeding dietary aflatoxin produced by *A. parasiticus* produced in rice culture (Howarth and Wyatt, 1976). Rice culture was added to the diets to give dose levels of 0, 5 and 10 µg aflatoxins/g for 4 weeks. Feeding aflatoxins significantly decreased egg production at 3 and 4 weeks. Egg fertility was not affected by dietary aflatoxins, but hatchability decreased significantly within 1 week. At the third week, chicks from hens on the 10 ppm aflatoxins diet had decreased body mass at hatching. An Egyptian study feeding 100 ppm aflatoxins to mature Mamourah hens

for 6 weeks showed that the hatch weight of the chicks was higher than controls (Abdelhamid and Dorra, 1990). Aflatoxins have been shown to be disruptive of sperm production and fertility in mice. An intraperitoneal dose of 50 µg of AFB<sub>1</sub>/kg body weight/day (estimated to be equivalent to ~330 ppm in diet) was given to male mice for varying intervals (Agnes and Akbarsha, 2003). At 35 days, fertility testing showed a decrease in litter size, and tissue examination showed a decrease in spermatozoa numbers present in the caudal epididymis. When the numbers of spermatozoa decreased, forward mobility of spermatozoa was decreased and abnormal spermatozoa were observed.

The effects of aflatoxins on human reproduction have been reviewed (Shuaib *et al.*, 2010b). There is evidence that dietary aflatoxins decrease male fertility (Ibeh *et al.*, 1994). A study at an infertility clinic showed that there is a correlation between dietary levels and serum levels of aflatoxins. The mean aflatoxin levels in serum were  $1.660 \pm 0.04$  µg/ml (infertile men) and  $1.041 \pm 0.01$  µg/ml (fertile men). The infertile men had a higher percentage (50%) of abnormal spermatozoa and aflatoxin in their semen. Exposure to AFs decreased human fertility by increasing fetal loss (Gupta, 2011). Women with high serum levels of AFB<sub>1</sub>-lysine adduct ( $\geq 11.34$  pg/mg of albumen) are at greater risk for delivering a child with low birth weight. There is a trend for delivery of low birth weight babies with increasing levels of AFB<sub>1</sub>-lysine adduct. Women with increased blood levels of AFM<sub>1</sub> had increased risk to give birth to a baby with abnormally low birth weight (Abdulrazzaq *et al.*, 2002).

Fetal loss and possible teratogenic effects have been reported for AFs. Sows were fed a diet containing 800 ppb AFB<sub>1</sub> or 400 ppb AFB<sub>1</sub> + 400 ppb AFG<sub>1</sub> from day 60 of pregnancy to day 28 of lactation (Mocchegiani *et al.*, 1998). Pigs born to the sows on the 800 ppb AFB<sub>1</sub> diet had reduced birth weights. Reduced birth weight was more pronounced in piglets born to sows consuming the diet containing 400 ppb AFB<sub>1</sub> + 400 ppb AFG<sub>1</sub>. Pregnant rats were administered 0.3 mg of AFB<sub>1</sub>/kg body weight on gestation days 11 to 14 or gestation days 15 to 18 (Kihara *et al.*, 2000). The offspring of these rats showed that prenatal exposure to AFB<sub>1</sub> caused a delay in early response development, decreased learning ability and impaired locomotor coordination. The effects of aflatoxins on weight gains have been modeled using previously published studies (Dersjant-Li *et al.*, 2003).

## CLINICOPATHOLOGY

### Introduction

Acute aflatoxicosis causes changes in clinicopathology parameters. The activities of liver enzymes in serum

are increased and the increased activity is indicative of hepatic damage. Increased activity of hepatic enzymes in serum include  $\gamma$ -glutamyl transpeptidase (transferrase) (GGT), aspartate aminotransferase (AST, previously identified as SGOT), alkaline phosphates (ALP), sorbitol dehydrogenase (SDH), ornithine carbamyl transferase (OCT) and isocitric dehydrogenase (ICD). Once released into serum the activities of hepatic enzymes decrease as metabolic processes remove the hepatic enzyme from serum. The activities of hepatic enzymes in serum that have been reported to be the most consistently elevated in aflatoxicosis are GGT, AST and SDH. The elevated activity of ALP is variable in aflatoxicosis. The timing of hepatic enzyme determinations in terms of the pathogenesis of aflatoxicosis is important and enzymatic activity must be interpreted in the context of the temporal aspect of aflatoxicosis. The activity of GGT has a slower temporal decrease than AST. Research studies comparing treatment to control animal can have statistically significant increases in clinicopathology parameters that are inside the expected normal range for the species. The interactions with duration of exposure can be statistically significant. Serum chemistry is useful in the diagnosis of aflatoxicosis. Prothrombin time is generally increased and frank hemorrhage can occur. Serum bilirubin levels are also increased and photosensitization can occur. The changes in hematological parameters generally are due to hemoconcentration and blood loss.

## Cattle

Steers were given single oral doses (0.2, 0.4, 0.6 and 0.8 mg/kg body weight) of aflatoxins (Cook *et al.*, 1986). Increases in the serum activity of SDH and AST and not ALP were observed. The increase started at 8 h after dosing and reached maximal activity at 24 to 48 h and then rapidly decreased. Brucato *et al.* (1986) administered a single oral dose of 1 mg AFB<sub>1</sub>/kg body weight to calves. Serum AST and GGT activities were increased within 2 days. After 2 days, the AST activity rapidly decreased whereas the GGT activity was elevated for 3 weeks. Aflatoxicosis from consuming high levels of aflatoxins in a concentrate has occurred in cattle with an increase in serum activity of AST and no increase in GGT activity (Crockcroft, 1995). Feedlot steers fed a diet containing 600 ppb AFB<sub>1</sub> for 155 days had an increase in AST, ALP and SDH (Helferich *et al.*, 1986). Steers fed diets containing 60 and 300 ppm AFB<sub>1</sub> did not have an increase in AST, ALP and SDH. Holstein calves (70 kg) were fed a diet containing 5 ppm aflatoxins for 3 weeks (Wyatt *et al.*, 1985). Serum activity of lactic acid dehydrogenase (LDH) decreased, ALP peaked on treatment day 7 and then decreased, and AST increased to study day 14 and then plateaued. Holstein steers (183 kg) fed a diet containing ~375 ppb aflatoxin for 17.5 weeks were observed to

have an increase in SDH and a decrease in AST activities (Richard *et al.*, 1983). Vaid *et al.* (1981) reported chronic aflatoxicosis in cattle consuming AFB<sub>1</sub> (0.11 ppm) contaminated groundnut cake. Hepatic enzymes in serum with increased activity were ALP and AST in one of four animals sampled. Timing of the blood sampling in terms of aflatoxicosis was not given, and these animals had histopathology consistent with aflatoxicosis. A study by Lynch *et al.* (1970) in calves suggested that the threshold dose for AFB<sub>1</sub> to increase AP was 0.1 mg/kg body weight fed for 6 weeks.

## Sheep and goats

Goats given 3 mg of AFB<sub>1</sub>/kg body weight by intramuscular injections had increased serum activity of AST which peaked at 32 to 40 h and then decreased (Hatch *et al.*, 1982; Clark *et al.*, 1984). Sheep fed mold-damaged wheat that contained an estimated 50 ppb AFB<sub>1</sub> had a linear decrease in total serum protein, serum albumin and serum globulins (Tripathi *et al.*, 2008). Serum urea nitrogen and glucose increased, AST slowly increased with the duration of feeding and IgG decreased. Histopathology was not done and the feed was not assayed for other mycotoxins. Lambs fed aflatoxins produced from a culture of *A. parasiticus* for 37 days had decreased feed intake and average daily gains did not have a decrease in WBC and RBC numbers (Fernandez *et al.*, 2000). Parameters assessing immune function were decreased. Wethers did not have elevated serum activity of AST and GGT and hematology parameters after consuming groundnut cake containing an estimated level of 750 ppb AFB<sub>1</sub> (Suliman *et al.*, 1987). Hepatic necrosis and other hepatic and renal lesions were observed. The timing of clinicopathologic determinations with the onset of clinical signs was not given. Sheep given 0.1 mg of AB<sub>1</sub>/kg body weight for 34 days had decreased albumin, increased  $\gamma$ -globulins and decreased  $\beta$ -globulins (Miller *et al.*, 1984).

## Swine

Growing barrows were fed a diet containing 1, 2, 3 or 4 ppm aflatoxins for 28 days (Harvey *et al.*, 1988). On day 14, serum activity of AST and GGT increased in pigs fed the 4 ppm diet, on day 21 ALP increased in barrows fed the 4 ppm diet and AST increased in all pigs fed aflatoxins, and on day 28 ALP activity was increased in pigs fed aflatoxins, GGT was increased in pigs fed the 3 and 4 ppm diets and serum AST activity was increased in pigs fed the 4 ppm diet. Barrows were fed diets containing 0, 250 and 500  $\mu$ g AFB<sub>1</sub>/kg of feed (Rustemeyer *et al.*, 2010). The source of AFB<sub>1</sub> was rice culture of *A. parasiticus* and the whole culture material was added

to the finished ration. When compared to controls AST was increased, and at 5 weeks of exposure BUN was increased. Minimal histopathology (mild biliary hyperplasia and nuclear pleomorphism) was observed. At both treatment levels, changes were observed in performance parameters.

## Dogs

Dogs (1.5 years old) administered intravenously 15 doses of 0.05mg AFB<sub>1</sub>/kg body weight for 15 days had increased serum activity of ALP and ICD (Chaffee *et al.*, 1969). Nine dogs that had consumed commercial dog food containing aflatoxin-adulterated corn were evaluated by clinicopathology parameters (Newman *et al.*, 2007). Findings were 5/8 with elevated WBC numbers, 6/9 with decreased platelets, 7/7 with increased prothrombin and partial thromboplastin times, 6/7 with decreased total serum protein, 7/7 with decreased serum albumen, 6/8 with decreased serum globulin, 7/9 with elevated ALP, 9/9 with elevated ALT, 6/6 with elevated AST, and 9/9 with elevated total bilirubin. Aflatoxin levels in the finished dog food were from ~223 to 579ppb AFB<sub>1</sub> and 16 to 10ppb AFB<sub>2</sub>. AFM<sub>1</sub> levels in the liver ranged from 1.20 to 4.40ppb. Dogs have died from aflatoxicosis in human outbreaks (Wild and Gong, 2010).

## Horses

The clinicopathology of aflatoxicosis has been studied in horses. Weanling ponies were administered AFB<sub>1</sub> at 0.0, 0.5, 1.0 and 2.0mg/kg body weight (Boatell *et al.*, 1983). Serum activity of GGT was increased in all ponies administered AFB<sub>1</sub>. The GGT activity increased until day 3 and then decreased. Serum activity of ALT was not increased. Ponies given 4, 5, 6 and 7.4mg AFB<sub>1</sub>/kg body had an increase in serum ALT and the activity of ALT increased until the ponies died at 33 to 46h after dosing.

## Poultry

Clinicopathology has been described for aflatoxicosis in poultry (Hashem and Mohamed, 2009), with decreased erythrocyte numbers, hemoglobin, leukopenia consisting of heteropenia and lymphopenia. Elevations occurred in ALT, AST, GGT and ALP, uric acid and creatine. Total serum protein, globulins and albumin were also decreased. Wild turkey poults were fed diets amended with rice culture (*A. parasiticus*) to give 0, 100, 200 and 400ppb aflatoxin/kg of feed (Quist *et al.*, 2000). The poults were 4 months old at the start of the study which

lasted for 14 days. Trends were observed for treated birds to have an increase in heterophil and lymphocyte numbers, and a decrease in basophil numbers. Serum AST was increased, and triglycerides and prothrombin time had a trend to decrease.

## Humans

Aflatoxicosis in humans has been reported. It is estimated that an intake >20µg/kg body weight/day is fatal for humans and deaths can occur within 7 to 21 days (Wild and Gong, 2010). Studies on reproduction have been done in humans endemically exposed to aflatoxins. Pregnant women with lower socio-economic status have higher risk for increased AFB<sub>1</sub>-lysine adduct in their serum (Shuaib *et al.*, 2010a). The levels of AFM<sub>1</sub> in cord blood of humans are correlated with the levels of AFM<sub>1</sub> in maternal blood (Abdulrazzaq *et al.*, 2002). The range of AFM<sub>1</sub> in maternal blood was 0.05 to 10.44ng/ml and the range of AFM<sub>1</sub> in cord blood was 0.03 to 8.49ng/ml. Other authors have postulated that a reduction of maternal AF-lysine adducts from 110pg/mg of albumin to 10pg/mg of albumen would give a 0.8kg increase in body mass and a 2cm increase in height during the first year of life (Turner *et al.*, 2007).

## MACROSCOPIC AND MICROSCOPIC PATHOLOGY

### Edema

The pathology of aflatoxicosis has been described in several species. Edema including anasarca and edema fluid in the peritoneal and thoracic cavities can be observed (Osweiler and Trampel, 1985; Bastianello *et al.*, 1987; Coppock *et al.*, 1989; Hall *et al.*, 1989). The gall bladder, bile duct, abomasal wall and colonic mesentery may be edematous. There may be edema of the omentum near the stomach or abomasum and in the colonic mesentery. Gall bladder edema may be marked in cattle and pigs. Edema of the brain has been reported for horses (Angsubhakorn *et al.*, 1981).

### Hemorrhage

Hemorrhage into the gastrointestinal tract, into body cavities and on body organs has been reported. Hemorrhage is due to decreased production of clotting factors by the liver. Acute aflatoxicosis in cattle, horses, pigs and dogs may result in serious hemorrhages in the gastrointestinal tract, on serosal surfaces, on the

epicardium and endocardium, in skeletal muscle, perirenal and in the urinary bladder (Cysewski *et al.*, 1968; McKenzie *et al.*, 1981; Boatel *et al.*, 1983; Jakhar and Sadana, 2004). Pigs can also have hemorrhage occurring in the pleural and peritoneal cavity. The urine may be dark red colored.

## Hepatic lesions

Histopathology includes bile duct proliferation, hepatocyte necrosis and early fibrosis of the liver (Newberne and Butler, 1969). Regeneration of hepatocytes may be found in dogs, and nodular hyperplasia may be present in turkeys, trout and ducklings (Newberne *et al.*, 1966b; Newberne and Butler, 1969; Bastianello *et al.*, 1987). Variation in the size of hepatocytes, with some megacocytes and binucleate cells, is recorded in many reports. Chronic liver lesions are characterized by firm, fibrous pale livers, by nodular hyperplasia, and in some cases neoplasia. Icterus is present. The liver may be swollen, friable and congested. Histologically, the liver may have necrosis in variable patterns. In the rat, monkey and duckling, the necrosis is reported to be periportal, while in cattle, pigs, horses, goats and sheep, the pattern is recorded to be centrilobular (Butler, 1964; Newberne *et al.*, 1966a; Samarajeewa *et al.*, 1975; Carlton and Szczech, 1978; Abdelsalam *et al.*, 1989; Coppock *et al.*, 1989; Mathur *et al.*, 1991). In the dog the pattern may be either or both periportal and centrilobular, while in the rabbit the pattern is reported to be midzonal (Newberne *et al.*, 1966a; Chaffee *et al.*, 1969; Clark *et al.*, 1980). Hyperplasia of the bile duct cells occurs rapidly in ducklings and may be present in horses, dogs and chickens, and mild bile duct cell hyperplasia may be seen in cattle and pigs (Newberne and Butler, 1969; Ketterer *et al.*, 1975; Coppock *et al.*, 1989). Multinucleated hepatocytes have been observed in dogs, cattle and other species. Reactive fibroblasts have been observed in dogs. Humans infected with hepatitis B virus appear to be at greater risk for hepatic neoplasia when they are exposed to aflatoxins (Wild and Gong, 2010). Chronic liver injury and regenerative hyperplasia are considered critical for the development of liver neoplasia. Dividing liver cells are more likely to form DNA adducts. In sub-Saharan Africa, consumption of corn is associated with increased HIV and consumption of rice is associated with increased liver cancer (Williams *et al.*, 2010). Hepatic encephalopathy could occur.

## Other lesions

Renal lesions of protein in proximal tubules and glomerular spaces are recorded in horses and rats (Butler,

1964; Newberne and Butler, 1969; Boatell *et al.*, 1983). Hemosiderin deposition in tubule cells occurs in horses (Angsubhakorn *et al.*, 1981). Cardiac myofiber degeneration is recorded in horses and rats (Butler, 1964; Angsubhakorn *et al.*, 1981). Brain lesions described as focal malacia in the cerebral hemispheres in horses were reported (Angsubhakorn *et al.*, 1981). Focal malacia has not been reported by others or in other species. However, hepatic encephalopathy could occur as a result of liver damage. Subacute lesions observed at necropsy include firm, pale livers in all species and clear yellow ascites and pleural fluid accumulation especially in pigs and dogs (Newberne and Butler, 1969). Icterus is usually present. Edema of the mesentery near the colon and perirenal edema may be present in pigs and cattle (Osweiler and Trampel, 1985; Bastianello *et al.*, 1987; Coppock *et al.*, 1989; Hall *et al.*, 1989). Pulmonary edema may occur. Pneumonia is reported in calves as likely secondary to edema and the effects of aflatoxin on the immune system. Lesions of photosensitization have been reported in cattle.

## DIFFERENTIAL DIAGNOSIS

The lesions of aflatoxicosis and those of pyrrolizidine alkaloid toxicosis have been observed to be very similar especially in cattle (Loosmore and Markson, 1961). Cattle are generally considered to be more susceptible to pyrrolizidine alkaloids. When aflatoxins and pyrrolizidine alkaloid are at issue, it is important to examine pasture, forage, concentrate feeds and gastrointestinal contents to determine the presence of poisonous plants that may contain pyrrolizidine alkaloids. In some geographic areas seeds containing pyrrolizidine alkaloids can be present in grain screenings, and their identity lost in the grinding and pelleting processes. It is the experience of the authors that domestic animals with signs of aflatoxicosis never fully recover.

## TREATMENT AND OUTCOMES

A specific treatment for aflatoxicosis has not been identified. Aflatoxins from all sources should be removed from the diet. Symptomatic care of the affected animals is recommended. Animals on a low protein diet are more susceptible to aflatoxins (Cullen and Newberne, 1994). Supplementing diets with choline and methionine and N-acetylcystine is probably beneficial (Cullen and Newberne, 1994; Valdivia *et al.*, 2001). Adding vitamin E to swine diets containing 2.5ppm aflatoxins did not

have a protective effect on the severity of aflatoxicosis (Harvey *et al.*, 1994). Vitamin E was observed to have an ameliorative effect on the adverse effects of AFs on weight gain in hens, but did not prevent the pathologic effects in liver and kidney (Kahn *et al.*, 2010). Increasing dietary zinc did not appear to be of benefit to calves fed a diet containing 5 ppm aflatoxins (Neathery *et al.*, 1980). There is some suggestion that selenium provided some protection to Japanese quail fed a diet containing 1 ppm AFB<sub>1</sub> (Jakhar and Sadana, 2004). Excessive dietary selenium increases the toxicity of aflatoxins. Pimpukdee (2004) found that a proprietary alumino-silicate (feed anti-caking agent) protected chicks from hepatic loss of vitamin A linked to aflatoxins in the diet. Feeding sodium bentonite was considered protective to pigs (Schell *et al.*, 1993). Diaz *et al.* (2004) showed that sodium bentonite and MTB-100 (derived from the cell wall of yeast) reduced AFM<sub>1</sub> in milk.

## PREVENTION OF AFLATOXINS

Avoidance of formation and consumption of AFs is the best prevention (Mishra and Das, 2003). Different materials have been shown to reduce the toxic effects of AFs. Green tea, likely polyphenols, reduces or blocks initiation of AFB<sub>1</sub>-induced hepatocarcinogenesis. Enteric binding of AFs has been studied (Phillips *et al.*, 2008). Studies have shown that clays in the smectite group, including hydrated sodium calcium aluminosilicate (calcium montmorillonite), reduce the toxicity of dietary aflatoxins in a number of species. The smectite clay in the gut adsorbs the AFs making them biologically unavailable. The surface activity of the smectite clay appears to have a unique affinity for AFs. Studies in Africa showed that ingestion of a heat-processed montmorillonite clay reduced aflatoxin adducts in blood and excretion of AFM<sub>1</sub> in urine (Wang *et al.*, 2008). It is of interest to point out that clay eating has been observed to be a long-standing practice in some African societies. Modified yeast cell wall *Saccharomyces cerevisiae* can decrease absorption of AFs in some species and not in others with the results being variable (Battacone *et al.*, 2009; Firmin *et al.*, 2010).

## AFLATOXIN INTERACTIONS

Multiple mycotoxins can occur when different feed ingredients are blended to manufacture a finished feed, or a feed or feed ingredient has supported the growth of a succession of fungi. When one mycotoxin is found

in feedstuffs, the toxicologist should consider that additional mycotoxins of a different group could be present (Huff *et al.*, 1988). The presence of multiple mycotoxins can alter the dose-response curve. Therein, the level of a mycotoxin that is generally considered to be safe can be altered by the presence of other mycotoxins. The interactions of mycotoxins may vary between the indicators of effect. The interactions could be additive for one parameter and synergistic for another. A feeding study in mice showed that a combination of fumonisin B<sub>1</sub> (FB<sub>1</sub>) at 10 ppm and AFB<sub>1</sub> at 10 ppb increased feed consumption and decreased weight gains over a 90-day study interval (Casado *et al.*, 2001). Liver lesions were considered to be intensified by the combination and this effect increased temporally. AFB<sub>1</sub> and FB<sub>1</sub> combination were shown to decrease feed conversion and feed consumption in feeder pigs (Dilkin *et al.*, 2003). The dietary levels were 30 ppm FB<sub>1</sub> and 50 ppb AFB<sub>1</sub>. Pigs were fed a diet containing aflatoxins produced in rice culture, a diet containing FB<sub>1</sub> produced in corn culture and a diet containing both the rice and corn cultures (Harvey *et al.*, 1995). The interactions of aflatoxins and FB<sub>1</sub> for immunologic and liver disease parameters were essentially additive. Cultures containing aflatoxins and T<sub>2</sub> toxin when fed in combination to Japanese quail showed interactions appeared to be additive (Madheswaran *et al.*, 2004). Increased abnormal chicks were observed when ochratoxin A (2 µg) and AFB<sub>1</sub> (0.5 µg) were injected into eggs on day 3 of incubation (Edrington *et al.*, 1995). Calves were fed diets containing ochratoxin A and AFB<sub>1</sub> (Patterson *et al.*, 1981). The sources of the mycotoxins were naturally contaminated barley or naturally contaminated groundnut meal. The dose of ochratoxin A was 390 to 540 µg/kg body weight and the dose of AFB<sub>1</sub> was 10 to 13 µg/kg body weight. No adverse health effects were observed when the toxins were fed individually or as a mixture, possibly because of the ability of rumen organisms to degrade the mycotoxins. The interactions of AFs and deoxynivalenol (DON) in naturally contaminated maize were studied in pigs (Chaytor *et al.*, 2011). This study showed that diets containing both AFs and DON greater than 60 and 300 µg/kg, respectively, may diminish growth and reduce feed intake. Diets containing 120 µg of AFs/kg and 600 µg of DON/kg may reduce native resistance to disease, alter systemic inflammation and cause liver damage.

Preexisting disease can increase susceptibility to aflatoxins. Osuna *et al.* (1977) concluded that preexisting liver flukes increased the susceptibility of cattle to aflatoxins and the interactive effect was additive. Henry *et al.* (2002) estimated that the presence of hepatitis B surface antigen in serum increased the human susceptibility to aflatoxins by a factor of 30. Shivachandra (2003) showed the immunosuppression of aflatoxins was additive with fowl adenovirus serotype-4. Ethanol was

found to potentiate AFB<sub>1</sub>-induced hepatocarcinogenesis (Tanaka *et al.*, 1989).

## CONCLUDING REMARKS AND FUTURE DIRECTIONS

Aflatoxins, on a world scale, are one of the most important groups of mycotoxins (Lanyasunya *et al.*, 2005). Aflatoxins target the liver immune system, kidney and other body organs. Aflatoxin B<sub>1</sub> is the most potent known naturally occurring carcinogen. Metabolism of AFs varies between species and likely explains the species differences in toxicity. Reactive metabolites of AFs form adducts with nucleic acids and proteins. Human and animal populations are exposed to AFs in foodstuffs and feedstuffs, respectively. The parent aflatoxin and its toxic metabolites can be present in edible animal products. The interactive effects of aflatoxins with infectious and parasitic diseases and other toxins have been demonstrated. Agronomic practices, pest control and ensuring that stored commodities cannot support growth of fungi are the best control for prevention of aflatoxin contamination of foods and feeds.

# Ergot

Steven S. Nicholson

## INTRODUCTION

Ergot is a general term that applies to all species of the fungus *Claviceps*. Ergotism refers to the disease conditions associated with ingestion of toxic levels of ergot by animals and humans. Ergot contaminated rye (*Secale cereale*) used as flour was responsible for episodes of human ergotism in Europe during the Middle Ages. Significance, chemistry and determination of ergot alkaloids were reviewed recently by Krska and Crews (2008). The genus *Claviceps* includes very specialized fungi which parasitize the flowers of grasses and cereal grains with no other part of the plant infected. Recently, ergot alkaloids produced by *Claviceps cyperi* in nut sedge were described as a toxicant in dairy cattle (Naude *et al.*, 2005). *Claviceps africana* ergot in sorghum produces dihydroergosine (DHES) and related alkaloids, which cause hyperthermia in cattle but dilution in ensilage reduced average concentrations of DHES to approximately 1 mg/kg, a relatively safe level for cattle (Blaney *et al.*, 2010). This chapter primarily addresses alkaloids produced by *Claviceps purpurea* and the various toxic effects, called ergotism, which they produce in animals and humans. The source of exposure to animals includes ergot-infected grains in feeds such as barley, rye, wheat and oats as well as infected seeds in forages consumed while grazing or in hay and silage. Removal of ergotized seeds along with broken grain kernels and debris by the process of mechanical screening of harvested and stored grain concentrates the ergot in the screenings. Utilizing such contaminated grain screenings for human food or animal feed would create a distinct hazard.

Clinical syndromes include gangrene of the extremities of cattle and horses, hyperthermia and production loss in cattle, agalactia and abortion in swine, agalactia

and reproductive effects in mares. Most countries have a regulatory limit of 0.1–0.2% ergots in flour. The suggested maximum level for safety is 0.05%. In the U.S., wheat and rye with 0.3% sclerotia are considered unsafe and oats, triticale, or barley having more than 0.1% sclerotia are deemed unfit for human consumption.

Clinical disease associated with *Claviceps* has a parallel in fescue grass toxicosis (see Chapter 87) where gangrenous ergotism, hyperthermia, production loss in cattle and adverse effects on reproduction and lactation in horses are similar (Evans *et al.*, 2004). The seeds of fescue grass can be infected with *Claviceps purpurea* but the ergot alkaloids of fescue grass toxicosis are produced by the endophyte fungus *Neotyphodium coenophialum*. Ergot alkaloid-induced fescue toxicosis has been studied in much more detail than has ergotism from ingested *C. purpurea* sclerotia.

Ergovaline produced in perennial and annual ryegrasses by the endophyte fungus *Neotyphodium lolii* is associated with clinical toxicosis (Schneider *et al.*, 1996; Bourke, 2003).

## BACKGROUND

*C. purpurea* has a host range exceeding 200 species of grasses. It is distributed worldwide in temperate climatic zones. During infection by *C. purpurea*, the ovary of the grass seed or cereal grain is replaced by fungal mycelia. A sticky exudate known as honeydew is produced that contains conidia which can be transferred to infect other seeds. The honeydew hardens to form a hard brown, purple or black compact mass of fungal tissue called a sclerotium. The ergot bodies or sclerotia contain up to

1.2% dry weight of toxic alkaloids (Burrows and Tyrll, 2001). Sclerotia of most *Claviceps* species are one to four times larger than the host seed and are readily identified in cereal grains. Compared to sclerotia in oats or barley the sclerotia are quite small in grass seeds such as Bahia grass (*Paspalum notatum*). Sclerotia fall to the ground over winter and later complete the fungal life-cycle by germinating and producing ascospores capable of infecting the ovary of developing seeds.

Alkaloids from *C. purpurea* are among the most important natural products used by the pharmaceutical industry. Prior to the industrial cultivation of *C. purpurea* in pure culture, ergot was grown as a crop on rye (*Secale cereale*) under field conditions for use in the manufacture of important medicinal drugs. Synthesized ergot alkaloids have a variety of uses in human and veterinary medicine. Chemical structures of some of the ergot alkaloids are shown in Figure 89.1.

## PHARMACOKINETICS/ TOXICOKINETICS

Ergot alkaloids responsible for most clinical signs and lesions are of the ergopeptine class including ergotamine, ergocristine, ergosine, ergocornine, ergocryptine and ergovaline (Cheeke, 1998; Carson, 1999; Burrows and Tyrll, 2001; Evans *et al.*, 2004). Injected intravenously, ergopeptine alkaloids are rapidly cleared from the blood by the liver (Cheeke, 1998) and excreted in the bile (Evans *et al.*, 2004). These alkaloids are not secreted in the milk of cows (Cheeke, 1998).

## MECHANISM OF ACTION

Ergot alkaloids have structures similar to the biogenic amines norepinephrine, serotonin and dopamine. Vasoconstriction is produced by an agonist activity and this effect varies with different vascular beds. Hyperthermia and uterine stimulation are other effects. The alkaloids are antagonistic to dopamine at D<sub>1</sub> vasodilatory receptors. Dopaminergic activity at D<sub>2</sub> receptors causes inhibition of prolactin secretion (Goldstein *et al.*, 1980). The dopamine antagonist domperidone is an effective treatment in mares suffering agalactia and uterine effects induced by ergot alkaloids in endophyte-infected tall fescue grass (Redmond *et al.*, 1993).

## TOXICITY

Expression of clinical toxicosis caused by ergot alkaloids occurs in four forms in livestock. These include: cutaneous

and gangrenous lesions of the tail and extremities, hyperthermia and production loss, reproductive failure, and a convulsive or nervous form. The latter is apparently uncommon, not well documented and is perhaps caused by acute ingestion of a large dose of sclerotia. Muscle tremors and hyperexcitability are signs in cattle caused by non-ergot compounds produced by *Claviceps paspali* in seeds of paspalum grasses (Cole *et al.*, 1977). Staggers in horses grazing paspalum grass seeds infected with *Claviceps paspali* occur as well (Cawdell-Smith *et al.*, 2010). Indole-diterpenes and ergot alkaloids were confirmed in Bermuda grass (*Cynodon dactylon*) infected with *Claviceps cynodontis* from an outbreak of tremors in cattle in South Africa (Uhlig *et al.*, 2009). In countries where cereal grains in commerce are subject to regulatory oversight, the presence of ergotized seed at significant levels in food and feedstuffs is not common. Ergotism in cattle caused by sclerotia ingested while grazing remains a sporadic problem in the United States (Burrows and Tyrll, 2001).

The cutaneous and gangrenous form of ergotism is associated with subacute or chronic ingestion of the ergopeptine alkaloids. Cold temperatures enhance the clinical effects. Constriction of small arteries and arterioles leads to necrosis affecting all four limbs, tips of the ears and distal third of the tail. Distinct lines separating normal tissue from nonviable tissues appear. The odor of rotting flesh may be obvious and affected animals may continue to walk until sloughing of the digits occurs.

Hyperthermia was noted in steers exposed to sunlight and fed 180 mg/kg body weight of *C. purpurea* even at moderate ambient temperatures and humidity (Bourke, 2003).

Hyperthermia induced by high ambient temperature and humidity in lactating dairy cattle reduces feed intake and milk production, and increases embryonic losses. Ingestion of ergot alkaloids enhances this effect (Al-Tamimi *et al.*, 2003). Hyperthermia and a 30% drop in milk yield occurred in succession in two Holstein dairy herds (n = 240 and n = 150 milking cows, respectively) on the South African Highveld (Naude *et al.*, 2005). Examination of the maize silage from both farms revealed that it was heavily contaminated with nut sedge which contained minute sclerotia, identified as those of *Claviceps cyperi*. This was the first report of bovine ergotism not associated with the grass family Poaceae infected with *C. purpurea* or endophytes. High levels of total ergot alkaloids, predominantly ergocryptine, were found by LC-MS in the silage as well as in the total mixed ration (115–975 ppb and 65–300 ppb, respectively). The ergot alkaloid content (mainly ergocryptine) of the maize silage on the second affected farm was 875 ppb. A significant 4.6 liter decrease in milk production in a herd of Holstein-Friesian dairy cows in Australia was associated with high concentrations of

FIGURE 89.1 Chemical structures of some ergot alkaloids.

endophyte produced ergovaline ( $1.6\mu\text{g/g}$ ) in ryegrass silage (Lean, 2001). Simultaneously, milk somatic cell counts increased significantly and reproductive performance declined. Body condition score and coat condition of cows were adversely affected. In a study to determine if ergot alkaloids from *Claviceps purpurea* were carried

over to the milk, Holstein cows were fed contaminated diet (concentrate contained 2.25% ergot, which caused an alkaloid concentration of the daily ration between 504.9 and  $619.5\mu\text{g/kg DM}$ ) over a period of 4 weeks. Daily feed amounts were adjusted to the current performance which resulted in a dry matter intake variation between

6.0 and 18.5 kg/day. The actual alkaloid exposure varied between 4.1 and 16.3 µg/kg body weight when the ergot-contaminated concentrate was fed. Approximately 67% of the alkaloids fed were recovered in the duodenal ingesta, and approximately 24% were excreted with the feces. No alkaloid residues could be detected in the blood or milk samples (Schumann *et al.*, 2009).

Sheep are susceptible to the vasoconstrictive effects of ergopeptine alkaloids but ergot toxicosis is described as typically mild and not accompanied by gangrenous lesions (Greatorox and Mantle, 1973). Sloughing of the tip of the tongue is said to occur (Burrows and Tyrl, 2001).

The effects of ergot alkaloids in swine are primarily those of agalactia, production loss and an impact on reproduction. Diets containing 0, 1 and 10 g ergot (*C. purpurea*) per kg were fed to 12 pigs in the body weight range of 30–115 kg. Tendencies towards reduced feed intake and low rate of weight gain were observed at a feeding level of 4.66 mg total alkaloids per kg diet. At that level, protein digestibility was significantly reduced (Mainka *et al.*, 2005). Birth weight in pigs is reduced, stillborns increased and neonatal mortality increased due to agalactia in the sow (Lopez *et al.*, 1997).

Agalactia, small, weak foals, stillborn foals and placental edema occur in pregnant mares ingesting ergot alkaloids in the last month of gestation. This is a common occurrence in mares grazing endophyte-infected tall fescue grass in the United States. Similar effects caused by ingestion of *C. purpurea* sclerotia are seldom reported, perhaps because heavily infected ergot cereal grains are generally kept out of feed grain commerce. There remains the situation where heavily contaminated cereal grain screenings could be fed to horses. Twelve pregnant mares fed black oat (*Avena strigosa*) during the pre-delivery period experienced agalactia and delivered weak and unviable foals, which showed no suckling reflex and died within a few hours of birth. *C. purpurea* sclerotia were identified in 0.22% of the examined oat seeds (Copetti *et al.*, 2002).

Chickens develop gangrene involving the comb, beak and toes, weight loss and debilitation. Rabbits are extremely sensitive to the hyperthermic effects caused by ergot alkaloids (Burrows and Tyrl, 2001). Ergot alkaloids are embryocidal and abortifacient in laboratory animals (Mantle, 1969).

In dogs and rodents, corpora lutea are essential to maintain pregnancy. In these animals, ergot alkaloids inhibit prolactin secretion causing loss of corpora lutea and abortion.

Ergot alkaloids in oats fed to female mink bred to untreated males caused reduced numbers of kits born compared to controls (Sharma *et al.*, 2002). There was a significant effect on kit survivability with no kits surviving in the 12 ppm group. Serum prolactin was significantly depressed in the three ergot alkaloid groups compared to the control group. This study indicated that

ingestion of ergot alkaloids at 3 ppm or higher resulted in reproductive toxicity in mink.

## TREATMENT

Removing the source of ergot from the animals' diet is an obvious first step in treatment. The hyperthermic effect in dairy cattle should abate within 1 to 2 weeks. Animals that have developed gangrene of the extremities would not be expected to recover and should be euthanized.

The dopamine antagonist domperidone is an effective treatment in mares to prevent agalactia and uterine effects induced by ergot alkaloids in endophyte-infected tall fescue grass (Redmond *et al.*, 1993, 1995).

## CONCLUDING REMARKS

Ergot infection in cereal grains and grasses remains a concern for livestock and horses. Commercial cereal grain screenings and cereal grains produced and fed on the farm, and not inspected, are potential sources of ergotized grain. Exposure while grazing infected grasses may go unnoticed initially, especially if management is not aware of the risk.

# Fumonisin

Geof W. Smith

## INTRODUCTION

Fumonisin ( $B_1$  and  $B_2$ ) are a group of naturally occurring mycotoxins produced by the fungus *Fusarium verticillioides* (formerly *F. moniliforme*). These toxic metabolites in corn have been implicated in field cases of porcine pulmonary edema (Harrison *et al.*, 1990; Osweiler *et al.*, 1992; Colvin *et al.*, 1993) and equine leukoencephalomalacia (Wilson *et al.*, 1990a). Experimentally, fumonisin has been shown to cause liver damage in multiple species including pigs, horses, cattle, rabbits and primates (Jaskiewicz *et al.*, 1987; Voss *et al.*, 1989; Haschek *et al.*, 1992; Osweiler *et al.*, 1993; Ross *et al.*, 1993; Gumprecht *et al.*, 1995) as well as species-specific target organ toxicity, such as lung in pigs (Haschek *et al.*, 1992), brain in horses (Ross *et al.*, 1993), kidney in rats, rabbits and sheep (Voss *et al.*, 1989; Edrington *et al.*, 1995; Gumprecht *et al.*, 1995) and esophagus in rats and pigs (Casteel *et al.*, 1993; Lim *et al.*, 1996). Epidemiologic data have linked ingestion of corn contaminated with *F. verticillioides* to human esophageal cancer (Rheeder *et al.*, 1992) and infant neural tube defects (Voss *et al.*, 2011); and fumonisins have been shown to be hepatocarcinogenic in rats and mice (Gelderblom *et al.*, 1988; Howard *et al.*, 2001).

## BACKGROUND

### Chemical structure

First isolated in 1988, the fumonisins are a group of structurally related compounds with the terminal carboxy group composed of propane-1,2,3-tricarboxylic

acid involved in ester formation with the C-14 and C-15 hydroxy groups. The 20 carbon chain base carries either 2-acetylamino or 2-amino-12,16-dimethyl-3, 5,10,14,15, pentahydroxyicosane (Figure 90.1). The structures of  $FB_1$  and  $FB_2$  have been shown to have the empirical formulas of  $C_{34}H_{59}NO_{15}$  and  $C_{34}H_{59}NO_{14}$ , respectively, with the only difference being the hydroxyl group present at the C-10 position in  $FB_1$  (Bezuidenhout *et al.*, 1988). Several additional fumonisin metabolites have been isolated ( $B_3$ ,  $B_4$ ,  $B_5$ ,  $B_6$ ,  $A_1$  and  $A_2$ ), but appear to occur in much lower concentrations than  $FB_1$  or  $FB_2$ , and are not considered important at this time (Gelderblom *et al.*, 1992; Mansson *et al.*, 2010). More recently, fumonisins have also been found in grapes and wine associated with the fungus *Aspergillus niger* (Mansson *et al.*, 2010; Mogensen *et al.*, 2010).

### Occurrence and distribution

Apart from reports of fumonisin  $B_1$  and  $B_2$  in “black oats” feed from Brazil (Sydenham *et al.*, 1992), and in New Zealand forage grasses (Mirocha *et al.*, 1992), the only commodities in which fumonisins have been detected so far are corn and corn-based foods. The occurrence of  $FB_1$  in the forage grass was accompanied by mono- and dimethyl esters which may or may not have been artifacts (Mirocha *et al.*, 1992). Equine leukoencephalomalacia (ELEM) has long been associated with the consumption of moldy corn, and has been reported in many areas of the world. However, cases of ELEM that were directly associated with fumonisin-contaminated feed have been reported in South Africa and Egypt (Thiel *et al.*, 1991), the United States (Wilson *et al.*, 1990a;

Ross *et al.*, 1991), Brazil (Sydenham *et al.*, 1992), Hungary (Bela and Endre, 1996), Spain (Cerrillo *et al.*, 1996), New Caledonia (Bailly *et al.*, 1996), Mexico (Rosiles *et al.*, 1998) and Iran (Raooofi *et al.*, 2003). Additionally cases of porcine pulmonary edema (PPE) have been associated with fumonisin-contaminated feeds in the United States (Harrison *et al.*, 1990; Osweiler *et al.*, 1992), Brazil (Sydenham *et al.*, 1992), Hungary (Fazekas *et al.*, 1998) and Thailand (Patchimasiri *et al.*, 1998).

Commercial corn-based human feedstuffs from retail outlets in several countries frequently contain fumonisins (Sydenham *et al.*, 1991; Pittet *et al.*, 1992; Stack and Eppley, 1992). Corn meal and corn grits appear to be the biggest problems, as up to 2.98 µg FB<sub>1</sub>/g and 0.92 µg FB<sub>2</sub>/g have been found in corn meal and up to 2.55 µg FB<sub>1</sub>/g and 1.07 µg FB<sub>2</sub>/g in corn grits (Sydenham *et al.*, 1991). Only very low incidences and levels of FB<sub>1</sub> have been recorded for corn flakes breakfast cereal in Switzerland, the United States and South Africa (Sydenham *et al.*, 1991; Pittet *et al.*, 1992; Stack *et al.*, 1992). A survey in Maryland showed that nearly 100% of corn-based food products (including corn muffin mixes, corn chips, corn tortillas, cornflakes breakfast cereal, corn starch, infant mixed cereal and corn grits) purchased in grocery stores contained some level of fumonisins with concentrations ranging up to 7.5 µg/g (Castelo *et al.*, 1998). Corn-based food products purchased in Arizona and Nebraska were also frequently (>85%) contaminated with fumonisins with concentrations up to 5.2 µg/g being reported (Castelo *et al.*, 1998).

## PHARMCOKINETICS/TOXICOKINETICS

The pharmacokinetics of fumonisin B<sub>1</sub> have been examined in several species including rats, pigs, cattle, laying hens and primates (Prelusky *et al.*, 1994, 1995; Vudathala *et al.*, 1994; Shephard *et al.*, 1995; Richard *et al.*, 1996; Martinez-Larranaga *et al.*, 1999). In general, fumonisin is rapidly absorbed following intravenous or intraperitoneal administration and is eliminated in both the feces and urine. Levels are undetectable by 24 hours after dosing in virtually all species and significant concentrations (residues) have not been found in muscle, milk or eggs. Following oral dosing, very little fumonisin B<sub>1</sub> is typically found in the serum of animals indicating low bioavailability.

More specifically, the toxicokinetics of radiolabeled fumonisin B<sub>1</sub> were examined after intragastric (0.5 mg fumonisin B<sub>1</sub>/kg) or intravenous (0.4 mg fumonisin B<sub>1</sub>/kg) administration to bile-cannulated and non-cannulated pigs (Prelusky *et al.*, 1994). Fumonisin-derived radioactivity was not detected in the plasma of pigs

dosed intravenously after 180 minutes in the non-cannulated group, or after 90 minutes in the cannulated group. Urinary excretion began within 3 hours of administration and virtually ended after 8 hours, accounting for only a small amount of administered toxin. Fecal excretion of fumonisin persisted for 48 hours. The excretion in the intravenously dosed group occurred primarily via the bile, with biliary excretion greatest during the first 4 hours, but persisting for 24–36 hours.

Plasma radioactivity in intragastrically dosed pigs was first detected 30–45 minutes after dosing, with maximal activity present between 60 and 90 minutes. As reflected in plasma and elimination data, systemic bioavailability of the dose ranged from 3 to 6%. Excretion of the fumonisin occurred primarily via feces, with only trace amounts excreted via urine or bile.

At 72 hours after administration, tissue radioactivity was highest in the liver, kidney and large intestine in all groups. Intragastrically dosed groups had 10–20-fold lower tissue concentrations than did intravenously dosed groups, and only intravenously dosed groups had measurable radioactivity in brain, lung and adrenal. Thus, it seems that liver and kidney are the primary organs of fumonisin metabolism and excretion in the pig, and that enterohepatic circulation prolongs the persistence of fumonisin in the body. The toxicokinetics of fumonisin B<sub>1</sub> in horses has not been evaluated.

When pigs were fed fumonisin at daily concentrations between 50 and 500 µg of fumonisin B<sub>1</sub> per kg of body weight for the last 5 months before slaughter, no muscle or kidney residues were detected (Liguoro *et al.*, 2004). Fumonisin B<sub>1</sub> was not detected in the eggs from laying hens following either intravenous or oral administration (Vudathala *et al.*, 1994). Although negligible concentrations have been shown to cross the mammary barrier (Spotti *et al.*, 2001), the toxin was not detected in milk from cattle that consumed a diet containing fumonisins (Richard *et al.*, 1996). Therefore, it appears that fumonisin residues in meat, milk or eggs does not represent a hazard or food safety concern for humans consuming these products.

## MECHANISM OF ACTION

### Sphingolipid alterations

Fumonisin is structurally related to sphingosine, the major long chain base backbone of cellular sphingolipids (Figure 90.1). They are competitive inhibitors of sphingosine and sphingosine N-acyltransferase (also known as ceramide synthase), key enzymes in the *de novo* sphingolipid biosynthetic pathway (Figure 90.2). These N-acyltransferase enzymes are responsible for catalyzing

**FIGURE 90.1** The structure of fumonisin B<sub>1</sub>, fumonisin B<sub>2</sub>, sphingosine and sphinganine. (Modified from Diaz and Boermans, 1994, reprinted with permission from Smith and Constable, 2004.)

the acylation of sphinganine and the reutilization of sphingosine derived from sphingolipid turnover. This inhibition by fumonisin has been characterized *in vitro* using liver and brain microsomes, as well as in intact mammalian cells in culture (hepatocytes, neurons, renal cells and macrophages) (Merrill *et al.*, 1995). Fumonisin B<sub>1</sub> blocks the incorporation of radiolabeled serine into the sphingoid base backbone of ceramides and complex sphingolipids and prevents the conversion of sphinganine to sphingosine via addition of the 4,5 *trans* double bond, which occurs after acylation of sphinganine. Fumonisin also blocks reacylation of sphingoid bases (primarily sphingosine) released by hydrolysis of more complex sphingolipids (Merrill *et al.*, 1995).

Sphingolipids are located in cellular membranes, lipoproteins (especially low-density lipoproteins) and other lipid-rich structures. Complex sphingolipids are critical for the maintenance of membrane structure, particularly microdomains such as caveolae. They also serve as binding sites for extracellular matrix proteins as well as for some microorganisms, microbial toxins and viruses, and regulate the behavior of growth factor receptors (Merrill

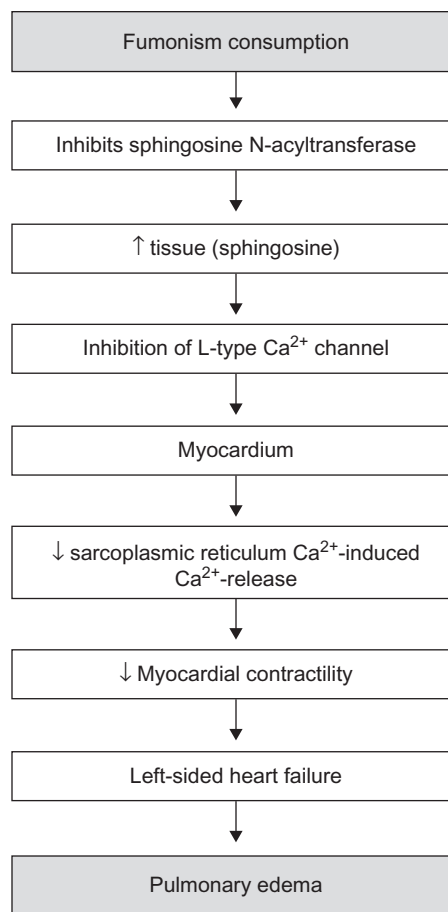

**FIGURE 90.2** The effects of fumonisin on the sphingolipid biosynthetic pathway. (Modified from Diaz and Boermans, 1994, reprinted with permission from Smith and Constable, 2004.)

and Sweeley, 1996). Complex sphingolipids function as precursors for second messengers that mediate cell responses to growth factors, cytokines (including tumor necrosis factor- $\alpha$ ), differentiation factors and 1,25-dihydroxy-vitamin D<sub>3</sub>. Therefore sphingolipids are involved in the regulation of cell growth, cell-to-cell communication, differentiation and neoplastic transformation (Hannun and Bell, 1989).

This enzyme inhibition by fumonisin produces a disruption of sphingolipid metabolism resulting in increased sphinganine and sphingosine along with a decrease in complex sphingolipids in the serum and tissues of animals (Wang *et al.*, 1991). These elevations in concentrations of sphinganine and sphingosine have also been observed *in vivo* in several species including pigs, horses and calves (Riley *et al.*, 1993; Goel *et al.*, 1996; Smith *et al.*, 1999, 2000; Mathur *et al.*, 2001). This disruption of sphingolipid metabolism is generally accepted as the probable mechanism of fumonisin toxicity; however, only in pigs has the pathophysiology been definitively determined.

Porcine pulmonary edema has been shown to be a direct result of acute left-sided heart failure related to an increase in plasma and myocardial sphinganine and sphingosine concentrations (Constable *et al.*, 2000; Smith *et al.*, 1999, 2000). Sphingosine is an important intracellular second messenger that inhibits L-type calcium channels in myocardial cells, thereby decreasing sarcoplasmic reticulum Ca<sup>2+</sup>-induced Ca<sup>2+</sup>-release and cardiac contractility (McDonough *et al.*, 1994; Webster *et al.*, 1994). As sphingosine concentrations begin to increase in pigs that consume fumonisin, myocardial calcium channels are blocked and contractility begins to decrease (Constable *et al.*, 2000; Smith *et al.*, 2000). Ultimately this decrease in cardiac contractility causes acute left ventricular failure and pulmonary edema (Figure 90.3).

The mechanism of equine leukoencephalomalacia may also be a direct result of fumonisin-induced increases in sphingosine concentrations. A recent study demonstrated that fumonisin administration induced cardiovascular dysfunction in horses (Smith *et al.*, 2002). This study reported an association between neurologic signs, increased serum and myocardial sphingosine concentrations, and cardiovascular depression in fumonisin-treated horses. At necropsy, horses with leukoencephalomalacia have histologic evidence of cerebral edema in the brain. Another study has reported that fumonisin-treated horses also have elevated protein, albumin and IgG levels in cerebrospinal fluid samples (Foreman *et al.*, 2004). Taken together, these findings indicate that fumonisin toxicity in horses is associated with the development of vasogenic cerebral edema as a direct result of increased blood-brain barrier permeability. Horses are a species that is dependent on autoregulation of cerebral blood flow when they lower their

**FIGURE 90.3** Mechanism of fumonisin-induced pulmonary edema in swine. Fumonisin inhibition results in increased tissue sphingosine and sphinganine concentrations. The increased sphingosine concentrations inhibit the L-type Ca<sup>2+</sup> channels of cardiac myocytes resulting in decreased myocardial contractility. This decrease in contractility results in acute left-sided heart failure and pulmonary edema.

head to graze. Because of gravitational forces, distal carotid artery pressure can increase tremendously when the animal bends to eat or drink. However, this rise in carotid pressure does not create a significant increase in cerebral blood flow due to the constriction and dilation of cerebral arterioles which maintain normal cerebral blood pressures (Faraci and Heistad, 1990). It has been shown that L-type calcium channels are the primary mediators of vascular tone in these cerebral arterioles (Michelakis *et al.*, 1994). Therefore, it has been hypothesized that fumonisin-induced increases in sphingosine concentrations inhibit the calcium channels in cerebral arterioles leading to the inability to maintain normal cerebral blood pressure and vasogenic cerebral edema. This hypothesis will require further research to be proven definitively.

## TOXICITY

Fumonisin has been shown to cause liver damage in multiple species including pigs, horses, cattle, rabbits and primates (Jaskiewicz *et al.*, 1987; Voss *et al.*, 1989; Haschek *et al.*, 1992; Osweiler *et al.*, 1993; Ross *et al.*, 1993; Gumprecht *et al.*, 1995) as well as species-specific target organ toxicity, such as lung in pigs (Haschek *et al.*, 1992), brain in horses (Ross *et al.*, 1993), kidney in rats, rabbits and sheep (Voss *et al.*, 1989; Edrington *et al.*, 1995; Gumprecht *et al.*, 1995) and esophagus in rats and pigs (Casteel *et al.*, 1993; Lim *et al.*, 1996). This chapter is focused on fumonisin toxicity in pigs and horses since they are the most common clinical poisonings dealt with in veterinary medicine; however, cattle and poultry are briefly discussed.

### Spontaneous and experimental fumonisin toxicosis in swine

In early research prior to the initial isolation and characterization of fumonisins, *Fusarium verticillioides* culture material was reported toxic to swine (Kriek *et al.*, 1981). In that experiment, three pigs were fed *F. verticillioides* culture material grown on corn. Two of the three pigs fed the culture material in this study died within 5 days of pulmonary edema. The third pig was fed culture material for 89 days and was then killed following a period of feed refusal.

The 1989 corn crop in many Midwestern and southeastern parts of the United States was heavily infected with *F. verticillioides*, and contaminated screenings fed to animals led to fatal outbreaks of porcine pulmonary edema (Harrison *et al.*, 1990; Osweiler *et al.*, 1992). This syndrome was also reproduced experimentally with contaminated corn screenings and purified fumonisin B<sub>1</sub> (Harrison *et al.*, 1990; Osweiler *et al.*, 1992).

Lung and liver are the major target organs of fumonisin toxicosis in pigs; however, other organs have been reported to be affected. Pigs which ingest fumonisin at concentrations high enough to cause pulmonary edema usually die after about 4 days in field cases (Osweiler *et al.*, 1992) and after 3–6 days of fumonisin exposure experimentally (Haschek *et al.*, 1992; Motelin *et al.*, 1994; Gumprecht *et al.*, 1998). Pigs which survive chronic exposure to high doses of fumonisin without developing pulmonary edema typically demonstrate hepatic disease with anorexia, weight loss and generalized icterus (Osweiler *et al.*, 1992; Colvin *et al.*, 1993). Hepatic toxicity occurs at doses significantly lower than those necessary to cause pulmonary edema (Colvin *et al.*, 1993; Motelin *et al.*, 1994).

### Fumonisin in swine – pulmonary effects

Pulmonary edema (Figure 90.4) has been reported in pigs fed naturally contaminated fumonisin-containing

**FIGURE 90.4** Lung from a pig fed fumonisin-containing culture material at a dose of 20 mg fumonisin B<sub>1</sub> per kg of body weight for 4 days. Pulmonary edema is characterized by severe widening of the interlobular septa. (Reprinted with permission from Smith and Constable, 2004.)

food, fumonisin-containing culture material or following IV administration of fumonisin (Harrison *et al.*, 1990; Haschek *et al.*, 1992; Osweiler *et al.*, 1992; Motelin *et al.*, 1994). Reported concentrations of fumonisin required to produce pulmonary edema have been variable, presumably due to variability in susceptibility among exposed animals (Table 90.1). However, other constituents in the diet and analytical detection related to the ability to extract fumonisin from different matrices could account for some of the variability. In addition, some reports have documented only the concentration of fumonisin B<sub>1</sub> associated with the development of pulmonary edema, while others have reported both fumonisin B<sub>1</sub> and fumonisin B<sub>2</sub>. Fumonisin B<sub>2</sub> usually occurs at about 30% of fumonisin B<sub>1</sub> in naturally contaminated corn, and is generally considered to be equitoxic to fumonisin B<sub>1</sub> (Ross *et al.*, 1994). Reported doses that induced pulmonary edema in swine include 100 ppm of fumonisin B<sub>1</sub> and fumonisin B<sub>2</sub> in naturally contaminated corn (Motelin *et al.*, 1994), 16 mg fumonisin B<sub>1</sub>/kg/day as fumonisin-containing culture material (Colvin *et al.*, 1993) and 20 mg fumonisin B<sub>1</sub>/kg/day as culture material (Gumprecht *et al.*, 1998). Fumonisin-induced pulmonary edema has also been reported with naturally contaminated corn (330 mg of fumonisin B<sub>1</sub> per kg of feed) in Hungary (Fazekas *et al.*, 1998), Brazil (Sydenham *et al.*, 1992) and Thailand (Patchimasiri *et al.*, 1998).

A more recent study has suggested that even lower concentrations of fumonisins may be able to induce pulmonary edema in swine (Zomborszky *et al.*, 2000). Fumonisin B<sub>1</sub> was added to the feed of weaned pigs at doses of 0, 10, 20 and 40 ppm for 4 weeks as fumonisin-containing culture material (five pigs per group). Computed tomography of the lungs and magnetic

TABLE 90.1 Effects of fumonisin in pigs

Number of animals	Dose and route	Duration	Toxic effects	Reference
<b>Experimental studies using purified fumonisin</b>				
4 pigs	0.174 to 0.4 mg FB <sub>1</sub> per kg of BW/day, IV	4 to 8 days	2 high dose pigs developed pulmonary edema	Harrison <i>et al.</i> (1990)
2 pigs	0.88 to 1.15 mg FB <sub>1</sub> per kg of BW/day, IV	1 pig for 4 days (0.88 mg/kg/day) – 2nd pig for 9 days (1.15 mg/kg/day)	Mild interstitial pulmonary edema histologically in one pig; hepatic lesions; pancreatic lesions	Haschek <i>et al.</i> (1992)
3 pigs	4.5 to 6.6 mg FB <sub>1</sub> per kg of BW/day in feed	5 to 15 days	2 of the 3 pigs developed severe pulmonary edema; hepatic lesions and mild pancreatic lesions noted	Haschek <i>et al.</i> (1992)
2 pigs	0.4 mg FB <sub>1</sub> per kg of BW/day, IV	12 to 14 days	Elevated AST, GGT, bilirubin; liver lesions	Osweiler <i>et al.</i> (1992)
8 pigs	10 ppm FB <sub>1</sub> added to the diet – fed ad libitum	8 weeks	Decreased weight gain	Rooter <i>et al.</i> (1996)
6 pigs	1 mg FB <sub>1</sub> per kg of BW/day, IV	4 days	Elevated cholesterol Decrease in left ventricular contractility and mild pulmonary edema	Smith <i>et al.</i> (2000)
<b>Experimental studies using fumonisin-containing culture material</b>				
6 pigs	Feeds containing 100 and 190 ppm FB <sub>1</sub> – fed ad libitum	100 ppm diet fed ad libitum for 7 days followed by 190 ppm diet for 83 days	Elevated AST, ALP, GGT; nodular hyperplasia of the liver; histologic esophageal lesions	Casteel <i>et al.</i> (1993)
4 pigs	Feed containing 200 ppm of FB <sub>1</sub> – fed ad libitum	Up to 43 days	Elevated bilirubin, AST, cholesterol; hepatic lesions; decreased weight gain	Colvin <i>et al.</i> (1993)
7 pigs	16 to 64 mg FB <sub>1</sub> per kg of BW/day as oral gavage	3 to 5 days	All pigs developed pulmonary edema within 5 days	Colvin <i>et al.</i> (1993)
3 pigs	4 to 16 mg FB <sub>1</sub> per kg of BW/day as oral gavage	Up to 45 days	Severe hepatic disease; icterus; elevated liver enzymes; no pulmonary edema	Colvin <i>et al.</i> (1993)
11 pigs	Feeds containing 100, 160 and 190 ppm FB <sub>1</sub> – fed ad libitum	6 pigs were fed 100 ppm for 10 days then 190 ppm for up to 83 days; 5 pigs were fed 100 ppm for 5 days and then 160 ppm for up to 205 days	Nodular hyperplasia of the liver; elevated AST, ALP, GGT, bilirubin Right ventricular hypertrophy; medial hypertrophy of the small pulmonary arteries	Casteel <i>et al.</i> (1994)
6 pigs	Feed containing 47 ppm FB <sub>1</sub> – fed ad libitum	28 days	Decreased feed consumption; elevated AST, GGT, ALP and creatinine; hepatic and renal lesions; medial hypertrophy of the pulmonary arteries	Harvey <i>et al.</i> (1996)
10 pigs	20 mg of FB <sub>1</sub> per kg of BW/day, in feed	7 days	Pulmonary edema and cardiovascular abnormalities	Smith <i>et al.</i> (1996a); Smith <i>et al.</i> (1996b)
2 pigs	14.5 and 16 mg of FB <sub>1</sub> per kg of BW/day, in feed	4 days	Severe pulmonary edema; renal lesions	Fazekas <i>et al.</i> (1997)
24 pigs	20 mg of FB <sub>1</sub> per kg of BW/day, in feed	Up to 5 days – some pigs were euthanized each day of the study	All 12 pigs euthanized on days 0, 1 and 2 had no lesions 2/5 day 3 pigs and all of the day 4 and 5 pigs had pulmonary edema Elevations in liver enzymes and hepatic lesions seen on day 2 – bile acids first liver parameter to increase	Gumprecht <i>et al.</i> (1998)
6 pigs	20 mg of FB <sub>1</sub> per kg of BW/day, in feed	5–6 days – pigs were euthanized as they developed pulmonary edema	Increased pulmonary artery pressure, pulmonary artery wedge pressure and decreased cardiac output, heart rate and mean arterial pressure	Smith <i>et al.</i> (1999)
5 pigs	Feed containing 40 ppm FB <sub>1</sub> – fed ad libitum	4 weeks	No clinical signs – gross pulmonary edema evident at necropsy	Zomborszky <i>et al.</i> (2000)
5 pigs	Feed containing 20 ppm FB <sub>1</sub> – fed ad libitum	4 weeks	2 of the 5 pigs had gross pulmonary edema – 2 additional pigs had mild evidence of edema present histologically	Zomborszky <i>et al.</i> (2000)

(Continued)

TABLE 90.1 (Continued)

Number of animals	Dose and route	Duration	Toxic effects	Reference
4 pigs	Feed containing 20 ppm FB <sub>1</sub> – fed ad libitum	28 days	3 of the 4 pigs had mild pulmonary edema evident histologically	Zomborszky <i>et al.</i> (2000)
7 pigs	20 mg of FB <sub>1</sub> per kg of BW/day, in feed	3 days	Decreased left ventricular contractility; heart rate, cardiac output, and mechanical efficiency of the left ventricle	Constable <i>et al.</i> (2000)
<b>Experimental studies using naturally contaminated corn screenings</b>				
6 pigs	105 to 155 ppm FB <sub>1</sub> in corn screenings – fed ad libitum	Up to 28 days	3 of 6 pigs developed pulmonary edema; liver and pancreatic lesions	Harrison <i>et al.</i> (1990)
8 pigs	92 ppm FB <sub>1</sub> in corn screenings – fed ad libitum	Up to 21 days	6 of 8 pigs developed pulmonary edema; the remaining 2 pigs were icteric with increased liver enzymes	Osweiler <i>et al.</i> (1992)
5 pigs	175 ppm (FB <sub>1</sub> + FB <sub>2</sub> ) as corn screenings mixed in a complete ration	Up to 14 days	3 of 5 pigs developed pulmonary edema; hepatotoxicity; decreased weight gain	Motelin <i>et al.</i> (1994)
5 pigs	101 ppm (FB <sub>1</sub> + FB <sub>2</sub> ) as corn screenings mixed in a complete ration	Up to 14 days	Elevated GGT, ALT, AST, ALP and bilirubin; liver lesions; decreased weight gain	Motelin <i>et al.</i> (1994)
5 pigs	39 ppm (FB <sub>1</sub> + FB <sub>2</sub> ) as corn screenings mixed in a complete ration	14 days	Histologic liver lesions	Motelin <i>et al.</i> (1994)
5 pigs	39 ppm (FB <sub>1</sub> + FB <sub>2</sub> ) as corn screenings mixed in a complete ration	14 days	Histologic liver lesions	Motelin <i>et al.</i> (1994)
<b>Reported fumonisin concentrations from naturally occurring outbreaks</b>				
34 pigs from 2 farms	105 to 155 ppm FB <sub>1</sub>	Unknown	Lethal pulmonary edema	Harrison <i>et al.</i> (1990)
16 pigs from 9 farms	All feed samples associated with pulmonary edema contained $\geq 20$ ppm FB <sub>1</sub> to a maximum of 330 ppm FB <sub>1</sub>	Unknown	Lethal pulmonary edema	Osweiler <i>et al.</i> (1992)

resonance imaging of the brains were performed prior to the study and at 2 and 4 weeks of fumonisin feeding. Histopathology was also done at the time of necropsy (4 weeks). The results of this study showed that all five pigs fed fumonisin B<sub>1</sub> at 40 ppm developed “severe” pulmonary edema as assessed by computed tomography and histopathology. Two of the five pigs fed fumonisin B<sub>1</sub> at 20 ppm had “severe” pulmonary edema while two other pigs in the group had “mild” edema. In the 10 ppm group, three of the five pigs were reported to have “mild” pulmonary edema. Magnetic resonance studies of the brain were not able to identify any significant changes during the course of the study in any group.

Clinical signs associated with the development of pulmonary edema consistently begin 3–6 days after initiation of exposure to a high concentration of fumonisins. These include dyspnea and open-mouthed breathing, increased respiratory rate, cyanosis of skin and mucous membranes, inactivity and sudden death (Osweiler *et al.*, 1992). Pigs usually die within a few hours after the onset of definitive respiratory distress. Histologically, pulmonary edema is present by day 3 of fumonisin exposure

(Gumprecht *et al.*, 1998) and is characterized by interstitial edema around airways and vessels, in interlobular and subpleural connective tissues, and in alveolar interstitium (Harrison *et al.*, 1990; Haschek *et al.*, 1992; Osweiler *et al.*, 1992; Gumprecht *et al.*, 1998). Lymphatics are dilated and alveolar edema is often present. Fluid is also present within the thoracic cavity.

In ultrastructural studies using immersion fixed lungs, the endothelium was found to be swollen, vacuolated and sometimes missing in pigs with pulmonary edema (Haschek *et al.*, 1992). Additional studies using intravascularly perfused lungs (to allow better examination of the vascular system) demonstrated accumulations of fragmented membranous material in the cytocavitary region of endothelial cells (Gumprecht *et al.*, 1998).

### Fumonisin in swine – hepatic effects

Hepatic changes in pigs exposed to fumonisins include elevation of liver-associated enzyme activities, altered clinical chemistries, changes in sphingolipid parameters

and morphological alterations. In pigs, hepatic toxicity occurs prior to the development of pulmonary edema, and alterations are time and dose dependent (Motelin *et al.*, 1994). Increased activities of serum enzymes such as alkaline phosphatase (ALP), aspartate aminotransferase (AST) and gamma glutamyl transpeptidase (GGT) and concentrations of total bilirubin, bile acids and cholesterol have been reported as early as 1 day after the initiation of fumonisin exposure (Harrison *et al.*, 1990; Haschek *et al.*, 1992; Osweiler *et al.*, 1992; Colvin *et al.*, 1993; Motelin *et al.*, 1994; Gumprecht *et al.*, 1998). These alterations reflect hepatocyte damage as well as altered hepatic function.

Morphologic alterations are dose related and progressive with continued ingestion of fumonisins. Following short-term exposure, changes include hepatic cord disorganization, cytoplasmic vacuolation, apoptosis, scattered necrosis and increased cell proliferation (Harrison *et al.*, 1990; Osweiler *et al.*, 1992; Motelin *et al.*, 1994; Gumprecht *et al.*, 1998). Histologic alterations were observed as early as 2 days after the initiation of treatment with a lethal dose (Gumprecht *et al.*, 1998), and at a concentration as low as 23 ppm when fed for 14 days (Motelin *et al.*, 1994). Long-term fumonisin exposure can result in fibrosis or development of hyperplastic nodules in the liver (Harrison *et al.*, 1990; Casteel *et al.*, 1993). Ultrastructurally, large accumulations of proteinaceous and membranous material were observed in the Space of Disse in pigs that developed fumonisin-induced pulmonary edema (Haschek *et al.*, 1992). Hepatocytes lost microvilli from their sinusoidal face while numerous Kupffer cells contained multilamellar bodies.

### Fumonisin in swine – cardiovascular effects

Fumonisin have been shown to decrease left ventricular contractility, heart rate, cardiac output, mean arterial pressure, arterial and mixed venous blood O<sub>2</sub> tensions, and systemic oxygen delivery, while increasing mean pulmonary artery pressure, oxygen consumption and oxygen extraction ratio in swine (Constable *et al.*, 2000; Smith *et al.*, 1996a,b, 1999, 2000). The decrease in cardiac contractility leads to acute left ventricular failure and pulmonary edema in pigs exposed to high concentrations of fumonisin in feed. Chronic exposure to lower levels of fumonisin leads to the development of right ventricular hypertrophy and medial hypertrophy of the small pulmonary arteries in pigs, likely a result of pulmonary hypertension (Casteel *et al.*, 1994).

### Fumonisin in swine – immunologic effects

Fumonisin have also been shown to predispose pigs to respiratory disease. In one case-control study, swine

farms with  $\geq 20$  ppm of fumonisin in the feed were at significantly greater risk for pneumonia as compared to farms with low fumonisin concentrations (Bane *et al.*, 1992). As the concentration of fumonisin in the feed increased, the risk of respiratory disease continued to increase. Later it was shown that exposure to fumonisins depressed pulmonary intravascular macrophage function, and pigs exposed to this toxin had decreased pulmonary clearance of blood-borne particulates and bacteria when compared to control animals (Smith *et al.*, 1996c). In a more recent study, exposure to fumonisin exacerbated respiratory disease in a *Pasteurella multocida* challenge model (Halloy *et al.*, 2005). Pigs that were fed 0.5 mg of FB<sub>1</sub> per kg of body weight/day for 7 days had delayed growth, increased coughing and more severe lung lesions than control pigs. Therefore, at levels well below those needed to cause hepatic lesions or pulmonary edema, fumonisins are likely to reduce growth rates and increase disease in pigs.

### Fumonisin toxicosis in horses – historical

Several outbreaks of a neurologic disease in horses occurred in the United States in the early 1900s with thousands of deaths reported in several states. The earliest citation of neurologic deaths associated with the feeding of contaminated corn was from Maryland (MacCallum and Buckley, 1902). The condition was commonly referred to as “cerebrospinal meningitis” and presented with fairly characteristic signs. The duration of disease varied from a few hours to a week, and the brains from affected horses had “softened” areas in the cerebrum involving only the white matter. Additional outbreaks were subsequently reported from Kansas, Iowa, Mississippi and North Carolina. A similar disease, described as “epizootic cerebritis,” had been encountered in 1891; however, it is not known whether this was associated with corn (Butler, 1902). When feed from an outbreak of “leucoencephalitis” in Kansas was fed to a horse, it died after developing neurologic signs (Butler, 1902). At necropsy, the left cerebral hemisphere was “soft to the touch, and when cut through, the white matter was broken down extensively, nearly the entire hemisphere being involved.” Several attempts were made to identify an infectious agent in the brain of affected horses and all were negative (MacCallum and Buckley, 1902). The authors concluded that a toxic etiology was likely.

In central Illinois, more than 5000 horses died during the winter of 1934 to 1935 from a syndrome referred to as “cornstalk disease” (Graham, 1935). Brain tissue suspensions and filtrates were inoculated into laboratory animals; however, no infectious etiology could be identified. Graham then placed eight horses into a field containing cornstalks in Rantoul, Illinois. Two of these animals died

23 and 26 days after being placed in the field (Graham, 1936). These outbreaks were similar to those reported in 1893 and 1914 which had occurred following a summer drought (Graham, 1936). Neurologic deaths with similar lesions were also reported in Iowa during the winter of 1914 and in the spring of 1935 (Schwarte *et al.*, 1937). Histologic examination of the brain revealed no evidence of infectious agents. This “syndrome” was then subsequently reproduced by feeding moldy corn and corn fodder to five horses (Schwarte *et al.*, 1937). A similar disease syndrome was identified and confirmed by feeding trials in Egypt (Badiali *et al.*, 1968; Wilson and Maronpot, 1971) and in South Africa (Marasas *et al.*, 1976). At necropsy, these studies were able to consistently demonstrate swelling of the cerebral hemispheres and flattening of the overlying gyri. On coronal sections, there were cavities of varying sizes with liquefactive necrosis of subcortical white matter in one or both cerebral hemispheres (Figure 90.5). There were also scattered multifocal hemorrhages in the surrounding white matter (Marasas *et al.*, 1976; Haliburton *et al.*, 1979). Based on these findings, Marasas *et al.* (1976) coined the term “equine leukoencephalomalacia” as a distinct clinical and morphologic syndrome in horses associated with the feeding of corn.

*Fusarium verticillioides* was later isolated from corn collected from field outbreaks in Egypt, and leukoencephalomalacia was subsequently reproduced in donkeys fed corn inoculated with the fungus (Wilson and Maronpot, 1971). In South Africa, however, samples of corn inoculated with *F. verticillioides* produced liver damage and icterus in several horses and donkeys, but not brain lesions (Kellerman *et al.*, 1972). Marasas *et al.* (1976) then produced a batch of culture material using a strain of *F. verticillioides* from an outbreak of leukoencephalomalacia

**FIGURE 90.5** A cross-section of a cerebral hemisphere from a horse demonstrating liquefactive necrosis of the white matter typical of equine leukoencephalomalacia. (Reprinted with permission from Smith and Constable, 2004.)

to produce liver damage and neurologic disease in a horse. It was then concluded that both hepatic disease and equine leukoencephalomalacia (ELEM) were manifestations of the same toxicosis, with different clinical syndromes occurring depending on toxin dose and length of exposure. Following the isolation and purification of fumonisin B<sub>1</sub> in the late 1980s, ELEM was experimentally induced by the administration of purified toxin (Marasas *et al.*, 1988; Kellerman *et al.*, 1990).

### Spontaneous and experimental fumonisin toxicosis in horses

Since the discovery of fumonisin B<sub>1</sub> as the causative agent of ELEM, many more disease outbreaks associated with the feeding of corn have been reported (Wilson *et al.*, 1990a; Ross *et al.*, 1991, 1993; Uhlinger, 1991; Binkerd *et al.*, 1993; Christley *et al.*, 1993; Wilkins *et al.*, 1994; Bailly *et al.*, 1996; Bela and Endre, 1996; Cerrillo *et al.*, 1996; Rosiles *et al.*, 1998). Purified fumonisin B<sub>1</sub> has induced equine leukoencephalomalacia (ELEM) when administered orally (Kellerman *et al.*, 1990) and intravenously (Marasas *et al.*, 1988; Laurent *et al.*, 1989; Foreman *et al.*, 2004). Purified fumonisin B<sub>2</sub> has also induced ELEM when given orally (Ross *et al.*, 1994). Fumonisins B<sub>3</sub> is suspected to be much less toxic than either B<sub>1</sub> or B<sub>2</sub>. Fumonisin B<sub>1</sub> is considered to be the primary cause of ELEM, however, as fumonisin B<sub>2</sub> is usually present in concentrations that are 20–40% of fumonisin B<sub>1</sub> (Ross *et al.*, 1991). Although ELEM has occurred in horses eating commercial feedstuffs (Wilson *et al.*, 1990b; Ross *et al.*, 1991), the feeding of corn screenings has been more frequently associated with ELEM, because fumonisin concentrations are much higher in screenings than in whole kernels of corn (Binkerd *et al.*, 1993). Fumonisin B<sub>1</sub> also appears to survive the pelleting process for equine feeds (Ross *et al.*, 1991).

Leukoencephalomalacia has been reproduced with intravenous administration of fumonisin B<sub>1</sub> in three separate studies (Marasas *et al.*, 1988; Laurent *et al.*, 1989; Foreman *et al.*, 2004). Marasas *et al.* (1988) administered 0.125 mg fumonisin B<sub>1</sub>/kg of body weight, IV, q24h which produced ELEM in 9 days. Laurent *et al.* (1989) administered 0.1 mg fumonisin B<sub>1</sub>/kg of body weight, IV, q24h for 16 days followed by 0.2 mg/kg/day for 2 additional days. Leukoencephalomalacia was induced in 18 days. Foreman *et al.* (2004) administered 0.05, 0.1 or 0.2 mg fumonisin B<sub>1</sub>/kg of body weight, IV, q24h to 10 horses and all developed neurologic signs and were euthanized between days 4 and 12 of the study. In contrast, horses dosed with 0.01 mg fumonisin B<sub>1</sub>/kg of body weight for 28 days in this study did not develop neurologic signs. Purified fumonisin B<sub>1</sub> has also been administered orally in other studies (1.25 or 2.5 mg

fumonisin B<sub>1</sub>/kg of body weight, PO, q24h), producing mild edema of the brain stem and hepatic disease in 11–12 days in two horses. In a subsequent study, animals were fed 0.6 to 4.0 mg fumonisin B<sub>1</sub>/kg of body weight, PO, q24h for 33 or 35 days, producing hepatotoxicity and neurologic signs starting on days 22 and 24 in two weanling horses (Kellerman *et al.*, 1990).

Doses of fumonisin reported from naturally occurring cases of fumonisin have varied (Table 90.2). One field report calculated that the ingestion of 0.6 to 2.1 mg fumonisin B<sub>1</sub>/kg of body weight would induce ELEM in 24–28 days (Wilson *et al.*, 1990b). Another study found that leukoencephalomalacia was associated with ingestion of feed containing fumonisin B<sub>1</sub> concentrations greater than 10 ppm, and concluded that feed with fumonisin B<sub>1</sub> concentrations greater than 10 ppm was not safe to be fed to horses (Ross *et al.*, 1991).

### Neurologic and hepatic effects in horses

Several reports have considered ELEM and hepatotoxicity to be two separate syndromes associated with fumonisin toxicity in horses, with the terms “classic neurotoxic syndrome” and “hepatic syndrome” being used (McCue, 1989). However, it appears more likely these are not true “distinct” syndromes but are related to the concentration of fumonisin in the feed, the duration of toxin consumption and the tolerance of the individual horse to fumonisin. In some outbreaks, horses have died from ELEM while other horses have died from hepatotoxicity, and occasionally individual horses exhibiting both neurologic and hepatic signs have been described. Reported clinical signs associated with hepatic disease include icterus, mucous membrane petechiae and swelling of the lips or muzzle (Uhlinger, 1991; Ross *et al.*, 1993).

Ross *et al.* (1993) described an experimental study where one horse died acutely with “mild encephalopathy and hepatic necrosis” after 9 days of fumonisin exposure whereas two other horses died after 75 and 78 days of ELEM. The horse that died on day 9 showed neurologic signs prior to death (“visual impairment, mild ataxia and slight head tremors”) and had histologic evidence of leukoencephalomalacia at necropsy; however, his death was primarily attributed to hepatotoxicity. This study led to a common generalization that high doses of fumonisin were likely to induce hepatotoxicity, whereas lower doses of toxin over a longer period of time were necessary to induce ELEM (McCue, 1989; Plumlee and Galey, 1994). However, in other experimental studies, intravenous administration of fumonisin B<sub>1</sub> induced ELEM in 9 days (Marasas *et al.*, 1988) and 18 days (Laurent *et al.*, 1989). In a large study with varying doses of fumonisin, horses treated with higher doses developed leukoencephalomalacia (in 5–8 days), whereas

horses that received lower concentrations developed primarily hepatic lesions without any evidence of neurotoxicity (Foreman *et al.*, 2004). Therefore it can be concluded that ELEM results from an acute exposure to feed containing high concentrations of fumonisin B<sub>1</sub>, while hepatotoxicity occurs with chronic ingestion of lower levels.

Serum biochemical changes associated with fumonisin toxicity in horses have been predominantly related to hepatotoxicity: increased AST (Wang *et al.*, 1992); increased AST and GGT (Laurent *et al.*, 1989; Kellerman *et al.*, 1990); increased GGT and SDH (Schumacher *et al.*, 1995); increased AST, GGT and ALP (Ross *et al.*, 1993); increased AST, GGT, ALP, total bilirubin and bile acids (Wilson *et al.*, 1992); and “elevated liver enzymes” (Ross *et al.*, 1994).

The neurologic signs are usually summarized as sudden onset of one or more of the following: frenzy, aimless circling, head pressing, paresis, ataxia, blindness, depression and hyperexcitability (Ross *et al.*, 1991; Wilson *et al.*, 1992). Other reports have stated that “the disease started with lack of appetite, followed by the disturbance of swallowing and chewing indicating the paralysis of cephalic and pharyngeal muscles. Paralysis of cephalic and cervical muscles spread to the muscles of the extremities and trunk. The animals moved with difficulties, and tottering and ataxia developed. Signs of “blindness” developed in one animal. At the final stage of disease, the affected animals “laid down and died” (Bela and Endre, 1996). In a comprehensive study, early neurologic signs included mild proprioceptive abnormalities, including hindlimb ataxia, delayed forelimb placing reactions and decreased tongue tone and movement (Foreman *et al.*, 2004). These signs progressed over 12 to 48 hours to become more readily apparent. Hindlimb and trunk ataxia in particular became more apparent with time. A variety of behavioral changes were observed including depression, hyperesthesia and intermittent dementia. All horses had intact menace and pupillary light responses at the time of death.

Cerebrospinal fluid findings from horses with ELEM include elevations in protein concentration, albumin and IgG concentrations and increased albumin quotients (Foreman *et al.*, 2004). Cerebrospinal fluid, red blood cell, leukocyte and glucose concentrations along with creatine kinase activity are not altered in horses with neurologic disease. Along with the histopathologic findings, these cerebrospinal fluid changes indicate the presence of a vasogenic cerebral edema in horses with leukoencephalomalacia.

### Fumonisin toxicity in cattle

Adult beef cattle appear relatively resistant to fumonisin. Feeder calves fed a diet containing fumonisin concentrations up to 148 ppm for 31 days had only mild

TABLE 90.2 Effects of fumonisin in horses

Number of animals	Dose and route	Duration	Toxic effects	Reference
<b>Experimental studies using purified fumonisin</b>				
1 horse	0.125 mg/kg/day, IV	7 treatments over 9 days	Leukoencephalomalacia Elevated AST, GGT	Marasas <i>et al.</i> (1988)
1 horse	2.5 mg/kg/day, PO (by gavage)	6 doses over 11 days	Severe hepatosis Elevated AST, GGT	Marasas <i>et al.</i> (1988)
1 horse	1.25 mg/kg/day, PO (by gavage)	6 doses over 11 days	Mild hepatosis Elevated AST, GGT	Marasas <i>et al.</i> (1988)
1 horse	0.1 mg/kg/day, IV and 0.2 mg/kg/day, IV	0.1 mg/kg dose given for 16 days then 0.2 mg/kg dose given for 2 additional days	Leukoencephalomalacia	Laurent <i>et al.</i> (1989)
1 horse	1.25 mg/kg to 4.0 mg/kg, PO	20 doses given over 35 days	Leukoencephalomalacia Elevated AST	Kellerman <i>et al.</i> (1990)
1 horse	1.0 mg/kg to 4.0 mg/kg, PO	20 doses given over 33 days	Leukoencephalomalacia Elevated AST, GGT	Kellerman <i>et al.</i> (1990)
13 horses	0.01 to 0.20 mg/kg, IV	Up to 10 days	Leukoencephalomalacia at 0.10 and 0.20 mg/kg – hepatic toxicity only at lower doses	Smith <i>et al.</i> (2002); Foreman <i>et al.</i> (2004)
<b>Experimental studies using fumonisin-containing culture material</b>				
2 horses	Diet contained 19 ppm FB <sub>1</sub> and was fed ad libitum	27 days	None	Schumacher <i>et al.</i> (1995)
2 horses	Diet contained 200 ppm FB <sub>1</sub> and was fed ad libitum	12 and 16 days	Leukoencephalomalacia Increased GGT	Schumacher <i>et al.</i> (1995)
2 horses	2 diets containing 65 and 130 ppm FB <sub>1</sub> and were fed ad libitum	–65 ppm fed for 10 days –130 ppm fed for an additional 17 days	Leukoencephalomalacia Increased GGT	Schumacher <i>et al.</i> (1995)
<b>Experimental studies using naturally contaminated corn screenings</b>				
4 ponies	Diet contained 44 ppm FB <sub>1</sub> and was fed ad libitum	10 to 97 days	2 horses died with ELEM on days 10 and 45 – 2 horses were normal after 97 days	Wang <i>et al.</i> (1992)
4 ponies	Diets contained between 1 and 22 ppm FB <sub>1</sub> and were fed ad libitum	238 to 326 days	ELEM in 2 of 5 horses Moderate to mild hepatosis in all 5 horses	Wilson <i>et al.</i> (1992)
5 ponies	Diet contained 8 ppm FB <sub>1</sub> and was fed ad libitum	180 days	Mild histologic lesions in the brain and liver at necropsy	Wilson <i>et al.</i> (1992)
4 ponies	Diets contained between 1 and 88 ppm FB <sub>1</sub> and were fed ad libitum	9 to 120 days	ELEM in all 4 ponies (day 9 to 120) – also severe hepatosis in 2 ponies	Ross <i>et al.</i> (1993)
<b>Reported fumonisin concentrations from naturally occurring outbreaks</b>				
18 horses	37 to 122 ppm FB <sub>1</sub>	Unknown	ELEM confirmed in 14 horses	Wilson <i>et al.</i> (1990)
45 horses	8 to 126 ppm FB <sub>1</sub>	7 to 35 days	All cases had confirmed leukoencephalomalacia	Ross <i>et al.</i> (1991)
6 horses	370 ppm FB <sub>1</sub> and 105 ppm FB <sub>2</sub>	Unknown	4 horses died with ELEM; 2 horses with neurologic signs apparently recovered	Wilkins <i>et al.</i> (1994)
100+ donkeys	4 to 29 ppm FB <sub>1</sub>	Unknown	Many donkeys died of neurologic disease – ELEM confirmed in 3 cases	Rosiles <i>et al.</i> (1998)

hepatotoxicity (Osweiler *et al.*, 1993). Although it is tempting to speculate that cattle are able to break down the toxin, it has been shown that fumonisin is poorly metabolized by the rumen. In general, cattle have an increased tolerance to fumonisin because of differences in the mechanism of action. In milk-fed calves treated with purified fumonisin B<sub>1</sub>, the kidney was the target organ of toxicity (Mathur *et al.*, 2001). However, this

study also demonstrated that sphingosine and sphinganine concentrations did not increase in the serum and tissues of calves to the same degree that has been shown in pigs and horses.

When a group of 26 dairy cattle were fed a ration containing 100 ppm of fumonisin for the first 70 days of their lactation period, they had a significant decrease in dry matter intake and a lower milk yield as compared to the

control group (Diaz *et al.*, 2000). Milk production averaged 7kg lower in the group fed the ration containing fumonisin and there was a 13% decrease in feed intake over the duration of the study period. Therefore, it has been recommended to avoid fumonisin concentrations higher than 30 ppm in the total ration of dairy cattle.

Fumonisin toxicity in poultry

Fumonisin can be toxic to both chickens and turkeys with concentrations in the feed as low as 100mg/kg causing decreased body weight gain, diarrhea and hepatotoxicity (Ledoux *et al.*, 1992; Bermudez *et al.*, 1997). There has also been an association between *Fusarium verticillioides* (the fungus that produces fumonisin) and an acute death syndrome recognized in young chicks called spiking mortality syndrome. It was initially hypothesized that fumonisins were directly cardiotoxic to poultry and were the cause of this syndrome; however, more recent research has suggested moniliformin (another *F. verticillioides*-produced mycotoxin) is primarily responsible.

DIAGNOSIS AND TREATMENT

In addition to pathologic findings in animals, diagnosis of fumonisin toxicosis typically relies on detecting the actual toxin in feed samples. Fungal culture of feeds has little value in diagnosing fumonisin toxicosis because some corn samples contain very high concentrations of toxin with low levels of fungus, while other samples have heavy growths of *Fusarium* fungus with little to no detectable fumonisin. This is partly because the fungus that produced fumonisin also produces other mycotoxins. Therefore, the definitive diagnosis of fumonisin toxicosis in animals must involve analyzing the feed for the presence of the actual toxin. Many diagnostic laboratories across the world offer assays to detect both fumonisin B<sub>1</sub> and B<sub>2</sub> in corn and feed samples. The two most commonly used methods for toxin detection are chromatography (HPLC) and immunologic (ELISA) assays. To date, there are no commercially available assays that detect fumonisin in serum or tissues of animals.

Another assay that may be used more commonly in the future to diagnose fumonisin toxicosis in animals is the sphinganine to sphingosine ratio (Sa:So ratio). Because of the fumonisin-induced disruption of sphingolipid biosynthesis (Wang *et al.*, 1992), the Sa:So ratio increases in the serum and tissues of pigs and horses exposed to fumonisin. It has been suggested that this assay could be used to diagnose fumonisin toxicosis when feed analysis is not possible. Sphinganine and

TABLE 90.3 Recommended levels for total fumonisins (B<sub>1</sub> and B<sub>2</sub>) in animal feeds

Animal	Recommended maximum level of total fumonisins in corn to be used for feed (ppm)	Recommended maximum level of total fumonisin in the ration (ppm)
Horse <sup>a</sup>	5	1
Swine	20	10
Ruminants <sup>b</sup>	60	30
Poultry <sup>c</sup>	100	50
Ruminant and poultry breeding stock <sup>d</sup>	30	15
Catfish	20	10
Other animals <sup>e</sup>	10	5

From the United States Food and Drug Administration, Center for Veterinary Medicine.  
<sup>a</sup>Includes donkeys, asses and zebras.  
<sup>b</sup>Cattle, sheep, goats and other ruminants that are >3 months of age and are being fed for slaughter.  
<sup>c</sup>Turkeys, chickens, ducklings and other poultry being fed for slaughter.  
<sup>d</sup>Includes lactating dairy cows, bulls, laying hens and roosters.  
<sup>e</sup>Includes dogs and cats.

sphingosine data may be available from enough pigs and horses in the near future to provide values for normal and affected animals.

To date there have been no treatments described for either equine leukoencephalomalacia or porcine pulmonary edema. Generally the onset of clinical signs is acute and the progression of disease is rapid for both syndromes. The most important treatment is to identify and remove the source of contaminated feed to prevent other animals from developing clinical signs.

Guidelines for the maximum recommended levels of fumonisins in animal feeds have been published by the FDA Center for Veterinary Medicine (Table 90.3). It is important that livestock producers be aware of these guidelines and have their corn periodically tested for mycotoxins. Research has not yet found effective ways to decrease fumonisin concentrations in animal feed-stuffs through processing or feed additives (i.e., binding agents). Corn containing significant levels of fumonisin should be discarded, diluted with corn containing lower concentrations of fumonisin, or fed to a less-sensitive species (i.e., ruminants or poultry interested for slaughter).

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Fumonisin remain an active research topic; however, most studies in the last few years have focused on the potential effects of this mycotoxin in humans. More

animal studies are needed to further define the mechanism of neurotoxicity in horses. Studies also need to be done examining the long-term cardiovascular effects associated with lower doses of fumonisin exposure in swine and humans. High fumonisin concentrations seem to appear in the corn crop from the United States every 3 to 4 years depending on weather, so they will continue to be a toxin of high regulatory concern in the future. Veterinarians and toxicologists must be familiar with this mycotoxin and should be able to quickly recognize clinical signs and gross lesions associated with fumonisin toxicity in animals.

# Ochratoxins and citrinin

Ramesh C. Gupta

## INTRODUCTION

Ochratoxins and citrinin are produced by several species of the genera *Aspergillus* and *Penicillium*. The two most common species that produce ochratoxin A (OTA) are *Aspergillus ochraceus* and *Penicillium verrucosum*. These fungi are ubiquitous and the potential for contamination of animal feed and human food is widespread. *Aspergillus* spp. appear to produce ochratoxins under conditions of high humidity and temperature, whereas some *Penicillium* spp. may produce ochratoxins at temperatures as low as 5°C. OTA has been found in a variety of food/feed, with levels in commodities used as feed ranging up to 27 ppm, and with levels in foodstuffs for human consumption in the range of trace to about 100 ppb. OTA is a pentaketide-derived dihydroisocoumarin moiety coupled with a 12-carboxy group by a peptide bond to *L*-phenylalanine. There are two commonly recognized OTA analogs, ochratoxin B (OTB) and ochratoxin C (OTC), and, of course, alkyl esters of ochratoxins. Unlike ochratoxin A (OTA), the occurrence of OTB and OTC is rare. Chemical structures of ochratoxins are shown in Figure 91.1 and the order of their toxicity is OTA > OTB > OTC. All metabolites of OTA are less toxic than the parent compound.

Citrinin was first isolated as a pure compound from a culture of *P. citrinum* in 1931. Later, it was also isolated from *A. ochraceus*, *P. verrucosum* and related species that contaminate grain. In 1951, yellowish colored rice imported from Thailand to Japan was found to be contaminated with *P. citrinum*, which contained citrinin. Synthesized citrinin is also used in molecular biological research, as it induces mitochondrial permeability

pore opening and inhibits respiration by interfering with complex I of the respiratory chain. The chemical structure of citrinin is shown in Figure 91.2.

Both OTA and citrinin cause nephropathy in animals and they have also been implicated as the cause of Balkan Endemic Nephropathy (BEN) in humans.

FIGURE 91.1 Chemical structures of ochratoxins.

FIGURE 91.2 Chemical structure of citrinin.

Literature reveals that OTA has been studied to a greater extent than citrinin, because OTA is at least ten times more toxic than citrinin. This chapter describes in detail the toxicity of ochratoxins and citrinin in animals.

## BACKGROUND

The fungi producing ochratoxins and citrinin are commonly encountered in animal feed and human food around the world. They are encountered with great frequencies in the Balkan and Scandinavian countries. There are three major ochratoxins (OTA, OTB and OTC), but OTA occurs naturally with a greater frequency in a variety of cereal grains (barley, wheat, oats, corn and beans), peanuts, dried fruits, grapes/raisins, cheese and other food products. OTA accumulates in the food chain because of its long half-life. Citrinin usually co-occurs with OTA, and commonly contaminates cereal grains, including wheat, barley, oats, corn and rice. Citrinin also contaminates peanuts and fruits. Levels of OTA and citrinin have been found far lower in human food than in raw animal feed, because during the processing and baking of human food, citrinin is almost eliminated and OTA is significantly reduced. Compared to OTA, OTB and OTC are rarely found and are much less toxic.

Both OTA and citrinin are well-known nephrotoxins. OTA is also carcinogenic to rodents (Creppy *et al.*, 1985) and possesses teratogenic (Arora *et al.*, 1983), immunotoxic (Stormer and Lea, 1995), neurotoxic (Bruinink and Sidler, 1997; Sava *et al.*, 2006), mutagenic (Stetina and Votava, 1986) and genotoxic (Meisner *et al.*, 1983) properties. In humans, exposure to OTA and citrinin has been linked with Balkan Endemic Nephropathy (BEN), a chronic kidney disease associated with tumors of the renal system, which can be fatal. However, recent findings doubt OTA as the etiological factor in BEN (Mally *et al.*, 2007). Co-occurrence of citrinin with OTA has been implicated in nephropathy of pigs in Denmark, Sweden, Norway and Ireland. Citrinin and OTA are also involved in avian nephropathies. Residues of OTA have been detected in the tissues of pigs in slaughterhouses, and it has been shown, under experimental conditions,

that residues can still be detected in tissues 1 month after the end of exposure. Due to the long half-life of OTA in feed and biological systems, serious concerns have been raised about animal health as well as the human consumption of meat.

## TOXICOKINETICS

In most animal species, OTA is absorbed from the stomach because of its lipid soluble, non-ionized and acidic properties ( $pK_a = 7.1$ ). Absorption of OTA also takes place in the duodenum and jejunum, is involved in enterohepatic circulation and its biliary excretion is very efficient (Kumagai and Aibara, 1982; Kumagai, 1988). OTA is distributed to various organs, mainly to the kidneys. Liver, muscle and fat contain lower concentrations. Following oral administration, the overall percentage of OTA absorption is found to be 66% in pigs, 56% in rats, 56% in rabbits and 40% in chickens (Suzuki *et al.*, 1977; Galtier *et al.*, 1981). After a single oral dose, the maximum concentrations of OTA are found within 10–48 h in pigs and rats (Galtier *et al.*, 1979, 1981), 2–4 h in calves (Sreemannarayana *et al.*, 1988), after 1 h in rabbits and after 0.33 h in chickens (Galtier *et al.*, 1981). Maximum tissue concentrations in rat tissues occur within 48 h.

When absorbed, OTA has shown a high binding affinity for plasma proteins. OTA was found in decreasing order of concentrations in kidney < liver < fat < muscle. The serum half-life of OTA is long and varies widely among species, e.g., 24–39 h in mice, 55–120 h in rats, 6.7 h in quail, 510 h in *Macaca mulata* monkeys (Hagelberg *et al.*, 1989), 72–120 h in pigs, 4.1 h in chicken (Galtier *et al.*, 1981) and 840 h in a human (Benford *et al.*, 2001).

Toxicokinetics of OTA in pigs revealed that the kidney is generally the most heavily contaminated tissue and that levels in the blood are about five-fold greater than in the kidney. Krog *et al.* (1976) illustrated that if the level of OTA in swine kidney is 12.1 ng/g (resulting from about 1000 ng/g in the feed), its levels would be 7.8 ng/g in the liver, 4.2 ng/g in the muscle and 2.8 ng/g in adipose tissue. OTA in ruminants is usually hydrolyzed in the forestomach by protozoans and bacterial enzymes, and consequently little OTA is found in the tissues (Hult *et al.*, 1976).

In various tissues of all species that are examined, OTA is hydrolyzed to ochratoxin *alpha*, which is the major metabolite. This detoxication process takes place in the cecum of rats and is facilitated by bacterial microflora (Galteir, 1978). The enzymes responsible for hydrolysis to ochratoxin *alpha* in cows, sheep and rodents are carboxypeptidase A and chymotrypsin. Suzuki *et al.*

(1977) demonstrated that the rat tissue homogenate of the duodenum, ileum and pancreas also has a high activity of these enzymes to catalyze this reaction. Activity of these enzymes in liver and kidney are low. Studies in mice suggest that OTA circulates from the liver into the bile and into the intestine, where it is hydrolyzed to ochratoxin *alpha* (Moroi *et al.*, 1985). About 25–27% of OTA, given either i.p. or orally to rats, was found as ochratoxin *alpha* in the urine. Its presence in the urine can be explained by reabsorption from the intestine. A similar mechanism of intestinal reabsorption of ochratoxin *alpha* has been suggested to occur in ruminant calves (Sreemannarayana *et al.*, 1988). In sheep, Höhler *et al.* (1999) demonstrated that OTA hydrolysis in the gastrointestinal tract was substantially less than previously described, especially if OTA was ingested in combination with concentrate-rich diets.

OTA excretes in the urine and feces in all species (Höhler *et al.*, 1999; Ringot *et al.*, 2006; Carone *et al.*, 2011). OTA also passes in the milk in some species (such as rats and rabbits), but very little is excreted in cows' milk because of its metabolism by the ruminal microflora (Breitholtz-Emanuelsson *et al.*, 1993). This route is of importance because the milk is consumed by the offspring. Subsequent to its urinary excretion, OTA is reabsorbed in all nephron segments. Excretion of OTA can be influenced by the route of administration, the dose and the gender, age and weight of the animal (Vettorazzi *et al.*, 2009). Excretion of OTA is also impacted by the extent of enterohepatic circulation and binding to serum albumin and other macromolecules (Galtier *et al.*, 1980; Hult and Fuchs, 1986). The association constant for the binding of OTA to serum albumin is  $7.1 \times 10^4$  per mol for pigs,  $5.1 \times 10^4$  per mol for chickens and  $4.0 \times 10^4$  per mol for rats (Galtier *et al.*, 1981).

Placental transfer of OTA in mammalian species like mice, rat and swine is well known. However, in ruminants the placental transfer of OTA is very little. After intravenous administration of a high dose of OTA (1 mg/kg body weight) to pregnant ewes, Munro *et al.* (1973) did not detect OTA in the amniotic fluid and fetal tissue levels were 400 to 1000 times lower than in the maternal blood. The exact mechanism involved in placental transfer of OTA is yet to be elucidated. OTA can be present in eggs if the hens are exposed to this toxin at higher doses.

From animal studies, it is clear that OTA has a high degree of bioavailability, a low plasma clearance rate and a long tissue half-life. Because of the differences in animal physiology, wide variations are seen in the toxicokinetic patterns of OTA. For further details on biotransformation, toxicokinetics and toxicodynamics of OTA, readers are referred to a recent publication elsewhere (Ringot *et al.*, 2009). No toxicokinetic data of citrinin are available to describe in this chapter.

## MECHANISM OF ACTION

Both OTA and citrinin are well-known nephrotoxics. In addition to nephrotoxicity, OTA is known to exert neurotoxic, immunotoxic, teratogenic and carcinogenic effects in mammalian species. OTA also disrupts blood coagulation and glucose metabolism. A brief description of the mechanisms involved in common toxic effects is given below.

### Nephrotoxicity

Both OTA and citrinin produce nephrotoxicity involving multiple mechanisms. At high doses, OTA affects both renal function and morphology, as indicated by increased weight, urine volume, blood urea nitrogen, urinary glucose and proteinuria. The last two findings indicate that the site of reabsorption (i.e., the proximal convoluted tubules) is damaged. OTA specifically causes defect of the organic anion transport mechanism located on the brush border of the proximal convoluted tubules and basolateral membranes. OTA also adversely affects the organic ion transport system by which OTA enters the proximal tubular cells. The middle (S2) and terminal (S3) segments of the proximal tubule of the isolated nephron are the most sensitive to the toxic effects of OTA, as evidenced by marked decreases in cellular and mitochondrial ATP contents.

Studies suggest that both OTA and citrinin cause mitochondrial dysfunction in renal and hepatic tissues (Aleo *et al.*, 1991; Chagas *et al.*, 1995). OTA toxicity is associated with inhibition of both protein and RNA synthesis (Dirheimer and Creppy, 1991). OTA is known to interfere with the charging of tRNA with amino acids. OTA treatment can increase oxidative stress in peripheral organs. Administration of OTA to rats (1 mg/kg) resulted in a 22% decrease in  $\alpha$ -tocopherol plasma levels and a five-fold increase in the expression of the oxidative stress responsive protein heme oxygenase-1, specifically in the kidney (Gautier *et al.*, 2001). Cell death occurs by apoptosis.

### Neurotoxicity

Toxic effects of OTA on the CNS have not yet been fully characterized. Evidence strongly suggests that OTA affects selected structures of the brain and it has the potential for neurotoxicity (Belamadani *et al.*, 1998; Bruinink *et al.*, 1998). This mycotoxin has multiple mechanisms of action, including oxidative stress, bioenergetic compromise, inhibition of protein synthesis, production of DNA single-stranded breaks and formation of OTA-DNA adducts (Sava *et al.*, 2006). These authors found that administration of OTA in mice, at a single dose (3.5 mg/kg) that is approximately 10% of the reported LD<sub>50</sub>, caused widespread oxidative injury in six discrete brain regions.

## Immunotoxicity

There is ample evidence from studies conducted in several animal species that under certain conditions of treatment, OTA can produce defects in the structure and/or function of elements comprising the immune system (Pohland *et al.*, 1992). The size of the mouse thymus was reduced to 33% of that of controls after four i.p. injections of OTA at 20mg/kg body weight on alternate days, a dose which caused minimal nephrotoxicity. Bone marrow depression was dose related, and changes included decreased marrow cellularity, a reduction in bone marrow macrophage-granulocyte progenitors, a decreased number of hematopoietic stem cells, a significant decrease in erythropoiesis and increased phagocytosis by macrophages (Boorman *et al.*, 1984). The effects of OTA on the bone marrow and lymphatic cell population may reflect the sensitivity of these cells to the inhibition of protein synthesis. These effects on the structural components of the immune system indicated that OTA adversely affects immune function.

In chickens fed diets containing OTA at a concentration of 2–4mg/kg for 20 days, the lymphoid cell population of immune organs was decreased, and IgA and IgM in lymphoid tissues and serum were decreased (Dwivedi and Burns, 1984a,b). Complement activity was slightly affected in birds fed diets containing 2mg/kg for 5–6 weeks (Campbell *et al.*, 1983). Immune suppression was observed in chickens fed diets containing OTA at 0.05mg/kg or 2mg/kg for 21 days. Treated animals showed reduced total serum protein, lymphocyte counts and weights of the thymus, bursa of fabricus and spleen (Singh *et al.*, 1990).

## Carcinogenicity

The exact mechanism by which OTA induces nephrocarcinogenicity is yet to be established, although both genotoxic and non-genotoxic modes of action seem to be involved (Pfohl-Leschowicz and Manderville, 2007; Marin-Kuan *et al.*, 2008; Golli-Bennour *et al.*, 2010). Recently, Cavin *et al.* (2007) suggested that the reduction of antioxidant defense appears to be involved in OTA toxicity and carcinogenicity.

## TOXICITY

The toxic effects of ochratoxin A (OTA) have been studied extensively in a number of domestic, companion and experimental animals. All evidence suggests that OTA continues to be a huge problem to animal health worldwide (O'Brien and Dietrich, 2005). Overall toxicity of OTA is greatly influenced by species, sex and route of administration. Based on acute toxicity data, dogs, pigs

and chickens are the most sensitive species and rats and mice the least sensitive. Oral LD<sub>50</sub> values (expressed as mg/kg body weight) of OTA are reported to be 46–58 in mouse, 20–30 in rat, 3.9 in neonate rat, 0.2 in dog, 1 in pig and 3.3 in chicken (Harwig *et al.*, 1983). LD<sub>50</sub> values via i.p. route are reported to be 22–40 in mouse and 20–30 in rat; and with i.v. route, 26–34 in mouse and 13mg/kg in rat. OTA causes renal toxicity, nephropathy, neurotoxicity, immunotoxicity, carcinogenicity and developmental toxicity in several animal species.

The acute LD<sub>50</sub> (expressed as mg/kg body weight) of citrinin is reported to be 50 (oral) and 67 (s.c. or i.p.) in rat, 35–58 in mouse and 19 (i.p. or i.v.) in rabbit. Citrinin toxicity, especially in terms of nephropathy, has been reported in various animal species, including rats, hamsters, dogs and poultry. Citrinin causes kidney damage and mild liver damage in the form of fatty infiltration. Other toxic effects include vasodilatation, constriction of the bronchi and increased muscular tone.

All animals studied so far have been found susceptible to orally administered OTA with a varying degree of response. It is important to mention that at higher doses, OTA causes alterations in kidneys and also in other organs and tissue, but renal lesions can be found at an exposure level that is identical to those occurring environmentally. Ochratoxin B (OTB) is rarely found as a natural contaminant and is much less toxic than OTA. The other ochratoxins have never been encountered in natural products.

Weanling Fischer 344/N rats of both sexes receiving OTA by gavage in maize oil at a dose of 0.06, 0.12, 0.25, 0.5 or 1 mg/kg body weight/day for 5 days/week for 91 days, showed growth retardation and a reduced relative kidney weight in males at the two higher doses. Karyomegaly of dose-related severity was observed in the proximal tubules at all doses. Milder renal changes consisting of tubular atrophy were seen at a dose of 1, 4 or 16mg/kg body weight/day on 5 days/week for a total of 12 doses over 16 days. Rats receiving the highest dose had diarrhea and nasal discharge and died before the end of the study. Increased relative weights of kidneys, heart and brain, thymus atrophy, forestomach necrosis and/or hyperplasia, and hemorrhage of adrenal glands were seen at the two higher doses. Bone marrow hyperplasia and nephropathy were seen at all doses, involving renal tubular degenerative and regenerative changes (NTP, 1989).

OTA has been shown to produce nephrotoxic effects in all animal species examined, with the exception of adult ruminants (Pohland *et al.*, 1992). The nephrotoxic potential of OTA is well documented from all experimental studies, with a feed level of 200ppb causing nephropathy in pigs and rats. Evidence strongly supports that OTA is involved in porcine nephropathy, which is characterized by degeneration of the proximal tubules, atrophy of the tubular epithelium, interstitial fibrosis in the

renal cortex and hyalinized glomeruli. Field cases of OTA-induced nephropathy in farm animals have long been recognized. Benford *et al.* (2001) suggested that the adverse effect at the lowest effective dose in several mammalian species is nephrotoxicity. Citrinin is also nephrotoxic, but it is ten times less toxic than OTA.

In a series of experiments, sows were given feed containing OTA at a concentration of 0.2, 1 or 5 mg/kg (equivalent to 0.008, 0.04 and 0.2 mg/kg body weight/day), for a period of 5 days, 8 or 12 weeks, or up to 2 years. Decreased renal function, nephropathy and reduced renal enzyme activity were observed. Progressive nephropathy but no renal failure was seen in pigs given feed containing 1 mg/kg for 2 years (Krog *et al.*, 1976; Elling *et al.*, 1985).

Beagle dogs receiving OTA in capsule form at a dose of 0.1 or 0.2 mg/kg body weight/day for 14 days showed tubular necrosis and ultrastructural changes in the proximal tubules at all doses. Necrosis of lymphoid tissues of the thymus and tonsils was also seen at all doses (Kitchen *et al.*, 1977a,b,c). In another set of experiments, young beagle dogs were given OTA and citrinin separately and combined for 14 days (Kitchen *et al.*, 1977b). OTA was administered by capsule at 0.1 and 0.2 mg/kg; and citrinin (5 and 10 mg/kg) dissolved in ethanol was given by i.p. injection. Clinical signs of toxicosis with 10 mg/kg citrinin and the higher combined doses included anorexia, retching, tenesmus, weight loss, prostration and death. Severity of the clinical disease and mortality were increased when the mycotoxins were combined, which indicated synergism. The clinicopathological abnormalities reflected renal damage, cellular and granular casts and ketones as well as protein and glucose in the urine of dogs given large doses of citrinin alone or combination with OTA. In pathological studies, these authors found gross lesions, such as focal peritonitis and intestinal intussusceptions with citrinin. Changes in the kidneys of dogs given OTA were degeneration and necrosis with desquamation of tubular epithelial cells, primarily in the straight segment of the proximal tubules. Dogs given 10 mg/kg citrinin had similar changes in the distal tubules and collecting ducts. Dogs given combined doses of citrinin and OTA had degeneration and necrosis in proximal and distal tubules, and in thin segments and the collecting ducts and ulceration of the mucosa of the intestine.

In experimental studies, dogs given citrinin showed serous nasal discharge and lacrimation (Carlton *et al.*, 1974; Kitchen *et al.*, 1977a,b). It is important to mention that citrinin is a very strong emetic in dogs, which is a protective mechanism in this species. Therefore, it is very unlikely that dogs will be poisoned by citrinin alone because high amounts of this mycotoxin will induce emesis and feed refusal.

Chickens, turkeys and ducklings are all susceptible to OTA and it appears that OTA-contaminated feed

has a major economic impact on the poultry industry. Field cases of OTA-induced nephropathy are regularly encountered in poultry. Clinical signs of ochratoxicosis include retarded growth rate, reduction in weight gain, poor feed conversion, reduced egg production, poor egg shell quality, nephrotoxicity/nephropathy and mortality. Feed refusal has been observed in turkeys.

In chickens, OTA at a dose rate of 3.6 mg/kg can cause 5% mortality. Ochratoxin B at a dose rate of 54 mg/kg causes lowered growth rate, edema of visceral organs, and accumulation of uric acid in kidneys, liver, heart and spleen. These mycotoxins induce suppression of blood formation in bone marrow, and lymph formation in spleen and bursa of fabricus. The highest toxicity of OTA is found to be in broiler chickens. OTA given to broiler chickens at a dietary concentration of 4 mg/kg for 2 months caused a 42% mortality (Gibson *et al.*, 1990). This toxin is involved in reduced growth rate at 5 ppm, high mortality rate at 4–8 ppm and cessation of egg production at 4 ppm.

In chickens, nephrotoxicity and hepatotoxicity occur at dietary levels of 250 µg/g of citrinin with liver and kidney enlargements of 11 and 22%, respectively. Necropsy of affected birds revealed the presence of pale and swollen kidneys (Wyatt, 1979). Citrinin is at least ten times less nephrotoxic than OTA.

Griffiths and Done (1991) described an outbreak of citrinin toxicosis in a herd of cows which ingested citrus pulp (visibly moldy) pellets that contained 30–40 ppb citrinin. Affected cows showed signs of pruritis, pyrexia and hemorrhagic syndrome. Signs of the syndrome occurred within 3 days of ingesting the citrus pulp, which was fed for 21 days. Five calves whose dams had been fed citrus pulp were subsequently born with superior prognathism. Older animals were more susceptible to citrinin. The clinical signs, gross pathology and histology were suggestive of citrinin involvement. OTA has been well tested for carcinogenicity by oral administration in mice and rats. When OTA was administered in the diet, hepatocellular tumors (designated as well-differentiated trabecular adenomas), renal cell tumors (renal cystadenomas and solid renal-cell tumors), hepatomas (some exhibiting the trabecular structure) and hyperplastic hepatic nodules were observed in male mice (IARC, 1993). In another study, administration of OTA in the diet induced hepatocellular carcinomas and adenomas in female mice. Gavage administration of OTA to male and female rats resulted in a dose-related increase in the incidence of renal cell adenomas and adenocarcinomas. Furthermore, metastasis of the renal-cell tumors was also observed in male and female rats. OTA also increased the incidence and multiplicity of fibroadenomas of the mammary gland in female rats (NTP, 1989; IARC, 1993). In essence, these data suggest that OTA increases the incidence of hepatocellular tumors in mice of each sex and produces renal-cell adenomas in male

mice and in rats of each sex. Based on sufficient evidence of carcinogenicity in experimental animals, OTA is classified as a possible carcinogen in humans (Group 2B) (IARC, 1993). Citrinin has been demonstrated to be mutagenic in hepatocytes (Bailey *et al.*, 2002). There is limited evidence for the carcinogenicity of citrinin to animals.

It is well established that OTA and citrinin are reproductive and developmental toxicants. OTA is known to induce teratogenicity in mice, rats, hamsters, chicken and pigs. In the rodent fetus, OTA targets the CNS, but skeletal deformities are also observed. While the mechanism involved in OTA-induced teratogenesis remains unclear, it seems to directly affect both the progenitor cells and the embryo. Details of reproductive and developmental effects can be found in recent publications elsewhere (Gupta, 2009, 2011).

## TREATMENT

There is no specific antidote for ochratoxin(s) or citrinin toxicity. Recovery is usually slow. Immediate removal of the suspected feed and replacement with clean feed supplemented with increased vitamin levels can be rewarding. Growth of *A. ochraceus* in a common food, such as cereals, can be controlled or minimized by drying them rapidly and thoroughly. Effective approaches to grain storage include fumigation, aeration and cooling, sealed storage, and controlled atmosphere in tropical and subtropical regions where insect damage is a major problem. Citrinin is less of a problem because it is heat unstable. Citrinin is also likely to be destroyed during brewing. Propionic acid, added as a preservative to protect barley in the feed from fungi, destroys citrinin during storage. Currently, highly sophisticated methods are available to detect these mycotoxins at ppb or lower levels in food/feed or their products, so as to prevent animal health from toxicosis and economic loss.

## CONCLUSIONS

Ochratoxin A (OTA) and citrinin both contaminate a wide range of animal feed and human food. Human risk is lower because the levels of these mycotoxins are minimized during processing and baking, but the raw feed remains a potential source for animal poisoning. Because of its long half-life, OTA accumulates in the body. These mycotoxins have a serious impact on the health of animals, especially pigs, dogs and poultry. Pigs and dogs are most sensitive, while rats and mice are least sensitive. In general, females are more sensitive than males.

The kidney is a major target organ (as evidenced by functional and morphological changes) for both mycotoxins, but other organs are affected as well. OTA and its analogs can produce a variety of toxic effects, referred to as "ochratoxicosis," including mutagenesis, carcinogenesis, embryotoxicity, teratogenesis and immune suppression, by damaging mitochondria, DNA, protein and RNA by lipid peroxidation and oxidative injury. Cell death occurs by apoptosis. Citrinin produces toxic effects similar to OTA but the severity is at least ten times less.

## ACKNOWLEDGMENTS

I would like to thank Mrs. Robin B. Doss and Mr. Michelle A. Lasher for their assistance in the preparation of this chapter.

# Slaframine

Geof W. Smith

## INTRODUCTION

Slaframine is an alkaloidal mycotoxin produced by the fungus *Rhizoctonia leguminicola* which causes profuse salivation (“slobbers”) in animals. *R. leguminicola* is a common fungal pathogen of red clover (*Trifolium pratense*) and causes a syndrome known as black patch disease in the plant. Ingestion of clover hay containing slaframine causes salivary episodes that last from several hours to over 3 days in ruminants and horses. Although the disease is short term and animals generally recover without treatment, the dramatic clinical signs associated with slaframine ingestion make it readily apparent to livestock owners. Diagnosis can be made by identification of *R. leguminicola* in suspect forage or by the detection of slaframine in plasma samples from exposed animals.

## BACKGROUND

Outbreaks of profuse salivation in cattle were initially reported in the late 1940s and 1950s from agricultural experiment stations in the Midwestern United States (O'Dell *et al.*, 1959). Most of these cases were associated with the feeding of second-cutting red clover hay. In 1956 it was first reported that fungal contamination of red clover with *R. leguminicola* was associated with a pasture disease called black patch, which derives its name from the appearance of affected areas in the field and not the characteristic black lesions on the leaves of affected plants (Croom *et al.*, 1995). Although its primary host is red clover, black patch disease has been

reported in other legumes including white clover, soybeans, kudzu, cowpea, blue lupine, alsike clover, alfalfa, lespedeza and milk vetch (Smalley and Sanderson, 1993). However, in most of these cases, infected red clover plants were present in the same areas of the field. Fungal infestations are usually associated with periods of wet weather and high humidity (Croom *et al.*, 1995). Transmission is thought to be primarily seed borne as the fungus overwinters on contaminated hay and can survive at least 2 years on contaminated seed.

## CHEMISTRY AND TOXICOKINETICS

Several laboratories were able to isolate the “slobber-causing” agent in *R. leguminicola*-contaminated red clover (Aust and Broquist, 1965; Rainey *et al.*, 1965) and in 1968 the chemical structure was described as 1-acetoxy-6-amino-8-hydroxyindolizidine (Gardiner *et al.*, 1968). The term slaframine became the most commonly used word for describing this compound (Aust *et al.*, 1966). Slaframine is a piperidine or indolizidine alkaloid (Figure 92.1) with the empirical formula  $C_{10}H_{10}N_2O_2$ , which gives it a molecular weight of 198 daltons (Croom *et al.*, 1995).

Slaframine is activated by hepatic microsomal enzymes into a ketoimine that is required to produce clinical signs (Figure 92.1). In cattle, the onset of salivation is shorter with more direct routes of administration; with intravenous injections producing salivation faster than intraperitoneal or intramuscular routes which are in turn faster than the subcutaneous route (Croom *et al.*, 1995). It has been suggested that slaframine is

metabolized in the liver by a microsomal flavoprotein oxidase to the ketoimine metabolite (Guengerich and Aust, 1977) consisting of a quaternary nitrogen separated from an acetate ester by two carbon atoms (Figure 92.1). This structure is very similar to that of acetylcholine, a parasympathetic neurotransmitter.

## MECHANISM OF ACTION

Pharmacologically, slaframine would be classified as a cholinergic agonist and/or a parasympathomimetic chemical. The majority of the available data indicate that the clinical signs produced by slaframine are due to its high affinity for the  $M_3$  muscarinic receptor subtype which is believed to be important in the control of exocrine and endocrine glands (Croom *et al.*, 1995). Early studies demonstrated that the increased salivation associated with slaframine toxicity could be blocked with pre-administration of atropine (Aust, 1970). Additionally, mortality in broiler chicks when slaframine is dosed at  $LD_{50}$  can be significantly decreased by the pre-administration of the muscarinic receptor antagonists atropine (which has affinity for  $M_1$ ,  $M_2$  and  $M_3$  receptors) and pirenzepine ( $M_1$  and  $M_2$  selective), but not gallamine which is  $M_2$  selective (Croom *et al.*, 1995). The pre-administration of the  $M_3$  selective antagonist 4-diphenylacetoxy-N-methylpiperidine methiodide (4DAMP)

can also block the increase in pancreatic fluid output induced by slaframine (Walker *et al.*, 1994). Furthermore, slaframine has no effect on the cardiovascular system or arterial pressure at doses stimulatory to exocrine glands (Aust *et al.*, 1968), nor does it inhibit blood cholinesterase activity (Crump *et al.*, 1967; Hagler and Croom, 1987).

The stimulation of  $M_3$  muscarinic receptors by slaframine produces a profound stimulation of exocrine glands, particularly the salivary gland and pancreas. Steers given an intramuscular administration of purified slaframine had resting salivary flow rates 50 to 70% greater than saline-treated controls (Froetschel *et al.*, 1986). Similar findings documenting increases in saliva production both in cattle and sheep have been reported in other studies as well (Bird *et al.*, 1993; Hibbard *et al.*, 1995). Additional reported physiological effects of slaframine include increased pancreatic enzyme secretion (Aust *et al.*, 1968, 1970), increased rumen pH and rate of nutrient passage, and decreased ruminal motility in cattle (Croom *et al.*, 1995).

## TOXICITY

Clinical signs of slaframine toxicity are similar in all species. Following exposure to contaminated forages, animals begin to salivate profusely. Experimentally, a single dose of slaframine produces salivation for 6 to 10 hours. However, clinically affected animals can "slobber" for several days, presumably because they have continued access to slaframine contaminated forages (Figure 92.2). Other clinical signs can include anorexia, diarrhea, frequent urination and bloat. Decreased milk production can be expected in dairy cattle, likely related

**FIGURE 92.1** The structures of slaframine and the active ketoimine metabolite.

**FIGURE 92.2** A horse showing profuse salivation from ingesting slaframine-contaminated red clover hay (photo courtesy of Dr. Cecil Brownie, North Carolina State University).

to a decrease in feed intake (Crump, 1973). Although slaframine toxicosis has been experimentally induced in a variety of species including swine, poultry, cats, dogs, guinea pigs and rodents, naturally occurring cases are primarily reported in horses and ruminants (Crump *et al.*, 1967, 1995; Sockett *et al.*, 1982; Wijnberg *et al.*, 2009).

Cyanosis and open-mouth breathing have been reported under experimental conditions in sheep, swine and guinea pigs. Pigs also were observed to vomit, became dyspneic and collapsed with stiffened pelvic limbs (Crump *et al.*, 1967). Only mild salivation was noted in a small chicken fed slaframine and clinical signs resolved within a few hours. The LD<sub>50</sub> in day-old broiler chicks was estimated at approximately 81.6 mg/kg of body weight (Croom *et al.*, 1995), but higher doses (250–300 mg/kg) were required to produce death in guinea pigs (Crump *et al.*, 1967). Gross lesions in these animals consisted of vascular congestion of the thoracic and abdominal cavities. Pulmonary edema, disruption of the alveolar structure, emphysema and hepatic centrilobular necrosis were noted histologically. Death in these animals was attributed to suffocation from pulmonary edema and/or emphysema.

The clinical signs associated with the “slobbers syndrome” as described under field conditions include salivation, lacrimation, feed refusal, bloating, stiff joints, diarrhea and weight loss. However, very few of these signs have been seen following the administration of purified slaframine under experimental conditions. That has led to speculation that the alkaloid swainsonine might also be involved in producing clinical signs in classic slaframine toxicity (Croom *et al.*, 1995). Swainsonine is another alkaloid produced by *R. leguminicola* and has a similar structure to slaframine. Although it is better known for its association with locoweed toxicity, it is possible swainsonine is partially

responsible for some of the clinical signs classically observed with the “slobbers syndrome.”

## DIAGNOSIS AND TREATMENT

Diagnosis of slaframine toxicity is generally made by observation of clinical signs (salivation) in animals consuming legume forage, particularly red clover hay. Further tests can identify the fungus *R. leguminicola* in the hay which usually can be easily isolated in culture (Figure 92.3). Although chemical analysis for slaframine is not usually necessary, chromatographic methods for detecting the toxin in hay, plasma or milk have been described (Hagler and Croom, 1989; Imerman and Stahr, 1998).

Treatment is not usually indicated as animals typically recover spontaneously when the contaminated hay is removed; however, clinical signs may persist for 1 to 2 days following removal of the toxic forage. In severe cases, atropine may be of benefit to reverse the parasympathomimetic effects of slaframine; however, it is unlikely to completely resolve clinical signs. In guinea pigs, simultaneous administration of atropine and a lethal dose of slaframine prevented clinical signs for 5 hours, after which mild salivation was observed. When atropine was given 2 to 4 hours after slaframine administration, profuse salivation was observed; however, there was no mortality (Crump *et al.*, 1967). Atropine should be used with caution in ruminants and horses because of possible gastrointestinal side effects. Therefore treatments other than removing the contaminated hay are not usually recommended in affected animals.

Control of black patch disease remains a major problem for agronomists. Fungicides applied before flowering do not reduce seed infection, and ground sprays at

**FIGURE 92.3** Two photomicrographs of *Rhizoctonia leguminicola* mycelia growing in culture – 200× magnification – note the normal difference in pigment color between the two isolates (photos courtesy of Dr. Paul Vincelli and Cheryl Kaiser, University of Kentucky).

the time of plant growth in the spring and/or immediately after the first hay cutting have not been shown to reduce fungal contamination. Prevention requires selecting *R. leguminicola* varieties that are less susceptible to fungal infection and chemically treating seed prior to planting. Feasible mechanisms to detoxify or degrade the toxin in pasture and/or hay have not been found. Therefore control of slaframine outbreaks rely on completely replacing contaminated forages.

## CONCLUSIONS

There has not been any active research on slaframine in the last 10–20 years; however, clinical cases still occur relatively frequently. It is important for veterinarians and toxicologists to be familiar with this mycotoxin, to recognize the likely cause of profuse salivation in horses and cattle consuming red clover hay and to be able to make appropriate recommendations for treatment and control.

# Tremorgenic mycotoxins

Timothy J. Evans and Ramesh C. Gupta

## INTRODUCTION

Fungi belonging to the genera *Penicillium*, *Aspergillus*, *Claviceps* and *Neotyphodium* can produce tremorgenic mycotoxins, which are secondary fungal metabolites that elicit either intermittent or sustained tremors in vertebrate species (Cole and Cox, 1981; Selala *et al.*, 1989; Burrows and Tyrl, 2001). Over 20 mycotoxins containing a tryptophan-derived indole moiety, including penitrems, roquefortine A, verruculogen, tryptoquivaline, aflatrem, paspalinine and paxilline, as well as the paspalitrems and lolitrems (Table 93.1 and Figure 93.1), have demonstrated tremorgenic potential in animals and humans (Selala *et al.*, 1989; Burrows and Tyrl, 2001). Several other fungal metabolites, such as roquefortine C, paspaline, paspalanine and cyclopiazonic, are chemically related to these mycotoxins but have been shown to not be tremorgenic (Knaus *et al.*, 1994; Tiwary *et al.*, 2009). With increased analytical capabilities, particularly the emergence of advanced NMR, HPLC-MS and LC-MS/MS spectroscopic methodologies, other “known” mycotoxins, with both related and unrelated structures, such as ergonovine (ergometrine), ergine (lysergic acid amide) and patulin, as well as “new” secondary fungal metabolites, like seco-penitrem D, have recently been detected in samples associated with clinical cases of tremogenic syndromes and their associated neurotoxicities (Sabater-Vilar *et al.*, 2004; Uhlig *et al.*, 2009; Moldes-Anaya *et al.*, 2011). However, the precise roles of these detected fungal metabolites in the pathogenesis of the observed tremogenic syndromes are yet to be determined, and this task is complicated by the diversity of fungal matrices, the propensity for myco- and

TABLE 93.1 Representative tremorgenic mycotoxins, associated fungi and substrates

Tremorgenic mycotoxin	Associated fungi	Common substrates
Penitrem A	<i>Penicillium crustosum</i> <i>Penicillium cyclopium</i> <i>Penicillium commune</i> <i>Penicillium</i> spp.	Meat, cereals, nuts, cheeses, eggs, fruits, processed/refrigerated foods, refuse, compost
Roquefortines <sup>1</sup>	<i>Penicillium roqueforti</i> Same as penitrem A and sometimes concurrently with penitrem A	Same as penitrem A
Janthitrems A, B and C	<i>Penicillium janthinellum</i>	Perennial ryegrass
Verruculogen	<i>Penicillium</i> spp. <i>Aspergillus</i> spp.	Soil, seeds, cereal crops
Tryptoquivaline tremorgens <sup>2</sup>	<i>Penicillium</i> spp. <i>Aspergillus clavatus</i>	Soil, seeds, cereal crops Sprouting cereal grains, malting byproducts
Territrems A and B	<i>Aspergillus terreus</i>	Cereal grains
Aflatrem	<i>Aspergillus flavus</i>	Corn
Lolitrems A, B, C and D	<i>Neotyphodium lolii</i>	Perennial ryegrass
Paxilline	<i>Neotyphodium lolii</i>	Perennial ryegrass
Lolitriol	<i>Neotyphodium lolii</i>	Perennial ryegrass
Paspalitrems A, B and C	<i>Claviceps paspali</i> <i>Claviceps cinerea</i>	Dallisgrass Bahia grass <i>Hilaria</i> spp.
Paspalinine	<i>Claviceps cynodontis</i> Same as paspalitrems	Bermudagrass Same as paspalitrems

<sup>1</sup>Roquefortine C has actually been associated with paralysis in several species.

<sup>2</sup>Includes quinazoline ring-containing indole alkaloids with structures similar to tryptoquivaline.

**FIGURE 93.1** The structures of selected indole-diterpene tremorgenic mycotoxins are shown. This figure was adapted, with permission, from CAST (2003) and from [Cole and Cox \(1981\)](#) (modifications courtesy of Don Connor and Howard Wilson).

phytotoxins to be present in complex mixtures, and difficulties inherent to relating xenobiotic structure to function and concentration to biological relevance.

Tremorgen-producing fungi grow on a wide variety of foodstuffs, including dairy or grain-containing products intended for human consumption (e.g., cheeses and pastas), stored grains and nuts (e.g., peanuts and walnuts) and a number of forages (e.g., legumes and grasses) consumed by livestock species, and even food or beverage manufacturing byproducts, garbage and compost piles can be sources of tremorgenic mycotoxins ([Burrows and Tyl, 2001](#); [Boysen et al., 2002](#); [Yount et al., 2003](#)). Although there have been several human cases

in which tremors and convulsions were attributed to consumption of mold-contaminated food containing penitrem A ([Gordon et al., 1993](#); [Lewis et al., 2005](#)), this chapter will focus on the toxicity of tremorgenic mycotoxins in animal species. Dogs, because of their relatively indiscriminate appetite and frequently unsupervised roaming behavior, appear to be very susceptible to intoxication by penitrem A, as well as roquefortines ([Boysen et al., 2002](#); [Yount et al., 2003](#)). Mycotoxin-associated stagger syndromes in livestock, also described in the literature as “grass staggers” (not to be confused with “grass staggers” or “grass tetany” related to hypomagnesemia), have most frequently occurred following the ingestion

of endophyte (*Neotyphodium lolii*)-infected perennial ryegrass (*Lolium perenne*) or consumption of Dallisgrass (*Paspalum dilatatum*) or Bahiagrass (*Paspalum notatum*) contaminated by sclerotia of *Claviceps paspali*.

## BACKGROUND

### *Penicillium*-associated tremorgenic mycotoxins

Although a variety of different fungi synthesize indole-diterpene mycotoxins having specific tremorgenic effects on the central nervous system (CNS), tremorgens produced by *Penicillium* spp. (especially penitrem A and roquefortines) are the most commonly encountered of these mycotoxins. Penitrem A is a potent neurotoxin which causes a syndrome characterized by sustained tremors and, at high doses, convulsions and death in laboratory and farm animals (Wilson, 1971; Arp and Richard, 1981; Peterson and Penny, 1982; Shreeve *et al.*, 1983; Hocking *et al.*, 1988; Breton *et al.*, 1998; Cavanagh *et al.*, 1998). Dogs can be poisoned by eating walnuts and a variety of other unused or discarded foodstuffs infected with *Penicillium* spp. (Boysen *et al.*, 2002; Yount *et al.*, 2003), and field cases of poisoning have also been documented in cattle, sheep and horses (Cavanagh *et al.*, 1998; Hocking *et al.*, 1988; Boysen *et al.*, 2002; Walter, 2002; Yount *et al.*, 2003). *Penicillium crustosum* is an especially common foodborne fungus that causes spoilage in a wide variety of foods, including meat, cereals, nuts, cheese, eggs, fruits and processed and refrigerated food, and almost all *Penicillium crustosum* isolates produce the mycotoxin penitrem A (Hocking and Pitt, 2003; Rundberget *et al.*, 2004). Roquefortines can also be synthesized by *Penicillium* spp. (Hooser and Talcott, 2006), and, interestingly, *Penicillium crustosum*, as well as several other *Penicillium* spp., can produce penitrem A and roquefortines concurrently following growth and sporulation (Vesonder *et al.*, 1980; Wagener *et al.*, 1980; Kyriakidis *et al.*, 1981; Mantle *et al.*, 1983; Boysen *et al.*, 2002; Yount *et al.*, 2003). In fact, roquefortine C, which has itself been associated with anorexia and paralysis, has been found to be a reliable biomarker for the tremorgenic mycotoxin penitrem A, in instances where that tremorgen was present in lower concentrations, at or slightly below its level of detection (Tiwary *et al.*, 2009). Additionally, three other tremorgenic mycotoxins, janthitrem A, B and C (molecular weight 601, 585 and 565, respectively), can also be produced by a species of *Penicillium* (i.e., *Penicillium janthinellum*), and these tremorgens have been associated with staggers outbreaks in sheep grazing ryegrass (Gallagher *et al.*, 1980; Burrows and Tyrl, 2001).

### *Aspergillus*-associated tremorgenic mycotoxins

Verruculogen, another tremorgenic mycotoxin containing the indole moiety and associated with tremors in mice, rats and farm animals, is produced by species of *Aspergillus*, as well as *Penicillium* (Gallagher and Latch, 1977). Likewise, tryptoquivaline and related quinazoline ring-containing indole alkaloids are also produced by *Aspergillus* and *Penicillium* spp. (Gao *et al.*, 2011). Tremorgenic mycotoxins isolated from *Aspergillus terreus* include territrems A and B, which were previously designated as C<sub>1</sub> and C<sub>2</sub>, respectively (Ling *et al.*, 1979), and *Aspergillus flavus* can, in addition to aflatoxins, also produce tremorgenic aflatrems and other indole-diterpene mycotoxins (e.g., paspalinine) in contaminated corn (Burrows and Tyrl, 2001).

### *Neotyphodium*-associated tremorgenic mycotoxins

In Australia, New Zealand and North America, perennial ryegrass (*Lolium perenne*) infected with the endophyte *Neotyphodium lolii* (formerly *Acremonium lolii*) has been associated with a “grass staggers” syndrome in horses, deer, cattle and, especially, sheep, which is frequently referred to as “perennial ryegrass staggers” and is distinct from annual ryegrass toxicosis (Galey *et al.*, 1991; Cheeke, 1998; Burrows and Tyrl, 2001). *Neotyphodium lolii* concentrates in the caryopsis/seed and the outer, lower leaf sheaths of perennial ryegrass and the “staggers” syndrome is most often observed after several days of exposure to endophyte-infected ryegrass during late summer when there is shortage of pasture (Galey *et al.*, 1991; Cheeke, 1998). Ergovaline and other ergot alkaloids associated with “fescue toxicosis” are also produced by *Neotyphodium lolii* (Cheeke, 1998), but the classic neurological signs of perennial ryegrass staggers are indistinguishable from those associated with *Penicillium* and *Aspergillus* species and the adverse effects of neurotoxic indole-diterpene tremorgens, including lolitrems A, C and D, lolitrem precursors (e.g., paxilline and lolitriol) and, especially, lolitrem B (Cheeke, 1998; Burrows and Tyrl, 2001).

### *Claviceps*-associated tremorgenic mycotoxins

While *Claviceps purpurea* is notoriously associated with “classic” ergotism in human and animals and, historically, occasional tremors or convulsions (i.e., nervous ergotism or convulsive ergotism) in livestock (Burrows and Tyrl, 2001; Evans *et al.*, 2004), other species of *Claviceps* produce toxicoses primarily characterized by a tremorgenic “staggers” syndrome (Burrows and Tyrl, 2001). Sheep, horses and cattle, in particular, can develop

a “grass staggers” syndrome several days following the ingestion of mature Dallisgrass (*Paspalum dilatatum*) or Bahiagrass (*Paspalum notatum*) infected with the sclerotia of *Claviceps paspali* (Cheeke, 1998; Burrows and Tyrl, 2001). “Dallisgrass staggers” and “Bahiagrass staggers” have most frequently been observed in the southeastern United States, Central and South America, parts of Europe and South Africa, as well as Australia and New Zealand. Traditionally, the ergot alkaloids produced in large quantities by *Claviceps purpurea* and in much smaller quantities by *Claviceps paspali* were thought to be responsible for the tremors observed in conjunction with exposure to both species of *Claviceps* (Cheeke, 1998). However, it is now understood, at least with respect to the “staggers” syndromes associated with *Claviceps paspali* and, less commonly, *Claviceps cinerea* (fungal infections of *Hilaria* spp. (curly mesquite, curlygrass, galleta, etc.)), that the large concentrations of indole–diterpene tremorgenic mycotoxins (i.e., paspalinine and paspalitrems A, B and C) found in the sclerotia of these species of *Claviceps* are responsible for the neurotoxicity. As with other “grass staggers,” *Claviceps*-related tremorgenic syndromes are characterized by exercise-exacerbated nervousness, “wild” facial expressions, belligerent attitude, tremors, ataxia, convulsions and occasional deaths attributed primarily to misadventure (Burrows and Tyrl, 2001).

### Bermudagrass staggers

Periodic episodes of tremors have been observed in cattle in the southern United States and Oklahoma and Texas, as well as horses in California, which have been ingesting mature Bermudagrass (*Cynodon dactylon*) (Cheeke, 1998; Burrows and Tyrl, 2001). Ergot-type alkaloids (ergine, ergonovine and ergonovinine) are produced by several species of *Claviceps*, including *Claviceps cynodontis*, and have been isolated in several instances of “Bermudagrass staggers” (Cheeke, 1998; Burrows and Tyrl, 2001; Uhlig *et al.*, 2009). However, higher concentrations of paspalitrem-type indole alkaloids have recently been detected in samples from a clinical case of this disease syndrome and are most likely the primary Bermudagrass tremorgens (Uhlig *et al.*, 2009).

## TOXICOKINETICS

It should be kept in mind that, while the onset and duration of the various “staggers” syndromes might vary somewhat, the tremorgenic neurotoxicities associated with the various grasses and aflatoxin-infected corn are essentially identical to one another (Cheeke, 1998). Tremorgenic indole-containing mycotoxins are lipophilic molecules that

easily cross the blood–brain barrier and rapidly gain access to the CNS (Patterson *et al.*, 1981). Although there might be some subtle differences between compounds and species of animals, tremorgenic indole–diterpene alkaloids are generally rapidly absorbed from the gastrointestinal tract, and the toxic signs, depending on the specific toxins and the exposed species, are usually seen within several hours (especially penitrem A and roquefortines in dogs) to a few days (frequently lolitrems and paspalitrems in ruminants) following ingestion of contaminated foodstuffs (Burrows and Tyrl, 2001; Hooser and Talcott, 2006). As evidenced by the lack of a cumulative effect following repeated doses, these particular mycotoxins do not appear to accumulate in the body (Peterson and Penny, 1982). Despite some hepatic metabolism, these mycotoxins are usually eliminated mainly through biliary excretion into the feces (Burrows and Tyrl, 2001; Hooser and Talcott, 2006). Young animals are more sensitive than adults to the toxicity of tremorgenic mycotoxins, with 5-month-old lambs being more susceptible than 15-month-old sheep to verruculogen toxicity (Patterson *et al.*, 1981).

## MECHANISM OF ACTION

It should be pointed out that, although related in structure, tremorgenic mycotoxins do not exert toxicity by a single common mechanism, and the exact mechanisms involved in neurotoxicity induced by these tremorgens are yet to be fully elucidated. These mycotoxins work at a different functional level of the nervous system than other mycotoxins having more widespread targets for toxicity associated with the inhibition of basic cellular functions, such as protein synthesis. Several pharmacological/toxicological mechanisms of tremorgenic action have been proposed, and, in general, tremorgenic mycotoxins interfere with inhibitory neuroreceptors and enhance excitatory amino acid neurotransmitter release mechanisms (Wilson, 1971; Norris *et al.*, 1980; Selala *et al.*, 1989). In experimental studies, the inhibitory action of this type of mycotoxin at gamma aminobutyric acid (GABA) receptors was demonstrated (Stern, 1971; Hotujac and Stern, 1974; Hotujac *et al.*, 1976; Selala *et al.*, 1989; Abramson, 1997). Gant *et al.* (1987) studied the effects of four fungal tremorgens and one nontremorgenic mycotoxin on GABA<sub>A</sub> receptor-binding in the rat’s brain, and, in high concentrations, the tremorgenic action of these mycotoxins was, in part, most likely due to inhibition of GABA<sub>A</sub> receptor function. Conversely, other studies have shown how tremorgenic mycotoxins increase the release of excitatory neurotransmitters (Norris *et al.*, 1980).

Among the tremorgenic mycotoxins, penitrem A has been studied the most for the elucidation of its mechanism

of action and toxicity. There is convincing evidence suggesting that penitrem A acts on the CNS to induce seizures (Sobotka *et al.*, 1978; Arp and Richard, 1981). Penitrem A was shown to increase the spontaneous release of aspartate and glutamate, as well as, interestingly, GABA (Norris *et al.*, 1980). Glutamate and aspartate are the neurotransmitters of the parallel and climbing fibers, respectively, which are two major excitatory inputs to Purkinje cells. There is also evidence for a penitrem A-induced partial decrease in glycine levels in the brain in association with pathology related to penitrem A exposure (Catovic *et al.*, 1975). Cavanagh *et al.* (1998) demonstrated that, in rats, penitrem A can cause widespread degeneration of Purkinje cells and foci of necrosis in the cerebellar granular cell layers. These striking lesions are confined to the cerebellum, with no lesions found elsewhere in the brain. Cerebellar Purkinje cells are the primary targets cells for the adverse effects of penitrem A. Penitrem A-induced tremors might also be partly explained by a presynaptic inhibition of inhibitory interneurons.

Similar mechanisms of action have been demonstrated for other tremorgenic mycotoxins. Verruculogen-induced tremors in rats have been associated with an increased level of excitatory neurotransmitters (glutamate and aspartate) in the lateral ventricle, suggesting subcortical, verruculogen-induced tremorgenic activity. Selala *et al.* (1989) demonstrated that tremorgenic mycotoxins can be partial agonists of GABA. Verruculogen increases spontaneous glutamate and aspartate release *in vivo* in guinea pig ileum preparations and also causes an increase in contractile responses to electrical field stimulation, which has been attributed to enhanced release of acetylcholine from presynaptic nerve terminals. Although paxilline blocks high-conductance  $\text{Ca}^{2+}$ -activated  $\text{K}^{+}$  channels, some related nontremorgenic fungal metabolites, such as paspaline, have also been shown to inhibit these particular ion channels (Burrows and Tyril, 2001). Paxilline also inhibits the cerebellar inositol 1,4,5-triphosphate receptor. Paspalinine and the paspalitrems are thought to impair GABA- and glycine-mediated inhibitory pathways (Burrows and Tyril, 2001).

## TOXICODYNAMICS

### Central effects

Tremorgenic mycotoxins are known to act on the CNS, causing sustained tremors, convulsions and, occasionally, deaths in animals. In general, the clinical signs and symptoms typically observed during tremorgenic mycotoxicoses include diminished activity and immobility, followed by hyperexcitability, muscle tremor, ataxia, tetanic

seizures and convulsions (Cole and Cox, 1981). These clinical signs are reversible if the affected animal is removed from the tremorgen-contaminated source. Death is limited by the emetic effect of these tremorgens. In dogs, the clinical disease involves the development of muscle tremors and seizures, vomiting, alterations in behavior, hyperthermia, depression, coma and pulmonary edema.

Depending on the level of tremorgenic mycotoxin exposure, death can occur in some instances within 2–4 h and is usually secondary to respiratory compromise, metabolic acidosis and/or hyperthermia. In severe cases, clinical signs of toxicosis can persist for several days, and fine tremors can be seen for a week or more. The tremors produced by penitrem A are very similar in most species and begin within a few minutes of intraperitoneal (IP) injection and even sooner with IV injection. The tremors can be sustained and lead to both ataxia and episodic spasms (Cavanagh *et al.*, 1998). Larger doses of penitrem A can cause seizures, massive liver necrosis and death (Hocking *et al.*, 1988). In a histopathological study in rats, Breton *et al.* (1998) revealed that penitrem A induced dose-related injuries in the cerebellum with massive degeneration of Purkinje cells and a significant vacuolization within the molecular layer. In one instance of neurological disorders in dairy cattle associated with *Aspergillus clavatus*-contaminated beer residues, neuronal degeneration was observed within the brainstem and ventral spinal cord, but no analyses for tremorgenic mycotoxins were performed in order to confirm a causal relationship between any tremorgens and the observed pathology (Loretti *et al.*, 2003).

### Peripheral effects

Tremorgenic mycotoxins have also been studied for peripheral effects (McLeay *et al.*, 1999). The tremorgenic mycotoxins, such as penitrem A, paxilline and lolitrem B, can have profound effects on electromyographic (EMG) activity of smooth muscle of the reticulorumen in conscious sheep, with a time course of action similar to their respective characteristic effects on the induction (1–2, 15–20 and 20–30 min) and the duration (1–2, 1–2 and 8–12 h) of tremors. Response to penitrem A revealed a greater sensitivity of smooth muscle than skeletal muscle. The excitatory local effects were partially blocked by atropine, indicating that stimulation of muscarinic cholinergic receptors was involved. Increased local activity may mediate a reflex inhibition of cyclical contractions. However, a nontremorgenic isomer of lolitrem B (31-epi-lolitrem B) had no effect on the reticulorumen. The intensity and duration of the effects of lolitrem B (up to 12 h) indicate that severe disruption of digestion may occur in animals grazing *Neotyphodium lolii*-infected pasture. Moderately severe muscle contractions, traumatic events

secondary to ataxia and prolonged recumbency, especially in large animals, can potentially result in muscle damage following suspected exposure to tremorgenic mycotoxins, but directly myotoxic effects of some mycotoxins cannot be ruled out (Loretta *et al.*, 2003).

### Genotoxicity

Five tremorgenic mycotoxins (fumitremorgen B, paxilline, penitrem A, verruculogen and verrucosidin), which have been associated with molds found in fermented meats, were assessed for genotoxicity (Sabater-Vilar *et al.*, 2003). The mycotoxins were tested in two short-term *in vitro* assays using different genotoxic endpoints, in different phylogenetic systems, with the use of mammalian-microsome assay and the single-cell gel electrophoresis assay of human lymphocytes. The findings revealed that all of the tested mycotoxins, with the exception of penitrem A, exhibited a certain degree of genotoxicity. Verrucosidin appeared to have the highest toxic potential, testing positive in both assays. Verruculogen tested positive in the *Salmonella*/mammalian-microsome assay, and paxilline and fumitremorgen B caused DNA damage in human lymphocytes.

### Acute toxicity

Acute toxicity data are available for only a few of the tremorgenic mycotoxins. It should be noted that the relative doses resulting in lethality in different species might not necessarily be reflective of the relative tremorgenic potentials of these mycotoxins. The LD<sub>50</sub> of penitrem A in mice is 15–19 mg/kg, IP (Ling *et al.*, 1979). The LD<sub>50</sub> of verruculogen is reported to be 15.2 mg/kg, IP, and 266 mg/kg, following oral exposure, in the chicken, with the corresponding LD<sub>50</sub> values in mice being 2.4 mg/kg, IP, and 127 mg/kg, following oral exposure. The LD<sub>50</sub> value of territrems A in mice is 15–19 mg/kg, IP (Ling *et al.*, 1979).

### Potential interactions

In previous studies, concurrent production of roquefortines and penitrem A by various species of *Penicillium* (e.g., *Penicillium crustosum*, *Penicillium cyclopium* Westling and *Penicillium commune*) was demonstrated in culture extracts (Vesonder *et al.*, 1980; Wagener *et al.*, 1980; Kyriakidis *et al.*, 1981; Mantle *et al.*, 1983). Braselton and Rumler (1996) first reported the concurrent presence of both tremorgenic mycotoxins in naturally occurring field cases of canine intoxication and raised the issue of the potential synergistic interactions between these tremorgens. In two recent cases, both Boysen *et al.* (2002)

and Yount *et al.* (2003) diagnosed concurrent intoxication with penitrem A and roquefortines in several dogs. Given that roquefortines and penitrem A can have similar mechanisms of action, there might be the potential for some synergism between these tremorgenic mycotoxins or at least a reduction in the amount of ingested contaminated material required for the onset of clinical signs. Likewise, it would seem logical in instances of “grass staggers” that a greater concentration of multiple, potential tremorgenic mycotoxins in contaminated forages would increase the likelihood and, potentially, the severity of observed intoxications. However, the behavior of mycotoxins, especially those interacting with specific receptors, might not be predictable in mixtures, and the paralytic tremorgen roquefortine C might actually be a reliable biomarker for penitrem A in some tremorgenic syndromes (Tiway *et al.*, 2009).

## CLINICAL ASPECTS OF TREMORGENIC MYCOTOXICOSES

### Diagnosis

Diagnosis of tremorgenic mycotoxin-related intoxication is based on clinical circumstances, a history of exposure to or consumption of moldy foodstuffs, clinical signs of tremors and seizures, and, ideally, detection of tremorgenic mycotoxin(s) in the suspected source material, vomitus, gastrointestinal tract contents, or bile. Detection of molds without detection of tremorgenic mycotoxins suggests the possibility but does not confirm the occurrence of a tremorgenic mycotoxicosis. Differential diagnoses should rule out ethylene glycol, strychnine, metaldehyde, methylxanthines, pyrethroid insecticide, nicotine, organochlorine insecticides, bromethalin, acetylcholinesterase-inhibiting insecticides, other potential neurotoxicants and eclampsia in pregnant animals (Hooser and Talcott, 2006). It needs to be pointed out that in field cases of perennial ryegrass staggers, as well as Dallisgrass and Bahiagrass staggers, the onset of clinical signs is most likely related to the intake of lolitrem B and paspalanine and/or paspalitrems, respectively. The effects of these tremorgenic mycotoxins could potentially be more insidious and longer lasting than those of penitrem A (Burrows and Tyrl, 2001; Hooser and Talcott, 2006). Depending on the laboratory, tremorgenic mycotoxins can generally be quantified using LC-MS/MS (Tiway *et al.*, 2009), HPLC-MS (Rundberget and Wilkins, 2002), GC-MS/MS (Braselton and Rumler, 1996), or TLC (Hooser and Talcott, 2006). Analyses for roquefortines and penitrem A are generally more likely to be available to clinicians than analytical procedures for the other tremorgenic mycotoxins.

Detection of roquefortine C in samples from a tremorgenic syndrome, especially in dogs, where penitrem A is not detected, might serve as a biomarker for exposure to this common tremorgen (Tiwary *et al.*, 2009).

## Treatment

In a small animal setting the minimum initial database should include a complete blood count, serum biochemical profile and assessment of acid–base status and urinalysis (Hooser and Talcott, 2006). Depending on the species, the time period since exposure and the presence and severity of clinical signs, suspected poisoned animals should be stabilized then decontaminated by emesis, gastric lavage, activated charcoal and/or administration of cathartics. Given that intoxications with tremorgenic mycotoxins can be characterized by convulsions or, conversely, severe depression and coma, care should be taken not to induce vomiting when contraindicated by an increased risk for aspiration pneumonia. Especially in companion animals, tremors and convulsions might be controlled by diazepam or methocarbamol, but animals unresponsive to these medications can be treated with barbiturates. The animal should be periodically assessed for metabolic acidosis, hyperthermia, pulmonary edema and aspiration pneumonia. With proper initial and ongoing assessment and in the absence of complications, affected animals should recover relatively uneventfully following removal from the source and appropriate decontamination and other therapeutic procedures. Animals with mild clinical signs or progression of clinical abnormalities following discharge should be reassessed to evaluate the potential for neuronal damage.

## Prevention

Care should be taken to avoid the presence of moldy feedstuffs in areas where animals have unsupervised and unrestricted access, and potentially contaminated materials should be disposed of properly. Trash receptacles should have securely fitting lids, and animals should not be free to roam in areas where discarded foodstuffs or refuse are stored or in the vicinity of compost piles. Livestock should not be fed overtly mold-contaminated forages or concentrates, and care should be taken when feeding food- or beverage-manufacturing byproducts. With respect to “grass staggers,” appropriate stocking rates should be maintained, and management practices should be instituted which ensure that animals have access to young growing plants, especially in pastures dominated by perennial ryegrass, Dallisgrass, Bahiagrass, or Bermudagrass (Burrows and Tyrl, 2001).

## CONCLUSIONS

Tremorgenic mycotoxins containing a tryptophan-derived indole moiety affect many mammalian species, especially sheep, cattle and dogs. Improved analytical techniques are likely to increase the likelihood of detection of “known” or, even, “new” tremorgenic mycotoxins in foodstuffs or biological samples associated with clinical neurological syndromes characterized by tremors and/or convulsions. Roquefortines and penitrem A are produced by several species of *Penicillium*, and dogs exposed to these potent tremorgens exhibit tremors and, potentially, severe convulsive episodes and seizures. Several common forages, especially perennial ryegrass, are susceptible to infection by fungi capable of producing indole–diterpene tremorgenic mycotoxins, such as lolitrems and paspalitrems, which cause “grass staggers” in susceptible species. Although multiple mechanisms are involved in the neurotoxicity of tremorgenic mycotoxins, impaired GABA- and glycine-mediated inhibitory pathways and enhanced excitatory neurotransmitter (i.e., glutamate and aspartate) release appear to play major roles in the onset of clinical signs. Removal of the animal from contaminated foodstuffs usually results in recovery, but severely poisoned animals should be properly assessed; their tremors and/or convulsions treated; and appropriate steps taken to avoid complications, such as aspiration pneumonia. Whenever possible, animals should not have unrestricted and unsupervised access to mold-contaminated foodstuffs.

# Trichothecenes

Michelle S. Mostrom and Merl F. Raisbeck

## INTRODUCTION

While hundreds of fungal metabolites have been discovered that are potentially toxic in animals, five mycotoxins are generally recognized as an agricultural problem in North America: deoxynivalenol (DON), fumonisin, zearalenone, aflatoxin and ochratoxin. This chapter focuses on DON and the other trichothecenes.

More than 180 trichothecene mycotoxins have been recognized in the past 40 years (Grove, 1988, 2000). These fungal metabolites are a group of sesquiterpenoids characterized by a tetracyclic 12,13-epoxytrichothec-9-ene skeleton and a variable number of acetoxy or hydroxyl group substitutions. The epoxy group at C-12 and C-13 is considered essential for toxicity (Figure 94.1). Trichothecenes can be broadly divided into two groups, macrocyclic and non-macrocyclic trichothecenes, based on the presence of a macrocyclic ring linking C-4 and C-15 with diesters (roridin series) and triesters (verrucarin series). *Fusarium* molds or fungi are the most economically important source of trichothecene mycotoxins. The genus includes many field fungi capable of infecting wheat, corn, barley, oats and forages. *Fusarium* is most common in temperate climates, but contamination of grains is reported worldwide (Placinta *et al.*, 1999; JECFA, 2001; CAST, 2003).

Trichothecenes are potent inhibitors of protein synthesis and are toxic to molds, bacteria, plants and animals. The hallmark clinical sign of trichothecene toxicosis in animals is feed refusal, which has led to speculation that animals may not voluntarily consume enough contaminated ration to cause marked poisoning; however, when the only available feedstuffs are contaminated with trichothecenes, poisoning may result. Clinical signs include emesis, feed refusal and weight loss, immunomodulation, coagulopathy and hemorrhage, and cellular necrosis of mitotically active tissues such as intestinal mucosa, skin, bone marrow, spleen, testis and ovary (CAST, 2003). Trichothecenes have caused lethality in horses (Rodricks and Eppley, 1974), man (Joffe, 1974) and cattle (Hsu *et al.*, 1972), but most recent scientific interest has focused on subclinical syndromes including nutritional impairment (Rotter *et al.*, 1996), loss of production from contaminated feeds and immunosuppression (Bondy and Pestka, 2000; Pestka and Smolinski, 2005).

Some of the confusion about clinical effects of trichothecenes results from the discrepancy between controlled experiments and field studies, and from the variable toxicity of contaminated feedstuffs. Studies

TABLE A

Trichothecene	R1	R2	R3	R4	R5
T-2 toxin	OH	OAc	OAc	H	OCOCH <sub>2</sub> CH(CH <sub>3</sub> ) <sub>2</sub>

using experimental animals and purified trichothecenes often suggest a dose–response relationship for a particular clinical effect that is not supported by field observations. Some naturally contaminated grains are more toxic than can be accounted for by their known mycotoxin content. Controlled experiments using identical methods and similar test animals may yield marked variation, both qualitatively and quantitatively, in response to different batches of naturally contaminated feed. It seems likely that spontaneous trichothecene mycotoxicoses in livestock are complicated by the presence of unidentified mycotoxins or additional fungal metabolites in the ration. Diagnosis may also be frustrated by the difficulty of obtaining a representative feed sample to test and appropriate analytical methodology to identify fungal metabolites.

## BACKGROUND

Mold-infected grains have been associated with ill health in livestock and man for over 100 years. In European Russia and Eastern Siberia, “scabby grains” and “moldy hay” have long been recognized as toxic, and in Japan, a red mold disease or “Akakabi-byo” of wheat caused gastroenteritis in man (Saito and Ohtsubo, 1974). Alimentary toxic aleukia (ATA) of human beings and a similar condition (stachybotryotoxicosis) of horses were associated with overwintered grains and hay during the 1930s and 1940s in the former USSR. Delayed harvest resulted in overwintering of grain, and the cold, wet conditions resulted in the growth of mold on overwintered grain and hay. These molds were later identified as *Fusarium sporotrichioides*, *Fusarium poae* and *Stachybotrys alternans* in grain and hay, respectively, and several trichothecene mycotoxins were isolated. The primary toxin associated with ATA was identified as 4 $\beta$ ,15-diacetoxy-3 $\alpha$ -hydroxy-8 $\alpha$ -[3-methylbutyryloxy]-12,13-epoxytrichothec-9-ene or T-2 toxin. A brief description of ATA is informative as it illustrates the classical effects of potent trichothecenes, mainly epithelial irritation or dermonecrosis, gastrointestinal irritation and immunosuppression (Joffe, 1974). Clinically, ATA involved four stages. Stage one occurred shortly after ingestion of toxic grains. Symptoms included a burning sensation of the mouth, tongue, esophagus and stomach and inflammation of the gastrointestinal mucosa accompanied by vomiting, diarrhea, salivation, dizziness and tachycardia. This stage lasted from 3 to 9 days, and coincided with the initial clinical appearance of leukopenia. Stage two was termed the latent or leukopenic stage because the victim felt normal and could function normally, but major changes were occurring in the

hematopoietic system including progressive leukopenia with granulocytopenia, and a relative lymphocytosis. Anemia, icterus and lowered immune resistance to infections were typical of this stage and some reports describe abnormalities in the central and autonomic nervous functions. Stage two lasted from 2 to 8 weeks, with eventual recovery if exposure stopped. If victims continued to consume contaminated grain, the syndrome progressed to a third stage. In stage three, leukopenia worsened and thrombocytopenia and decreased fibrinogen resulted in anemia and petechial hemorrhages on the skin of the trunk, lateral surfaces of the arms, the thighs, face and head. Nasal, gastric and intestinal hemorrhages were noted. Necrotic lesions could appear in the throat, gums, buccal mucosa, larynx and vocal cords with secondary bacterial infections. Lymph node enlargement was observed, and death from stenosis of the glottis was reported. If the victim survived, stage four consisted of a convalescent period of 2 or more months while bone marrow recovered. The clinical signs of ATA in humans have been reproduced in cats given repeated doses of T-2 toxin (Lutsky *et al.*, 1978).

The fungus usually involved in scabby grain blights was identified as *Gibberella zeae* (Schwabe) or *Fusarium graminearum*, its asexual or conidial phase (reviewed by Marasas *et al.*, 1984). A trichothecene, chemically described as 3,7,15-trihydroxy-12,13-epoxytrichothec-9-en-8-one, was isolated from barley (Morooka *et al.*, 1972) and field corn infected with *F. graminearum* (Vesonder *et al.*, 1973) and given the trivial name vomitoxin. Vomitoxin, also known as Rd toxin, 4-deoxynivalenol, or DON, was demonstrated to be the *Fusarium* toxin responsible for feed refusal and emesis in monogastric animals fed contaminated corn (Vesonder *et al.*, 1976). Subsequently, an acetylated form of DON, 3-acetoxy-7,15-dihydroxy-12,13-epoxytrichothec-9-en-8-one (3-ADON), was isolated from a *Fusarium* culture that was more toxic than DON in male DDY mice (Yoshizawa and Morooka, 1973).

## SOURCES

Trichothecenes are produced by several genera of fungi, including *Fusarium*, *Stachybotrys*, *Myrothecium*, *Trichothecium*, *Trichoderma*, *Cephalosporium*, *Cylindrocarpon*, *Verticimonosporium* and *Phomopsis* (Scott, 1989). Trichothecene mycotoxins (baccharinoids) have also been isolated from Brazilian plants, notably *Baccharis* spp.; however, all medically and economically important sources to date have been fungal, especially *Fusarium*. *Fusarium* is a major agricultural plant pathogen of temperate growing regions, where it causes *Fusarium*

head blight in wheat, barley, triticale and other grains. *F. graminearum* has an optimum temperature range for growth of 26–28°C at a water activity ( $a_w$ ) greater than 0.88. *Fusarium culmorum* grows optimally at 21°C when  $a_w > 0.87$ . While increased rainfall will increase *Fusarium* head blight, the incidence of blight is primarily affected by moisture at anthesis when the temperature is in the optimum range (Miller, 2002). Moisture at silk emergence and wet weather later in the season increase *Gibberella* or pink ear rot caused by *F. graminearum* in corn.

TABLE B

Trichothecene	R1	R2	R3	R4
Nivalenol	OH	OH	OH	OH
Deoxynivalenol	OH	H	OH	OH
Fusarenon-X	OH	OAc	OH	OH
Diacetylnivalenol	OH	OAc	OAc	OH
3-Acetyldeoxynivalenol	OAc	H	OH	OH
15-Acetyldeoxynivalenol	OH	H	OAc	OH

*Fusarium* species vary in toxigenic potential by strain, which in turn varies with geographic location. Mycotoxin production by *Fusarium* fungi is heavily dependent on oxygen, environmental pH, osmotic tension and sometimes temperature. For example, DON is produced under conditions of low oxygen tension, whereas zearalenone (a non-trichothecene, estrogenic mycotoxin) production by the same fungi requires oxygen saturation, usually occurring after field crops senesce (Miller, 2002). Unusually cool weather conditions in late summer and early fall, coupled with heavy rainfall in the upper Midwest of the United States, can result in widespread, severe *Fusarium* infestation and mycotoxin production. For example, the moldy corn epidemic in Wisconsin during 1962 and 1963 that led to the isolation of toxigenic fungi and the discovery of several important Type A trichothecenes, including T-2 toxin, occurred in such conditions (Bamburg *et al.*, 1968) and again in 1992, climatic conditions produced a bumper crop of various toxigenic *Fusarium*, *F. sporotrichioides*, *F. poae* and *F. graminearum* in Wisconsin corn samples and the isolation of several trichothecenes (DON, T-2 toxin, HT-2 toxin, diacetoxyscirpenol (DAS), neosolaniol and T-2 tetraol) and zearalenone (Park *et al.*, 1996).

Trichothecenes can be chemically classified into four types based on substitutions at five positions of the trichothecene skeleton, including Type A which includes T-2 toxin and HT-2 toxin (Figure 94.1); Type B including nivalenol and DON (Figure 94.2); Type C including crotoxin (Figure 94.3); and Type D or macrocyclics (Figure 94.4). Type A trichothecenes include some of the most toxic trichothecenes, T-2 toxin, its deacetylated metabolite, HT-2 toxin, and DAS (or anguidine). These are most

FIGURE 94.2 Chemical structure of Type B trichothecenes. Substitutions R1 through R4 are given above.

FIGURE 94.3 Chemical structure of Type C trichothecenes (crotoxin).

FIGURE 94.4 Chemical structure of Type D trichothecenes and one example substitution.

commonly produced for research in *F. sporotrichioides* and *F. poae* cultures. Both of these *Fusarium* spp. produce toxic metabolites in light or darkness and at low temperatures ( $< -2^{\circ}\text{C}$ ); however, sharp fluctuations in temperature increases the toxicity of extracts. In addition to ATA, moldy grains produced under low temperature conditions have been associated with moldy corn toxicosis (hemorrhagic disease), moldy bean hull intoxication, moldy cerealemesia, fusariotoxicosis and dendrodochiotoxicosis (myrotheciotoxicosis) (Smalley and Strong, 1974).

The Type B trichothecenes are characterized by a keto group at C-8 and hydroxyl group at C-7. These are common natural field contaminants of grains and include DON and its acetylated derivatives, nivalenol (3 $\alpha$ ,4 $\beta$ ,7 $\alpha$ ,15-tetrahydroxy-12,13-epoxytrichothec-9-en-8-one) and fusarenon-X (4-acetylnivalenol) produced by *F. culmorum* and *F. graminearum*, and other closely related fungi. They are less toxic than the other classes of trichothecenes

without the C-8 keto substitution, such as T-2 toxin, DAS and the macrocyclic trichothecenes.

*F. graminearum* most commonly occurs in southern China, North America and Eastern Europe, and *F. culmorum* more commonly occurs in Western Europe. In North America, *F. graminearum* characteristically produces DON, which can co-occur with another 8-keto-trichothecene, 15-acetyldeoxynivalenol (15-ADON), but in Asia *F. graminearum* almost always produces DON with 3-ADON (Miller *et al.*, 1991). Although not a trichothecene, the estrogenic mycotoxin zearalenone is often found together with DON in North America. Other strains of *F. graminearum*, mostly of Japanese origin, produced nivalenol and fusarenon-X, zearalenone and butenolide. *F. culmorum* strains from the Netherlands produced predominantly DON and 3-ADON, while strains of *F. crookwellense*, collected from four continents, produced 4,15-diacetylnivalenol regardless of the source. More serious adverse effects could be underestimated from moldy corn if only DON, and no acetylated DON or additional trichothecenes, are assayed.

The Type C trichothecenes typically have a second epoxide ring at C-7,8. These trichothecenes are neither produced by *Fusarium*, nor are they associated with adverse effects in livestock. Crotoxin (or antibiotic T) is a Type C trichothecene produced by *Cephalosporium crocinigenum* and *Trichothecium roseum* and has low toxicity in mice (Cole and Cox, 1981). In contrast with Type C trichothecenes, the Type D trichothecenes are potent, cytotoxic compounds with a macrocyclic ring linking C-4 and C-15 on the trichothecene skeleton. The genus *Myrothecium*, including *M. roridum*, *M. leucotrichum* and *M. verrucaria*, can produce verrucarins and roridins that are diesters of the trichothecene verrucarol and acutely toxic to mammalian cell lines *in vitro* and to a wide range of animals with *in vivo* exposure (Mantle, 1991). No consistent naturally occurring toxicoses have been attributed to the *Myrothecium* toxins (Mantle, 1991).

While *Fusarium* does not produce Type D trichothecenes, the fungus *S. alternans* Bonorden (synonyms *S. atra* Corda and *S. chartarum* (Ehrenberg ex Link) Hughes), which grows worldwide on cellulosic vegetation and particularly on mildewed wet straw, produces macrocyclic trichothecene mycotoxins (including satratoxins G and H, verrucarins J and roridin E) that are stable, highly toxic and cause characteristic cytotoxic effects (Bata *et al.*, 1985). Although horses are the most sensitive species, stachybotryotoxicosis has been described in numerous animals, including zoo animals, in many countries of Europe, South Africa and India.

In North America, the trichothecenes produced by *Fusarium* are the major contaminants in cereal crops. Optimal production of T-2 toxin by *F. sporotrichioides* in grains occurs at 6–12°C (as compared with zearalenone production at an optimal 19–20°C). Park *et al.* (1996)

noted that trichothecene concentrations were increased in corn kept in the field and harvested later in cold winter temperatures (grain moistures often greater than 40%), but zearalenone levels were highest in samples collected in the early fall. The co-occurrence of T-2 toxin, DON and zearalenone in field corn also occurs quickly after hail damage in the late summer or fall as hail damage allows fungi to invade the forming seed. Delayed harvests under wet conditions affect other crops. In the United States upper Midwest, a humid, wet fall allowed field molds, such as *Alternaria*, *F. graminearum* and *Phomopsis*, to infect soybeans and produce mycotoxins that include HT-2, DAS, DON and zearalenone (Jacobsen *et al.*, 1995).

In unusually wet, cool periods, *Fusarium* mycotoxins not only occur in the grain, but also in the vegetative part of the plant. *Fusarium* infection of immature corn generally results in higher trichothecene and zearalenone concentrations in the cob, as compared with the mycotoxin concentrations in the kernels. Thus, avoiding incorporation of the cob in animal feed can potentially reduce exposure to mycotoxins. Usually, grain stored at moisture concentrations less than 0.70  $a_w$  or 14.5% moisture by weight is not susceptible to fungal growth or mycotoxin production.

Mycotoxin production occurs in hay, green feed, straw and silage. Hay baled wet or stored in higher moisture conditions (>20%) is subject to molding. Fungal growth in silage usually takes place on the front edges of silage in bunker silos or where silage is not adequately packed and aerobic conditions exist. *Fusarium* occurrence increases with the practice of no-till farming and utilizing corn in crop rotations. Hay, straw, or silage from *Fusarium*-contaminated wheat, barley, oats and corn can contain high levels of trichothecenes, particularly DON and acetylated metabolites. Straw and hay contamination with DON may be as high as 100–150 mg DON/kg (dry weight basis) in wet years (Mostrom *et al.*, 2005).

Of the trichothecenes, DON is probably the most commonly detected in cereal grains throughout the world (Rotter *et al.*, 1996; CAST, 2003). This mycotoxin is resistant to milling and processing and readily enters the animal feed and human food chains. Foodborne trichothecene contamination, in particular DON, has been linked to acute human toxicoses in China, India and Japan, but little information is available regarding potential health effects from chronic exposure (Bhat *et al.*, 1989; Kuiper-Goodman, 1994; JECFA, 2001).

## TOXICOKINETICS

Trichothecenes undergo all four basic reactions in xenobiotic metabolism. Phase I hydrolysis and oxidation and phase II glucuronide conjugation occur in the body

tissues, while reduction of the 12,13-epoxide is thought to occur through microbial action in the gastrointestinal tract; although T-2 toxin is the only trichothecene for which all four basic reactions or pathways occur simultaneously in the same animal (Swanson and Corley, 1989). The ability to remove the epoxide oxygen (deep-oxidation) is an important step in the detoxification of trichothecenes. Orally administered trichothecenes do not accumulate to a significant extent in the body and are rapidly excreted within a few days in urine and feces (bile) (Swanson and Corley, 1989).

Understanding the toxicokinetics of trichothecenes is important for understanding potential effects in animals. Swine are especially sensitive to DON and kinetic parameters have been studied related to intravenous and acute and chronic oral DON exposures (Coppock *et al.*, 1985a; Prelusky *et al.*, 1988, 1990; Prelusky and Trenholm, 1991; Goyarts and Dänicke, 2006). Following an intravenous dose of DON at 1 mg/kg body weight in swine, the mycotoxin distributed rapidly to all tissues and body fluids and declined to negligible levels in all tissues sampled except urine and bile within 24 h (Prelusky and Trenholm, 1991). DON can be detected very rapidly (less than 2.5 min) in the cerebral spinal fluid following intravenous administration in swine; following oral administration of DON in pigs, the plasma DON concentrations correlated closely with cerebral spinal fluid DON levels (Prelusky *et al.*, 1990). Extensive DON tissue accumulation was not detected after dosage indicating that accumulation of edible tissue residues in swine is unlikely at low level DON exposure (Prelusky and Trenholm, 1991). Coppock *et al.* (1985a) reported no detectable residues of DON in skeletal muscle 24 h after intravenous DON administration in pigs. The reported half-life of DON in pigs after an intravenous injection of DON at 0.5 mg/kg body weight ranged between 2.08 and 3.65 h, suggesting that 97% of DON given would be eliminated in 10.1–18.3 h (Coppock *et al.*, 1985a). Following a lower intravenous dose of DON in pigs (0.053 mg/kg body weight), serum DON concentrations decreased biphasically with terminal elimination half-lives ( $t_{1/2\beta}$ ) of between 4.2 and 33.6 h (Goyarts and Dänicke, 2006).

After oral exposure, DON is rapidly and nearly completely absorbed in the stomach and proximal small intestine of pigs (Dänicke *et al.*, 2004a). Pigs dosed with DON at 5.7 mg DON/kg diet chronically for 4 weeks or with one single oral acute exposure (one feeding) had quick absorption of greater than 50% of the DON administered that was highly distributed, with an apparent volume of distribution ( $V_d$ ) higher than total body water, and serum elimination half-lives of 6.3 and 5.3 h in the chronic and acute DON-fed pigs, respectively (Goyarts and Dänicke, 2006). A total of 97% of the DON dose (five elimination half-lives) would be eliminated in 31.5 and 26.5 h after feeding DON chronically or in

one single, acute exposure, respectively. The majority of DON ingested from dietary exposure was eliminated in the urine and feces, with urine being the main excretory route of DON in an unmetabolized form. Similar results were reported by Prelusky *et al.* (1988) who observed that after intravenous DON administration (0.30 mg/kg) in swine, DON was rapidly cleared primarily unchanged in the urine, with minor elimination in bile. The metabolite deepoxy-DON was found in pigs fed the DON-contaminated diet chronically or for a period of longer than 4 weeks (Goyarts and Dänicke, 2006). Eriksen *et al.* (2003) fed pigs a commercial diet containing 3-ADON at 2.5 mg/kg for 2.5 days. Following ingestion, DON was quickly detected in the plasma (indicating deacetylation), with approximately 42% present as a glucuronide conjugate. DON was excreted mainly in urine, with a smaller amount excreted in feces. Deepoxy-DON constituted 52% of the 3-ADON metabolites detected in feces. The deepoxy-DON metabolite increased in concentration from the distal small intestine to the rectum indicating that deepoxidation occurs in the hindgut, which would have minimal influence on toxicity because of major absorbance of DON in the upper gastrointestinal tract.

In contrast with the poor metabolism of DON by swine, the rumen is capable of extensive metabolism of DON and other trichothecenes. The major metabolite of oral DON in ruminants is 3 $\alpha$ ,7 $\alpha$ ,15-trihydroxytrichothec-9, 12-diene-8-one (deepoxy-deoxynivalenol or DOM-1). Deepoxidation of DON to DOM-1 is considered a deactivation step resulting in a non-cytotoxic compound; thus, ruminal metabolism serves a protective function. Because biotransformation occurs in the rumen, little parent compound is available for absorption (Prelusky *et al.*, 1986a; He *et al.*, 1992). Côté *et al.* (1986) reported cows fed high concentrations of DON (66 mg/kg diet for 5 days) excreted approximately 20% of the DON fed in urine and feces as unconjugated DOM-1 (96%) and DON (4%). Preliminary data from the study suggested to the authors that a portion of the remaining 80% of the dose was excreted as glucuronide conjugates of DON and DOM-1 in urine. Dänicke *et al.* (2005) utilized six cannulated dairy cows to evaluate DON and zearalenone metabolism and the effects of *Fusarium*-contaminated wheat on nutrient utilization. The cows were fed a 50:50 mixture of grass silage and contaminated wheat (3.1 mg DON/kg and 0.186 mg zearalenone/kg total ration) providing approximately 25 mg DON/cow/day intake or 0.04 mg DON/kg body weight/day for 4 weeks. The ration was restrictively fed and no feed refusal was observed. Only a small fraction (about 4–28%) of DON was recovered at the duodenum in the form of DON and DOM-1. DOM-1 accounted for 89% of duodenal flow of this mycotoxin. The authors concluded that extensive ruminal metabolism or absorption by rumen mucosa resulted in low DON recovery in

the duodenum. No changes were detected in pH or volatile fatty acid concentrations in rumen fluid from cows fed control wheat versus *Fusarium*-contaminated wheat. In contrast, the ammonia concentrations in rumen fluid were significantly higher from 90 min to 5 h after feeding the *Fusarium*-contaminated wheat, as compared to control wheat. Additionally, the flow of utilizable protein and microbial protein were reduced at the duodenum, suggesting altered ruminal protein utilization could be either the result of mycotoxins in the rumen or from *Fusarium* damage to the structure (cell wall) of wheat grain.

Prelusky *et al.* (1986a) reported that sheep dosed intravenously with DON rapidly excreted two major metabolites of DON as conjugated DON and conjugated DOM-1 in urine, with elimination half-lives of 2.2 and 3.1 h, respectively. Total recovery was 66.5% of the dose, with 63% in the urine and 3.5% in the bile made up of primarily conjugated DOM-1. This suggests the predominant route for elimination in sheep is biotransformation prior to excretion.

Poultry have a greater tolerance to trichothecenes than monogastric mammals because of poor absorption following oral exposure, extensive metabolism and rapid elimination from the body (Prelusky *et al.*, 1986b; Gauvreau, 1991). Oral administration of DON in turkeys (*Meleagris gallopavo*) revealed that 0.96% of the dose was absorbed from the gastrointestinal tract with rapid excretion of DON and its metabolites in urine and excreta (Gauvreau, 1991). The terminal elimination half-life in turkeys following an intravenous dose of DON was about 44 min. Tissue residues of DON and/or metabolites declined rapidly to trace levels.

Lactating cows or laying hens consuming elevated concentrations of DON (>5 mg/kg) transfer minimal concentrations of DON to the milk or eggs, respectively. Charmley *et al.* (1993) fed 0.59, 42 and 104 mg DON/head/day from contaminated corn and wheat for 10 weeks in a lactation study and found no detectable residues (<1 ng/ml) of DON or DOM-1 in milk. Prelusky *et al.* (1984) evaluated the absorption and distribution of a single large oral dose, 920 mg of DON via rumen intubation, given to each of two lactating cows. Maximum blood levels occurred 4.7 and 3.5 h after DON administration and were 200 and 90 ng/ml serum (DON and conjugates, respectively). By 24 h post-dosing, only trace levels (<2 ng DON/ml serum) were detected. Free and conjugated DON were detected in cows' milk at low levels (<4 ng/ml) with an estimated 0.0001% of administered dose excreted in milk. Following a 5-day oral exposure trial to high concentrations of DON (~66 mg/kg in the diet), lactating dairy cows excreted unconjugated DOM-1 in the milk at concentrations up to 26 ng/ml (Côté *et al.*, 1986). No DON was detected (detection limit of 10 µg DON/kg tissue) in eggs or tissues of Leghorn chicks and laying hens and broiler chickens fed a ration containing

4–5 mg DON/kg for 28–160 days (El-Banna *et al.*, 1983). Valenta and Dänicke (2005) did not detect DON, DOM-1, or glucuronide conjugates of these compounds in the yolk or albumen of laying hens fed a maize diet containing 11.9 mg DON/kg dry matter for 16 weeks.

T-2 toxin metabolism has been studied in laboratory and agricultural animals. Metabolism of T-2 toxin generally results in reduced toxicity with deacetylation of T-2 toxin to HT-2 (at C-4), to 4-deacetylneosolaniol, and to T-2 tetraol. T-2 toxin is considered 1.5–1.7 times as toxic as HT-2, which is 4.8 times as toxic as T-2 tetraol (Ueno *et al.*, 1973). Human and bovine liver homogenates are capable of deacetylating T-2 toxin *in vitro* to HT-2 toxin (Ellison and Kotsonis, 1974). T-2 toxin and metabolites in swine can be eliminated as glucuronide conjugates into bile and undergo deconjugation in the intestinal tract by microbial action and enterohepatic recirculation (Corley *et al.*, 1985).

After receiving three daily oral doses of 180 mg T-2 toxin/day (equivalent to dietary levels of 31–35 mg T-2 toxin/kg), a lactating Jersey cow (375 kg) was orally dosed with 156.9 mg of tritium-labeled T-2 toxin (Yoshizawa *et al.*, 1981). The cow showed a good appetite, but milk and urine production decreased by 38 and 50%, respectively, during the experimental period. Plasma concentrations peaked at 8 h after the tritium-T-2 toxin dose, at 64 ppb (ng/g) T-2 toxin equivalents and by 72 h, almost all radioactivity had been eliminated in the urine and feces, in a ratio of 3:7, respectively. About 0.2% of the tritium-T-2 toxin dose was transmitted into the milk with the maximum level of radioactivity in milk at 16 h post-tritium dose of 37 ppb (T-2-toxin equivalents). The cow was killed and tissues were analyzed for T-2 toxin. T-2 toxin was rapidly metabolized and little T-2 toxin accumulated in organ tissues (muscle, liver, kidney, fat, heart, bile, ovaries and mammary gland), but bile and liver contained higher tritium residues than whole blood. The authors considered that a large amount of the absorbed toxin and its metabolites were eliminated via the bile into the intestinal tract. The delayed elimination of large amounts of radioactivity in the feces indicated that T-2 toxin and its metabolites probably recirculate in the enterohepatic system.

A pregnant Holstein cow was intubated with 182 mg of purified T-2 toxin daily (equivalent to about 0.5 mg T-2 toxin/kg body weight) for 15 consecutive days (Robison *et al.*, 1979). Milk samples collected on days 2, 5, 10 and 12 contained T-2 toxin ranging from 10 to 160 ng/g. The dose given to this cow corresponds to an unusually high feed concentration of 50 mg T-2 toxin/kg; therefore, the authors considered it unlikely that T-2 toxin would be detectable in milk at T-2 toxin concentrations found naturally in feeds. The authors fed a sow (170 kg) T-2 toxin at 12 mg/kg diet (equivalent to 0.5 mg T-2 toxin/kg body weight/day) for 220 days. Six days post-parturition a

milk sample was analyzed for T-2 toxin and contained 76 ng/g. Glávits and Ványi (1995) described a "perinatal form of T-2 toxicosis" in swine in Hungary. The authors reported T-2 toxin was excreted in the milk of sows causing lesions, characteristic of T-2, in organs of suckling pigs, including degeneration and necrosis of cells in the bone marrow, and death.

## MICROBIAL METABOLISM

In the ruminant, significant metabolism of trichothecenes occurs in the rumen and gastrointestinal tract prior to absorption. King *et al.* (1984) noted almost complete transformation of DON to a deepoxidation product when DON was incubated *in vitro* with rumen fluid for a 24 h period. Swanson *et al.* (1987) reported DON was partially converted to deepoxidated DON (DOM-1) by rumen microbes. Rumen microbes, in particular protozoa, appear to be active in the deacetylation of the trichothecenes T-2 toxin and DAS to HT-2 and monoacetoxyscirpenol (Kiessling *et al.*, 1984). The authors reported no effect of ovine rumen fluid on DON metabolism; however, the incubation only lasted 3 h. Several rumen bacteria with esterase activity (*Butyrivibrio fibrisolvens*, *Selenomonas ruminantium* and *Anaerobivrio lipolytica*) degraded T-2 toxin to HT-2 toxin and T-2 triol, but *B. fibrisolvens* also produced neosolaniol (Westlake *et al.*, 1987a,b). The authors suggested that at least two different *B. fibrisolvens* enzymes, differing in their specificity for side chains, were responsible for T-2 toxin degradation.

Microbes in the large intestines of chickens are capable of complete DON transformation *in vitro* to a deepoxy metabolite, whereas no metabolism of DON was reported with the *in vitro* incubation of swine large intestinal contents (He *et al.*, 1992). In contrast, Hedman and Pettersson (1997) reported that five of six pigs (weighing about 18 kg) fed nivalenol at 2.5 or 5.0 mg/kg in the diet for 1 week excreted a deepoxidated nivalenol in feces. After 3 weeks on the nivalenol diet, the sixth pig acquired the ability to deepoxidate nivalenol. Additionally, DON was deepoxidated during *in vitro* incubation with microbes that had deepoxidated nivalenol. No deepoxidated nivalenol was detected in feces after feeding a diet of 2.5 or 5 mg nivalenol/kg diet to broiler chickens for 3 weeks, although an unidentified metabolite was found (Hedman and Pettersson, 1997). The ability of microbes to acquire the capability to deepoxidate or detoxify trichothecenes may account for the time course of clinical signs associated with trichothecene ingestion. Microbial adaptation may require a period of several weeks during which the host animal

is exposed to more of the toxic parent trichothecene. The rate and location of deepoxidation of trichothecenes prior to absorption is important in the development of toxic effects. Formation of deepoxides higher in the gastrointestinal tract would reduce the potential toxicity of the trichothecene. Biotransformation of DON is inhibited by low pH *in vitro*, with a pH of 5.2 completely inhibiting DON metabolism either by inactivating the microorganisms or specifically inhibiting the deepoxidation process of DON (He *et al.*, 1992). This may have major implications in the metabolism of DON by ruminants on higher grain diets causing production of organic acids that reduce the rumen pH. As can be seen by the aforementioned, the apparent resistance of ruminants to trichothecenes is due to ruminal metabolism.

## MECHANISM OF ACTION AND TOXICITY

Trichothecenes have multiple effects on eukaryotic cells, including inhibition of protein, RNA and DNA synthesis, alteration of membrane structure and mitochondrial function, stimulation of lipid peroxidation, induction of programmed cell death or apoptosis, and activation of cytokines and chemokines (Table 94.1). It is believed that the primary effect of trichothecenes is inhibition of protein synthesis as all of the other reported effects might be secondary to decreased protein synthesis (Rocha *et al.*, 2005).

TABLE 94.1 Trichothecene effects on eukaryotic cell functions

Inhibit protein synthesis	Ehrlich and Daigle (1987), McLaughlin <i>et al.</i> (1977)
Inhibit RNA and DNA synthesis	Rosenstein and Lafarge-Frayssinet (1983), Thompson and Wannemacher (1986)
Stimulate lipid peroxidation	Rizzo <i>et al.</i> (1994), Vila <i>et al.</i> (2002)
Alter cellular membrane function	Bunner and Morris (1988)
Inhibit mitochondrial and electrontransport chain function	Pace <i>et al.</i> (1988)
Induce apoptosis	Pestka <i>et al.</i> (1994), Shinozuka <i>et al.</i> (1998), Islam <i>et al.</i> (1998)
Activate MAPKs	Zhou <i>et al.</i> (2005)
Modulate immune responses	Corrier (1991), Bondy and Pestka (2000)
Alter neurotransmitters	Prelusky <i>et al.</i> (1992), Swamy <i>et al.</i> (2004)
Induce gene expression of numerous chemokines and cytokines	Azcona-Olivera <i>et al.</i> (1995), Zhou <i>et al.</i> (1997), Moon and Pestka (2002), Ji <i>et al.</i> (1998), Pestka <i>et al.</i> (2005)

## PROTEIN SYNTHESIS INHIBITION

Trichothecenes bind to ribosomes in eukaryotic cells, in particular to the 60S ribosomal subunits, and interfere with peptidyl transferase activity (McLaughlin *et al.*, 1977). Inhibition of protein synthesis requires an intact 9,10 double bond and the C-12,13 epoxide. Trichothecenes can be divided into two groups based on their site of action on protein synthesis, either preferential inhibition of initiation or inhibition of elongation or termination. Trichothecenes with hydroxyl and acetyl substitutions at both C-3 and C-4, such as T-2 toxin, DAS, scirpentriol and verrucaric acid, predominantly inhibit initiation, and compounds such as trichodermin, crotoxin, crotoxin and verrucarol inhibit elongation or termination (McLaughlin *et al.*, 1977). The cytotoxicity of DON, a trichothecene with a keto group at C-8 and a hydroxyl group at C-7, results from protein synthesis inhibition at the ribosomal level during the elongation and termination step in mammalian cells (Ueno, 1983; Ehrlich and Daigle, 1987). In an *in vivo* study, Robbana-Barnat *et al.* (1988) dosed Balb-c mice with DON by intraperitoneal injection (4, 10, 20 and 80 mg DON/kg body weight) followed by an injection of radio-labeled leucine, killed the mice 5 h post-dosage, and determined leucine incorporation into proteins. Mice dosed intraperitoneally at 10 mg DON/kg body weight or more had marked inhibition of protein synthesis in cardiac tissue. Mice fed a diet with 10 mg DON/kg ration for several weeks exhibited cardiac lesions, primarily foci of calcified pericarditis, which suggested a preferential effect on cardiac tissue in the mice. In an *in vivo* low dose DON study in pigs, protein synthesis (using the "flooding dose technique" with radio-labeled phenylalanine as tracer and expressed as fractional synthesis rate) was significantly reduced in kidneys, spleen and ileum of pigs exposed orally to 5.7 mg DON/kg diet for about 4 weeks (Dänicke *et al.*, 2006). Protein synthesis of the liver, skeletal and cardiac muscle, mesenteric lymph nodes, duodenum, jejunum, pancreas and lung was not significantly affected by oral DON exposure.

Trichothecenes inhibit both RNA and DNA synthesis. Using hepatoma cells and phytohemagglutinin-stimulated lymphocytes in an *in vitro* culture, Rosenstein and Lafarge-Frayssinet (1983) reported T-2 toxin inhibited DNA synthesis. DON was demonstrated to inhibit DNA synthesis in splenic lymphocytes and human peripheral blood lymphocytes (Mekhancha-Dahel *et al.*, 1990). Thompson and Wannemacher (1986) reported trichothecenes strongly inhibited RNA synthesis in HeLa cells and had only slight inhibitory effects on Vero cells. The inhibition of nucleic acid synthesis is generally considered secondary to protein synthesis. T-2 toxin inhibited mitochondrial protein synthesis and electron

transport action in rat liver cells and *in vivo*, although high doses were used in the studies (Pace, 1983; Pace *et al.*, 1988).

## LIPID PEROXIDATION

T-2 toxin is thought to increase production of oxygen radicals, overwhelming the scavenging system for oxygen radicals and resulting in cell injury. Rizzo *et al.* (1994) administered a single oral dose of DON or T-2 toxin at 28 or 3.6 mg/kg body weight, respectively, to male Wistar rats on antioxidant-deficient diets. Liver peroxides, as measured by thiobarbituric acid-reactive substances, increased 21 and 268% in rats administered DON or T-2 toxin, respectively. Significant decreases in hepatic glutathione concentration and superoxide dismutase activity occurred in the treated rats, as compared with the controls.

Vila *et al.* (2002) studied the effects of T-2 toxin, given by oral gavage at dosages of 4 and 6.25 mg/kg body weight, on vitamin E status and lipid peroxidation in female CD-1 mice. Lipid peroxidation was evaluated by the plasma and organ content of malondialdehyde (MDA). Mice had a decrease in plasma vitamin E concentration 16 h after toxin treatment, and the concentration remained significantly depressed for up to 48–72 h. The MDA content of liver increased significantly 24–48 h after T-2 toxin administration, as compared with control mice, and returned to the control range after 72 h. These findings suggest that T-2 toxin results in lipid peroxidation in mice and vitamin E is consumed by scavenging free radicals from damage by T-2 toxin.

## NEUROTRANSMITTER EFFECTS

DON produced two main clinical signs in monogastrics, vomiting, or emesis at higher concentrations and reduced food consumption or feed refusal at lower concentrations (Forsyth *et al.*, 1977). The exact mechanism(s) of action of DON which result(s) in feed refusal is/are not known. DON could act directly via a central mechanism controlling hunger or satiety or possibly peripherally through non-specific mechanisms inducing lethargy or depression. Prelusky *et al.* (1992) evaluated the effects of DON on brain biogenic amine concentrations after administration of a single intravenous dose of 0.25 mg DON/kg body weight to young swine (15–23 kg body weight). Norepinephrine was significantly increased and dopamine significantly decreased

in the brain regions of the hypothalamus, frontal cortex and cerebellum for up to 8 h post-treatment, as compared with control animals. Serotonin or 5-hydroxytryptamine was initially increased 1 h post-treatment in the hypothalamus and by 8 h post-treatment was significantly decreased in the hypothalamus and frontal cortex, as compared with controls. The authors concluded that changes in neurotransmitters were not consistent with known neurochemical changes associated with chemically induced anorexia, but might be due to other toxicological responses, such as vomiting. Neurotransmitter concentrations were measured in the cortex, hypothalamus and pons of starter pigs (9.3 kg) fed 21 days of control and *Fusarium*-contaminated feeds (approximately 3.9 and 5.8 mg DON/kg diet) and in 1-day-old male broiler chicks fed *Fusarium*-contaminated feeds (approximately 6.3 and 9.7 mg DON/kg diet) for 56 days (Swamy *et al.* 2004). The pigs on mycotoxin-contaminated feeds had alterations in regional brain neurochemistry, including a linear increase in cortex serotonin concentrations with a linear decrease in hypothalamic tryptophan and norepinephrine concentrations and pons dopamine concentrations. At the end of the broiler study, chicks on mycotoxin-contaminated diets had linear increases of serotonin in the pons and cortex, and norepinephrine and dopamine concentrations in the pons. Perhaps through peripheral action on serotonin-3 receptors, rodents displayed inhibited gastric emptying in a dose-related manner when DON was given orally at 50–1000 µg/kg body weight (Fioramonti *et al.*, 1993). Intestinal propulsion was reduced at the highest dose (1000 µg/kg). This effect is not common to all trichothecenes because T-2 toxin accelerated gastric emptying under similar experimental conditions (Fioramonti *et al.*, 1987).

While the exact role(s) of these neurotransmitters in eating disorders is/are not known, Swamy *et al.* (2004) suggested that stimulation of serotonergic and  $\alpha_2$ -noradrenergic receptors in the hypothalamus of the brain was important in feeding behavior. The increase in serotonergic neurotransmitter concentrations and decrease in norepinephrine concentrations in the brains of pigs fed mycotoxin-contaminated diets might explain some aspects of feed refusal.

Borison and Goodheart (1989) evaluated neural factors involved in the acute emetic, cardiovascular and respiratory effects of T-2 toxin injected (intravenously or intraperitoneally) at 2 mg/kg body weight in cats. While the causation of vomiting has been attributed to the stimulation of the chemoreceptor trigger zone in the area postrema of the medulla oblongata, area postrema-ablated cats exhibited vomiting 5 h after T-2 administration, as compared with normal cats that vomited within an hour of T-2 administration, and generally persisted in vomiting until the time of death at about 12 h. The authors

concluded that the area postrema was not the sole receptor site of trichothecene action to induce emesis. They hypothesized that a possible mechanism of delayed vomiting from trichothecenes may be similar to that of acute radiation sickness in cats exhibiting emesis and malaise, which is mediated by neural afferent pathways from the abdomen that traverse the vagus nerve and dorsal columns of the spinal cord.

## IMMUNOTOXICITY

The molecular basis for cytotoxic effects of trichothecenes and immunosuppression is directly or indirectly related to inhibition of protein synthesis. The most potent immunosuppressive trichothecenes are T-2 toxin, DAS, DON and fusarenon-X, which are the most potent protein synthesis inhibitors (Corrier, 1991). In addition, the occurrence of other secondary metabolites from *Fusarium* associated with trichothecene biosynthesis, such as substituted neosolaniols and calonecetrins, inhibit T- and B-lymphocytes when evaluated in mouse spleen lymphocyte proliferation assays (Bondy *et al.*, 1991). The most widely studied trichothecene, because of potential acute toxicity and use as a chemical warfare agent, is T-2 toxin. T-2 toxin caused necrosis and lymphoid depletion in the thymus, spleen and lymph nodes of a variety of laboratory animals (Ueno, 1977; Hayes *et al.*, 1980; Taylor *et al.*, 1989), swine (Weaver *et al.*, 1978a), cattle (Osweiler *et al.*, 1981) and sheep (Friend *et al.*, 1983). Necrosis and thymic depletion have been reported in the thymus, bursa of Fabricius and spleen in chickens treated with T-2 toxin (Hoerr *et al.*, 1981). Age of exposure is important, as neonatal animals are more sensitive than older animals. Holladay *et al.* (1993) dosed pregnant mice by oral gavage with 1.2 or 1.5 mg T-2 toxin/kg body weight on gestational days 14–17 and found that lymphocyte progenitor cells appear to be more sensitive than thymocytes to T-2 toxin, and are responsible for fetal thymic atrophy and potential immunosuppression seen with T-2.

Trichothecenes have been shown to both stimulate and impair humoral immunity, cell-mediated immunity and host resistance in experimental and food animals (reviewed by Corrier, 1991; Pestka and Bondy, 1994; Rotter *et al.*, 1996; Bondy and Pestka, 2000; Pestka and Smolinski, 2005). The dose and duration of toxin exposure in relation to the timing of the immune assay determined whether stimulation or suppression resulted. For example, Bottex *et al.* (1990) reported contradictory effects in Swiss mice given intraperitoneal doses of 5.3 or 2.7 mg DAS/kg either prior to (range of –10 to –3 days) or following (range of +3 h to +5 days) intraperitoneal injection of *Salmonella typhimurium*. Mice injected with

DAS prior to *Salmonella* infection had a lower mortality rate than control mice given just *Salmonella*. In contrast, mice injected with DAS following infection had a significantly higher mortality than controls given *Salmonella*. Similar results were observed in mice given intraperitoneal injections of DAS either prior to or following antigenic stimulation with sheep erythrocytes. The splenic plaque-forming cell response against sheep erythrocytes was increased in mice given DAS prior to the antigenic stimulation and significantly inhibited in mice given DAS after antigenic stimulation.

Immunostimulation after small doses of trichothecenes apparently results from induction of immune- and inflammation-associated genes. Trichothecene doses that partially inhibited translation up-regulated expression of immune-related genes including proinflammatory cytokines and chemokines, cyclooxygenase 2 and inducible nitric oxide synthase (Azcona-Olivera *et al.*, 1995; Zhou *et al.*, 1997; Ji *et al.*, 1998; Moon and Pestka, 2002; Pestka *et al.*, 2005). DON regulated interleukin (IL) 2, a cytokine considered to be a central growth and death factor for antigen-activated T-cells, and IL-8, a proinflammatory chemokine that affects host-defense induction of trafficking neutrophils across vascular walls (Pestka *et al.*, 2005).

The frequent occurrence of DON in cereals and potential chronic exposures to contaminated feed sources has focused attention on DON immunomodulation in animals, particularly the impact on susceptibility to infections and altered vaccination responses. Tryphonas *et al.* (1986) suggested a no-effect level in Swiss-Webster mice of 0.25–0.50 mg DON/kg diet/day based on *Listeria monocytogenes* challenge, serum  $\alpha_2$ - and  $\beta$ -globulins, and splenic lymphocyte proliferation to phytohemagglutinin P. Rotter *et al.* (1994) reported no significant differences in lymphocyte proliferation responses to phytohemagglutinin or pokeweed mitogens between treatments of pigs fed 0, 0.95, 1.78 and 2.85 mg DON/kg diet. The pigs responded well to primary immunization with sheep erythrocytes. However, pigs fed higher concentrations of 1.78 and 2.85 mg DON/kg diet, and paired control pigs developed the maximum titer 7 days later than controls. As the level of DON contamination increased, pigs showed increased albumin concentrations, decreased  $\alpha$ -globulin concentrations and increases in the albumin/globulin ratios. Similarly, Accensi *et al.* (2006) observed no significant changes in lymphocyte proliferation to mitogens or in cytokine production of IL-4 and interferon- $\gamma$  in young swine fed low doses of DON (0, 0.28, 0.56 and 0.84 mg/kg diet) for 4 weeks. Øvernes *et al.* (1997) reported a reduction in secondary antibody responses to tetanus toxoid injections in pigs fed 1.8 and 4.7 mg DON/kg feed for about 9 weeks, but no titer reductions to sheep erythrocytes, human serum albumin, paratuberculosis vaccine, or diphtheria toxoid. Peripheral blood lymphocyte responses to

phytohemagglutinin were increased in pigs fed 4.7 mg DON/kg feed for 9 weeks.

In a high dose exposure of poultry to DON, Harvey *et al.* (1991) reported a reduction in immune responses to Newcastle vaccination in Leghorn hens fed a ration of naturally DON-contaminated wheat at 18 mg DON/kg feed for 18 weeks. DON fed at increasing concentrations (5.8–13.6 mg DON/kg feed) to day-old turkey poults for 12 weeks reduced contact sensitivity responses to dinitrochlorobenzene (a CD8<sup>+</sup> T-lymphocyte cell-mediated response), but DON-fed turkeys generated primary and secondary antibody responses to sheep erythrocytes (a CD4<sup>+</sup> T-lymphocyte humoral response) similar to the control group, which was exposed to very low concentrations of DON in the feed (Chowdhury *et al.*, 2005a). In a similar experiment with day-old Pekin male ducklings fed a naturally contaminated ration with DON (6.3–18.6 mg DON/kg feed) for 6 weeks, the cell-mediated response to dinitrochlorobenzene was decreased with no effect on the antibody response to sheep erythrocytes (Chowdhury *et al.*, 2005b). Consumption of contaminated grains by both turkey poults and ducklings resulted in only minor impacts on serum chemistries and hematology, and no effect on body weight gains or feed consumption in the duckling study.

While T-2 toxin exposure in numerous laboratory animal models and other species causes immunosuppression, the specific functions of various cell type affected by the mycotoxin have not been definitively ascertained (Taylor *et al.*, 1989). T-2 toxin given by intraperitoneal administration to mice reduced thymus weights, inhibited antibody synthesis against sheep erythrocytes and prolonged skin graft rejection times (Rosenstein *et al.*, 1979). Rabbits given 0.5 mg T-2 toxin/kg body weight *per os* for 17 or 28 days had reduced antibody responses to aerosolized *Aspergillus fumigatus* challenge (Niyo *et al.*, 1988). Calves dosed orally with T-2 toxin at 0.6 mg/kg/day for 43 days had depressed mitogen responsiveness to phytohemagglutinin at 1, 8 and 29 days of toxin administration and decreased mitogen responsiveness to concanavalin A and pokeweed mitogens on day 29 of toxin administration (Buening *et al.*, 1982). Phagocytosis of 2-hydroxymethacrylate particles by neutrophils was not altered in pigs fed T-2 toxin for 21 days (Rafai *et al.*, 1995b). The authors reported humoral immunity, as measured by titers against horse globulin, a T-dependent antigen, was significantly decreased in pigs fed 14–21 days of T-2 toxin at 0.5, 1, 2 and 3 mg/kg feed. Additional evidence of impaired T-lymphocyte function was found in the reduction of mitogen-induced lymphocyte proliferation tests with phytohemagglutinin, concanavalin A and purified horse IgG at 2 and 3 mg T-2 toxin/kg feed. The authors remarked on minor histological changes including a decrease in the size of thymic lobules and lobular cortex of the thymus, a decrease in white

pulp of the spleen and regressive changes (interpreted as depletion of lymphocytes) of the germinal centers of lymph nodes of T-2 treated pigs.

Humoral immune responses to anaplasma vaccine were not different between T-2-treated and control calves, but calves dosed with 0.6 mg T-2 toxin/kg body weight had significantly lower concentrations of  $\alpha$ -,  $\gamma$ -,  $\beta_1$ - and  $\beta_2$ -serum protein fractions and elevated albumin/globulin ratio compared with control calves (Osweiler *et al.*, 1981). Serum IgA and IgM concentrations were significantly lower for the high dose T-2 toxin calves, as compared with controls. Pathological changes included decreases in body and thymus weights of T-2 toxin-treated calves. Histologically, thymii from calves dosed with 0.3 mg T-2/kg body weight exhibited cortical thinning with loss of mature lymphocytes and fibrous connective tissue separating individual thymic lobules. The high dose calves had almost complete replacement of normal thymic architecture with fibrous connective tissue and loss of the normal lobular pattern and mature lymphocytes. Calves (158–225 kg) dosed orally with T-2 toxin at 0.5 mg/kg body weight for 28 days had reduced serum IgG, IgM, albumin, globulin and complement proteins (Mann *et al.*, 1983). Lambs treated orally with a high dose of T-2 toxin (0.6 mg T-2 toxin/kg body weight) daily were leukopenic on day 7 and lymphopenic on days 7 and 14 (Friend *et al.*, 1983). On day 7 of this study, lambs showed decreased lymphocyte blastogenic responses to concanavalin A and lipopolysaccharide. Mitogen responses improved by day 21 of T-2 exposure. At necropsy, no differences in parasite loads were noted among T-2 treated lambs, suggesting that the dosage of T-2 toxin did not reduce immunity to a threshold allowing a fulminating coccidiosis to occur in treated lambs. Lambs showed no significant alteration of peripheral blood lymphocyte blastogenesis to phytohemagglutinin after 34 days of DAS treatment (5 mg/kg diet), as compared with control lambs (Harvey *et al.*, 1995).

## IgA

Increased serum IgA and potential IgA dysregulation and nephropathy have been reported in rodents after high (about 25 mg/kg) dietary DON exposure. Forsell *et al.* (1986) reported dose-dependent increases in serum IgA and decreases in serum IgM in female B6C3F1 mice fed 0.5, 2, 5, 10 and 25 mg DON/kg diet for 8 weeks. Further investigation with B6C3F1 mice showed that feeding 25 mg DON/kg diet for 4 weeks increased serum IgA, and continued DON feeding for 24 weeks increased serum IgA 17-fold over controls (Pestka *et al.*, 1989). Mice exhibited a shift from primarily monomeric IgA to polymeric IgA and increased *in vitro* splenocyte production of IgA from both spontaneous- and

lipopolysaccharide-stimulated cultures. The DON-associated increase in serum IgA resulted from stimulation of CD4<sup>+</sup> and IgA<sup>+</sup> lymphocytes in Peyer's patches and in the spleen (Pestka *et al.*, 1989; Dong *et al.*, 1991). DON fed mice showed marked mesangial IgA accumulation based on immunofluorescence staining of kidney tissue (Pestka *et al.*, 1989). In humans, deposition of IgA in the mesangium and capillary loops of the kidney can lead to a focal, non-progressive glomerulonephritis (Jones *et al.*, 1997).

Elevated serum IgA in animals exposed to oral DON does not appear to be consistent across species. Elevations in serum IgA concentrations were not observed in horses fed DON-contaminated feed (exposure of ~0.06–0.1 mg DON/kg body weight/day) (Johnson *et al.*, 1997; Raymond *et al.*, 2005). Bergsjø *et al.* (1992) did not detect any significant differences in serum IgA concentrations in pigs fed DON-contaminated diets from 0.5 to 4 mg/kg feed for 100 days. The authors stated that variation between individuals in the group and the low number of pigs per group ( $n = 8$ ) might not have revealed small differences. Weaned pigs fed low concentrations of DON (<0.84 mg DON/kg diet) for 4 weeks (Accensi *et al.*, 2006) or fed higher concentrations of DON (at 5.8 mg/kg) for 3 weeks (Swamy *et al.*, 2003) showed no consistent changes in serum IgA. In contrast, Goyarts *et al.* (2005) found that finishing pigs fed DON-contaminated wheat (6.5 mg DON/kg diet) *ad libitum* had a significant increase in serum IgA concentrations, with male pigs significantly higher than females. Significant differences in serum IgA concentrations were not observed in control and DON-fed pigs on the restricted feeding regimen (assured similar feed intake at the lowest level for all animals of both control and DON groups).

## APOPTOSIS

Apoptosis, a form of programmed cell death, has been proposed to explain the loss of lymphocytes and hematopoietic cells during trichothecene poisoning (Pestka *et al.*, 1994; Shinozuka *et al.*, 1998). Apoptosis normally serves as a self-regulating pathway in the immune system that reduces excessive inflammation and prevents autoimmune disease (Dong *et al.*, 2002); however, inappropriate activation by trichothecenes results in dysfunction. Activation of mitogen-activated protein kinases (MAPKs) by satratoxins and other trichothecenes correlated with and preceded apoptosis (Yang *et al.*, 2000). The authors used two myeloid models, RAW 264.7 murine macrophages and U937 human leukemic cells, in a cleavage assay and determined the potency of cytotoxicity to be satratoxin G, roridin A, verrucarins A > T-2

toxin, satratoxin F, H>nivalenol and vomitoxin. Using flow cytometry cell cycle analysis and phenotypic staining to study *in vitro* effects, Pestka *et al.* (1994) demonstrated that DON could either inhibit or enhance apoptosis in T-, B- and IgA<sup>+</sup> cells from murine spleen and Peyer's patch. Apoptosis was dependent on lymphocyte subset, source of tissue and glucocorticoid induction. Islam *et al.* (1998) demonstrated *in vivo* that T-2 toxin, given by intraperitoneal injection to mice, induced thymic atrophy, DNA fragmentation and histopathological changes in thymic tissue characteristic of apoptosis, including cell shrinkage and nuclear condensation. Macrophages appeared to be very sensitive to trichothecenes and could undergo trichothecene-stimulated apoptosis (Zhou *et al.*, 2005). The authors suggested that in addition to trichothecenes binding to the 60S ribosomal subunits and producing translational inhibition, another molecular pathway for trichothecene induction of apoptosis was through triggering a ribotoxic stress response activating MAPKs. MAPKs modulate cell physiological processes, such as cell growth, differentiation and apoptosis, and are important for signal transduction in immune responses (Dong *et al.*, 2002). For example, T-2 toxin given orally to pregnant rats on day 13 of gestation induced apoptosis in neuroepithelial cells of the fetal rat brain that coincided with expression of oxidative stress-related genes (such as heat shock protein 70 and heme oxygenase) and subsequent activation of MAPKs and caspase-2, which are important factors in cell signaling pathways for apoptosis (Sehata *et al.*, 2004).

## CELL MEMBRANE FUNCTION

At low concentrations (0.4pg/ml to 4ng/ml), T-2 toxin altered several cell membrane functions in L-6 myoblasts, including uptake of calcium, rubidium and glucose, incorporation of thymidine or leucine and tyrosine into DNA or protein, and residual cellular lactate dehydrogenase (Bunner and Morris, 1988). Changes occurred within 10 min of exposure, suggesting to the authors that T-2 toxin directly or indirectly affected glucose, nucleotide and amino acid transporters and calcium/potassium channel activities independent of protein synthesis inhibition.

## REPRODUCTIVE TOXICITY

No studies have indicated that DON is a reproductive toxin at concentrations typical of naturally contaminated feed. Friend *et al.* (1986) reported significant weight

reductions in young male and female pigs fed DON-contaminated feeds at 3.7 and 4.2mg DON/kg (~0.14 and 0.17mg/kg body weight/day) feed for 7 weeks; however, no significant histological changes were observed in the testis (seminiferous epithelium) or ovary (follicle). In contrast, several studies indicate that T-2 toxin can affect reproduction. Glávits *et al.* (1983) reported in a field case involving a large swine herd infertility in gilts and sows that coincided with the detection of T-2 and HT-2 toxins at 1–2mg/kg feed. Pathology revealed cystic degeneration of the ovaries and uterine atrophy. Huszenicza *et al.* (2000) evaluated low oral T-2 toxin exposures of 0, 0.3 or 0.9mg T-2 toxin/day and 9mg T-2 toxin/day for 3 weeks in ewes and heifers, respectively, on a rich, acidosis-inducing concentrate diet. The results suggested that, in ewes and heifers, rumen acidosis along with exposure to low oral T-2 toxin intake might delay maturation of the dominant ovarian follicle and ovulation and shorten corpora lutea lifespan (lower plasma progesterone concentrations); although the number of animals in the experiment was small. In an equine study of trotter mares, the horses were given 7mg purified T-2 toxin/day in oats (~0.01mg/kg body weight/day) for 32–40 days beginning on estrous cycle day 10 (Juhász *et al.*, 1997). Skin lesions were noted around the mouth of three horses; however, no adverse effects were noted on the length of the interovulatory interval, luteal and follicular phases of the estrous cycle, plasma progesterone profiles, or follicular kinetics. Uterine flushing of five mares in the trial yielded three embryos suggesting that T-2 toxin had no detrimental effect on ovarian activity, fertilization, or oviductal transport.

In pregnant rats, T-2 toxin crosses the placenta and is distributed to fetal tissues (Lafarge-Frayssinet *et al.*, 1990). Rousseaux and Schiefer (1987) reported that T-2 toxin caused fetal death at high doses (associated with maternal toxicity), with fetal toxicity primarily in the central nervous system and skeletal system. T-2 toxin administered intravenously at approximately one-third or one-sixth of the LD<sub>50</sub> (0.41 or 0.21mg/kg body weight) to sows at the beginning of the third trimester of pregnancy caused vomiting 90 min post-injection with the sows becoming listless and aborting their litters 48–80 h later (Weaver *et al.*, 1978b). In another study, three sows were fed purified T-2 toxin in a standard swine ration at 12mg/kg diet for up to 220 days, causing clinical signs of repeat breeding, small litters (four piglets) and small (0.37–0.65kg) piglets, which had no gross or histological lesions attributable to T-2 toxin (Weaver *et al.*, 1978a). The sows did not develop changes in the complete blood count, total protein, or alterations in the bone marrow. These studies used concentrations of T-2 higher than commonly found in feeds screened for visible molds.

Thirty 3-week-old Single Comb White Leghorn hens were fed either purified T-2 toxin or DAS at 2mg/kg diet for 24 days (Diaz *et al.*, 1994). Egg production dropped

about 7% in hens fed either T-2 or DAS on days 13–18 of the study, but recovered to near normal by day 24. Shlosberg *et al.* (1984) reported acute, severe reduction in egg production, feed refusal, depression and recumbency, cyanotic appearance of the comb and wattles, and some blue-green discoloration of droppings in a flock of 8-month-old laying hens. Following delivery of new feed, the mean daily egg production dropped from about 2400 to 150 eggs on day 5 of the new feed (94% drop in production). The feed was changed on day 6 and improvement in clinical signs and normal levels of egg production resumed about 12 days later. Mortality was not changed in the flock; however, necropsies of hens that died after 4 days of the new feed revealed atrophy of the ovaries and abnormally small oviducts. The authors hypothesized that the hens were exposed to a small quantity of highly contaminated trichothecene mycotoxin feed causing direct effects on the female reproductive tract and drop in egg production. The feed sample analyzed for mycotoxins contained T-2 toxin and HT-2 toxin at 3.5 and 0.7 mg/kg, respectively, which the authors thought might be unrepresentatively low. Brake *et al.* (1999) reported low levels of purified DAS ( $\leq 5$  mg DAS/kg diet) fed to broiler hens from 67 to 69 weeks of age increased fertility, with little effect on hatchability of fertile eggs. In contrast, DAS fed at 10 or 20 mg/kg diet to broiler males from 25 to 27 weeks of age decreased the hatchability of fertile eggs, which the authors attributed to direct toxic effects on the testes (and obviously on sperm). Reproductive toxicity associated with trichothecenes generally occurs when exposures reach maternally toxic concentrations, but natural trichothecene-contaminated diets can pose a serious risk to reproductive performance of livestock (Francis, 1989).

## GENOTOXICITY AND TERATOGENESIS

Trichothecenes are not mutagenic in bacterial assays, but *in vitro* exposure of Chinese hamster cells to DON at concentrations less than 1 mg/ml caused chromatid breaks (Hsia *et al.*, 1988). A 2-year chronic study in B6C3F1 mice fed diets containing 0, 1, 5, or 10 mg DON/kg diet revealed no consistent toxic effects, though mice fed higher concentrations of DON gained less weight than controls (Iverson *et al.*, 1995). DON did not consistently alter clinical chemistry or hematology parameters. The pathology revealed a reduction in development of pre-neoplastic and neoplastic lesions in the liver that may have resulted from reduced feed intake and reduction and body weights.

When considering the etiology of congenital malformation, the role of maternal toxicity must be evaluated.

Maternally toxic doses of trichothecenes can be embryo-toxic, with fetal death common in both birds and mammals, generally few frank congenital defects are observed in surviving fetuses, though anomalies in the nervous and skeletal systems have been noted (Francis, 1989). Khera *et al.* (1982) studied the embryotoxicity of DON in pregnant Swiss-Webster mice dosed orally with purified DON at concentrations of 0–15 mg DON/kg body weight for 4 days on gestational days 8 through 11. Mice dosed with 5–15 mg DON/kg body weight apparently resorbed the embryos, but no adverse effects were noticed in the dams given 2.5 mg DON/kg body weight. A number of skeletal malformations were observed in offspring of mice dosed at 1, 2.5 and 5 mg DON/kg body weight, but no adverse effects were reported in offspring of mice dosed at 0.5 mg DON/kg body weight.

DON fed to rabbits on days 0 through 30 of gestation at increasing levels of 0.3–2.0 mg/kg body weight/day caused 100% fetal resorption at 1.8 and 2.0 mg/kg/day and reduced body weight in rabbit does (Khera *et al.*, 1986). Dosages of 0.3 and 0.6 mg DON/kg body weight/day did not produce adverse effects in rabbit fetuses at term and were not maternotoxic. The authors concluded that DON did not produce a teratogenic response in rabbits. A two-generation study of female reproduction and teratology in CD-1 mice fed 0, 1.5 and 3 mg T-2 toxin/kg in a semi-synthetic diet did not reveal any significant differences in major or minor defects among treatment groups (Rousseaux *et al.*, 1986). No long-term reproductive or teratological effects were noted.

Minor malformations described as delayed ossification and un-withdrawn yolk sac were reported in chick embryos from hens fed rations containing DON at 2.5 and 3.1 mg DON/kg diet (Bergsjø *et al.*, 1993a).

## Clinical pathology

Trichothecenes, in particular T-2 toxin, have been associated with hemorrhagic syndromes; however, the effects are not consistently seen in experimental studies across species (Raisbeck *et al.*, 1991). Prolonged activated partial thromboplastin time and decreased hematocrit, leukocyte count and serum alkaline phosphatase activity were observed in rabbits injected with 0.5 mg T-2 toxin/kg body weight (Gentry and Cooper, 1981). In contrast, rabbits given 2 mg T-2 toxin/kg body weight orally displayed oral lesions, diarrhea and anorexia but no significant changes in hematological and biochemical parameters. Young mice and rats fed purified T-2 toxin at concentrations of 10–20 mg/kg for 2–4 weeks were relatively resistant to hematopoietic suppression, but developed atrophy of the thymus and thymus-dependent lymphoid tissue and lymphopenia (Hayes and Schiefer, 1982). Lambs dosed orally with 0.6 mg T-2 toxin/kg

body weight/day displayed significantly prolonged prothrombin times on day 7 (Friend *et al.*, 1983). Although lambs fed DAS (5 mg/kg diet) for 34 days showed significant decreases in several serum clinical chemistry values (cholinesterase and urea nitrogen), no changes were noted in prothrombin times, white blood count, or other hematological parameters (Harvey *et al.*, 1995). Growing pigs fed purified DAS at 0, 2, 4, 8 and 9 mg/kg diet for up to 9 weeks exhibited decreased feed consumption and weight gain (Weaver *et al.*, 1981). No changes in hemoglobin concentration, total red or white blood cell counts, and terminal bone marrow smears or in serum activities of aspartate or alanine aminotransaminases or lactate dehydrogenase were reported in the pigs. DAS given intravenously to pigs, cattle and dogs produced moderate-to-severe necrosis of bone marrow hematopoietic elements 8 h post-administration (Coppock *et al.*, 1989). The authors ranked species sensitivity to DAS destruction of bone marrow hematopoietic elements; most sensitive species were pigs and dogs and least sensitive species were cattle.

The clinical signs observed in laboratory animals treated with T-2 toxin and DAS are those of a radiomimetic poison with damage to the lymph nodes, thymus, spleen and bone marrow. A single dose of a potent trichothecene releases stored leukocytes into the blood stream but repeated administrations damage the hematopoietic system, depleting the leukocyte population. Lutsky *et al.* (1978) reported a marked depletion of leukocytes, similar to ATA, in cats dosed orally at 0.06–0.10 mg T-2 toxin/kg body weight for 24 days. T-2 toxin given intravenously to calves at 0.25 mg/kg body weight caused a marked decrease in leukocyte and neutrophil counts, with a small increase in serum aspartate aminotransferase and lactate dehydrogenase activities (Gentry *et al.*, 1984). In a study of lambs dosed orally at 0, 0.3 and 0.6 mg T-2 toxin/kg body weight for 21 days, examination of the myeloid:erythroid ratio of sternal bone marrow of the lambs revealed on day 12 that the ratio was significantly increased in 0.6 mg T-2 toxin/kg body weight lambs (Friend *et al.*, 1983). The bone marrows of these lambs appeared hypocellular with degenerating cells and pyknotic nuclei, and cells of the myeloid series predominated with few metarubricytes and more immature erythroid cells. None of the lambs were anemic and no hemorrhage was observed; nor were any significant differences found in hematological parameters. At the end of the 21-day study, the lambs were killed and necropsied. The highest dosed lambs had little body fat and pale bone marrow. In the 0.6 mg T-2 toxin/kg body weight lambs, the splenic white pulp was less cellular than low T-2 dosed and control lambs. The cortices of the mesenteric lymph nodes of T-2 treated lambs were thin, as compared with control lambs, and the lymphocyte population of the medullary and

paracortical areas and germinal centers of the mesenteric lymph nodes were markedly depleted.

Starter pigs fed T-2 toxin at 0.5, 1, 2 and 3 mg/kg diet (average daily intakes 0.38, 0.81, 1.24 and 1.42 mg T-2 toxin, respectively) for 3 weeks showed significant decreases in leukocyte counts, and pigs fed 2 and 3 mg T-2 toxin/kg had significant decreases in red blood cell counts, mean corpuscular volume and hemoglobin concentration on day 21 of the study (Rafai *et al.*, 1995b). The authors suggested that T-2 toxin affects hematopoiesis in young pigs at low concentrations (0.5 mg T-2 toxin/kg diet). In contrast, no effects on leukocyte counts or lymphoid tissue morphology were found in pigs fed 1, 2, 4, or 8 mg T-2 toxin/kg diet for 8 weeks (Weaver *et al.*, 1978a), nor were changes in hematocrit, hemoglobin concentration, or erythrocyte counts found in pigs fed 0.4, 0.8, 1.6, or 3.2 mg T-2 toxin/kg feed for 5 weeks (Friend *et al.*, 1992). However, microcytic, hypochromic anemia was reported in pigs fed higher concentrations of T-2 toxin at 10 mg/kg diet for 21–28 days (Harvey *et al.*, 1990).

Patterson *et al.* (1979) could not reproduce a feed-associated hemorrhagic disease syndrome in weaned calves or piglets by dosing orally with either purified T-2 or DAS (0.1 mg toxin/kg body weight for 36 days to pigs and 0.2 mg toxin/kg body weight for 11 days to calves) or with whole cultures of *F. tricinatum* containing T-2 toxin. While none of the pigs displayed clinical signs of toxicity, the calves dosed with 0.2 mg T-2 toxin/kg body weight did become weak, anorectic and died with evidence of a prolonged partial thromboplastin time.

Oral lesions were observed in most birds fed T-2 toxin diets, but no significant changes were observed in hemoglobin, hematocrit and erythrocyte counts in the Leghorn laying hens fed T-2 toxin (0, 0.5, 1, 2, 4 and 8 mg/kg diet) (Chi *et al.*, 1977). Serum activities of alkaline phosphatase and lactate dehydrogenase and uric acid concentrations were elevated in hens fed 8 mg T-2 toxin/kg diet, as compared with controls. In a high dose T-2 toxin study, plasma protein concentrations decreased by 15% after the first week and by 20% after the third week in hens fed T-2 toxin (20 mg/kg diet) for 21 days, as compared with control birds (Wyatt *et al.*, 1975). After receiving T-2 toxin for 3 weeks, treated hens had about 30% lower leukocyte counts than the control hens. No differences were observed in prothrombin times, erythrocyte counts, hematocrit, hemoglobin concentrations, or spleen and heart weight.

No consistent changes in serum enzyme activities have been associated with trichothecenes in animals. Low dietary concentrations of DON (<0.84 mg/kg diet) fed to weanling pigs for 4 weeks caused no significant changes in plasma enzyme activities, glucose, urea, bilirubin and hematological parameters during the study (Accensi *et al.*, 2006). Controlled studies of T-2 toxin fed to swine resulted in altered serum concentrations of

glucose and other parameters associated with decreased feed intake and changes in metabolism. Pigs fed 1, 2 and 3 mg T-2 toxin/kg feed for 3 weeks had significantly lower plasma glucose concentrations, as compared with control pigs and pigs dosed at 0.5 mg T-2 toxin/kg diet (Rafai *et al.*, 1995a). The decrease in plasma glucose was attributed to glucose malabsorption or to enhanced glucose degradation. Schiefer and Beasley (1989) suggested that in acute T-2 toxicosis in pigs, the ability of glucocorticoids to induce enzymes associated with hepatic gluconeogenesis and convert amino acids into glucose is reduced. Following an acute, intravenous toxic dose of DAS in pigs, Coppock *et al.* (1985b) reported the pigs developed hypoglycemia and depletion of liver glycogen stores. The authors attributed changes in blood glucose concentrations to cellular damage of endocrine and exocrine pancreas and adrenal gland by DAS.

## TOXICITY

Trichothecenes are toxic to all animal species that have been tested. The Type D trichothecenes, macrocyclics such as the verrucarins and roridin E, are the most acutely toxic trichothecenes, followed by the Type A compounds, DAS and T-2 toxin, Type B, nivalenol and the lowest acute toxicity is associated with the Type C trichothecene, crotoxin (Ueno, 1983). Neonatal animals are more susceptible to trichothecene adverse effects. T-2 toxin, the first trichothecene recognized as a naturally occurring mycotoxin, has been studied extensively because of its relative ease of production and its potential as a chemical warfare agent, but T-2 toxicosis is rare in North America. Oral LD<sub>50</sub> concentrations for T-2 toxin in laboratory animals did not demonstrate marked species differences in sensitivity, but agricultural species do vary in their sensitivity to the different trichothecene toxins. For example, based on toxicity, the species susceptibility to DON is ranked as pig (most sensitive), followed by rodent > dog > cat > poultry > ruminants (least sensitive) (Prelusky *et al.*, 1994).

Diarrhea is fairly common following trichothecene ingestion and altered intestinal absorption of compounds and impaired permeability is caused by morphological and functional damage to intestinal mucosa (Ueno, 1983). Epithelial irritation, particularly associated with the metabolites of *F. sporotrichioides*, is considered the underlying cause of oral and cutaneous inflammatory lesions noted in ATA, stachybotryotoxicosis and fusario-toxicosis of chickens. Dermal toxicity is common to many trichothecenes and the basis for screening toxicity of trichothecenes using dermal bioassays. The chemical structure of trichothecenes determines their dermal toxicity

and their cytotoxicity in cultured cell lines. Macrocyclic trichothecenes and T-2 toxin, HT-2 toxin and DAS (Type A trichothecenes) caused marked epithelial irritation, while nivalenol and DON (Type B trichothecenes) were weak dermal irritants in a guinea pig dermal bioassay (Ueno, 1984). Topical applications of purified T-2 toxin to various animal species caused similar morphological changes, including hyperemia, swelling, exudation and necrosis with subsequent formation of scabs that fall off (Pang *et al.*, 1989). Histological changes included vascular dilation, edema, congestion and infiltration of neutrophils, mononuclear and mast cells in the dermis with varying degrees of epidermal necrosis. The mechanism by which trichothecenes induced cutaneous damage is unknown. Ueno (1984) suggested that increased vascular permeability has a role in inducing cutaneous injury from trichothecene administration. Release of chemical mediators of inflammation could initiate changes leading to microvascular injury in dermal tissue.

In addition to the direct clinical effects on animals, Goyarts *et al.* (2005) noted in natural DON-contaminated wheat that DON significantly increased metabolizable energy, nitrogen retention digestibility of organic matter, crude protein, crude fat and crude fiber of the cereal grain. However, positive effects of a DON-contaminated diet did not compensate for adverse effects on feed intake or performance in weight gain in swine. Matthaus *et al.* (2004) reported marked changes in nutrient characteristics in *Fusarium*-contaminated wheat, with increased activities of non-starch polysaccharide hydrolyzing enzymes. This may represent a type of "pre-digestion effect" (Dänicke *et al.*, 2004b). Contrary to the positive findings of DON on feed digestibility, DiCostanzo *et al.* (1994) reviewed data reporting that moldy corn had decreased nutritional value, particularly lowered crude fat, along with energy and crude protein values.

## Swine

Clinical effects associated with DON ingestion in pigs include feed refusal, weight loss, poor performance, gastrointestinal irritation (such as diarrhea, colic and rectal prolapse), squamous hyperplasia of the gastric lining and possible immunomodulation. The DON dose affecting feed intake and rate of gain in swine studies varied with the age of the pig, source of DON (purified versus natural contamination) and exposure conditions (*ad libitum* versus restrictive feeding and duration of exposure). In a chronic study of the effects of DON on grower (starting weight of about 26 kg) and finisher swine, Goyarts *et al.* (2005) fed DON-contaminated wheat at about 6.5 mg DON/kg diet for 11 weeks in both *ad libitum* and restricted feeding regimens. Swine fed the DON-contaminated diet *ad libitum* showed

significant reductions in feed intake (15% less) and weight gain (13% less), but the feed-to-gain ratio was not affected. The lower growth performance in swine fed the DON-contaminated diet was attributed to lower voluntary feed intake because no differences were detected in weight gain for control and DON fed swine on the restricted feeding regimen. Similarly, Rotter *et al.* (1994) attributed depressed growth of growing pigs to reduced voluntary feed intake of DON-contaminated diets. Chavez and Rheaume (1986) observed that pigs fed DON-contaminated diets generally consume small amounts of feed continuously throughout the day. Pigs not only consumed less DON-contaminated feed when fed *ad libitum*, but also required more time to consume an equivalent amount of feed compared with a control group (Goyarts *et al.*, 2005).

Pollmann *et al.* (1985) fed DON-contaminated wheat at increasing concentrations of 0–2.8 mg DON/kg diet to starter pigs (7.7–8.3 kg) and concentrations of 0–4.2 mg DON/kg diet to growing/finishing pigs (60.5 kg). In the starter pigs, feed intake declined when the DON concentration was greater than 1 mg DON/kg diet, which was more noticeable during the first week of exposure. No clinical signs, including vomiting, were observed nor were lesions observed in examined organs. Vomiting was the only adverse clinical sign observed in growers fed a diet of DON at 2.8 mg/kg for 42 days. Feed refusal was observed in growers fed DON at 2.2, 2.8 and 4.2 mg/kg diet. Pigs (25 kg) fed naturally contaminated oats at 2 and 4 mg DON/kg feed experienced a dose-related depression of weight gain in the first 8 weeks of the trial (Bergsjö *et al.*, 1992). The authors determined a no-effect level based on feed intake, weight gain and feed efficiency in growing pigs (25 kg initial weight) of 0.5 and 1.0 mg DON/kg feed. In contrast, Friend *et al.* (1982) fed pigs a diet of 0.7 mg DON/kg feed and saw an immediate reduction in feed consumption, which gradually recovered to nearly normal feed intake. Significant reductions in feed intake and weight gain occurred in pigs fed corn silage naturally contaminated with 1.3 mg DON/kg feed (Young *et al.*, 1983). However, Chavez (1984) reported no reduction in weight gain or feed consumption in piglets (initial weight 7 kg) fed naturally contaminated wheat at DON concentration <2.5 mg DON/kg diet. Williams *et al.* (1988) observed that naturally DON-contaminated wheat fed to growing pigs inhibited voluntary feed intake linearly with dietary concentrations of DON up to 16 mg DON/kg feed. They also noted vomiting and signs of abdominal distress at dose rates from 0.055 to 0.097 mg DON/kg body weight. These values are close to the minimum oral emetic dose of young swine (9–10 kg) at 0.1 mg DON/kg body weight (Forsyth *et al.*, 1977).

Using naturally contaminated oats at 0, 0.7, 1.7 and 3.5 mg DON/kg feed, Bergsjö *et al.* (1993b) examined

clinical effects in growing pigs (~21 kg) fed *ad libitum* for 95 days. The daily weight gain of pigs fed 3.5 mg DON/kg feed was 82% of the control pigs over the whole experiment. Significant decreases in body weight gain, slaughter weight and feed utilization were observed in pigs fed a diet of 3.5 mg DON/kg. The authors concluded that 1.7 mg DON/kg feed, in an otherwise adequate diet which contained only minor traces of other mycotoxins, depressed daily feed intake. Dänicke *et al.* (2004b) reported no significant effects on the performance of finishing pigs when fed DON at concentrations of 0.2, 0.7, 1.2, 2.5 and 3.7 mg/kg diet.

Pigs fed higher DON-contaminated diets (>3.6 mg/kg diet) have significant weight reductions (Friend *et al.*, 1986) and reduced feed consumption (Forsyth *et al.*, 1977), as compared with controls. Significant reductions in the feed-to-gain ratio in swine were only observed at higher DON and zearalenone concentrations, 9.1 and 11.0 mg DON/kg feed and 1.2 and 2.0 mg zearalenone/kg feed, and not at lower DON concentrations (<0.5, 2.6, 5.0 and 8.3 mg DON/kg feed) when naturally contaminated wheat was fed to growing pigs for 14 weeks (Williams *et al.*, 1988). In contrast, Swamy *et al.* (2002) reported a significant decrease of about 30% in feed intake and growth performance, but not in the feed-to-gain ratio, in growing pigs fed naturally contaminated DON at 5.6 mg/kg *ad libitum* for 21 days. In another study with swine, Swamy *et al.* (2003) reported an increase in feed efficiency in pigs fed DON and suggested that pigs adjusted to the reduction in feed intake by improving feed utilization.

Based on reviews of the literature, Dänicke *et al.* (2001) suggested dietary DON concentrations in livestock feeds that ensured no adverse effects on animal health or performance if all production conditions are optimal (Table 94.2). These suggested concentrations of DON in livestock feed are similar to the U.S. Food and Drug Administration (FDA) advisory guidelines for DON in livestock feed. Eriksen and Pettersson (2004) proposed lower guidelines for DON in livestock feed based on risk assessment of data from toxic effects (Table 94.2).

Sex-related differences have been reported in pigs fed DON-contaminated feed, but the findings are equivocal. Côté *et al.* (1985) reported lower weight gains in castrated male pigs, as compared to female pigs, in the first 4 weeks of feeding DON-contaminated feeds at 3.1 and 5.8 mg DON/kg. Conversely, Goyarts *et al.* (2005) reported that *ad libitum* fed castrated male pigs had significantly higher feed intake and weight gains, as compared with female pigs, during the 11-week exposure to DON-contaminated feed (about 6 mg DON/kg diet) in grower swine; whereas Bergsjö *et al.* (1992) and Williams *et al.* (1988) reported no interactions between sex and weight gains at any dietary DON concentrations.

Rotter *et al.* (1994) concluded that pigs show a physiological adaptation response to DON-contaminated

TABLE 94.2 Recommended values for concentrations of DON in the final ration

Animal species/type	DON <sup>a</sup>	DON <sup>b</sup>	DON <sup>c</sup>
Pigs	1	1	0.3

Dairy cow/pregnant cattle	5	2 <sup>d</sup>	–
Beef cattle	5	5	–
Poultry (laying hens, broilers)	5	5	2.5

<sup>a</sup>Values for critical concentrations of DON in diets of pigs, ruminants, gallinaceous poultry (mg/kg, 88% dry matter) (Dänicke *et al.*, 2001).

<sup>b</sup>Values are in mg/kg for the final ration (FDA advisory guidelines).

<sup>c</sup>Risk assessment guidelines (Eriksen and Pettersson, 2004).

<sup>d</sup>Under the “intended use” dairy cattle would be in the “all other animal species.”

diets ranging from 0.95 to 2.85 mg DON/kg. Even at the lowest dose, 0.95 mg DON/kg diet (0.11 mg DON/kg body weight/day), pigs showed a reduction in feed consumption over the first 2 days of the experiment but were able to adapt by the end of 28 days. Overall gains of pigs on DON-contaminated diets were no different than pair-fed controls. This result is consistent with those of Friend *et al.* (1986) and Bergsjö *et al.* (1992) who reported that swine could adapt to dietary DON contamination. Morphological changes in pigs fed the highest DON-contaminated feed were a reduction in thyroid size and a higher degree of folding and thickening of the esophageal region of the stomach (Rotter *et al.*, 1994). In a similar study, Øvernes *et al.* (1997) fed growing pigs (25 kg) naturally DON-contaminated oats at 0.6, 1.8 and 4.7 mg DON/kg feed, both restricted and *ad libitum* for about 100 days. No changes in feed intakes were detected in pigs fed DON-contaminated rations *ad libitum*, but feed intakes were significantly reduced in pigs fed restricted levels of 1.8 and 4.7 mg DON/kg feed. Post-mortem examination of the pigs revealed no differences in the stomach mucosal appearance between the different DON-treatment groups. The authors hypothesized that when DON-contaminated feed is freely available, pigs would reject less feed than when offered large quantities for a limited period. Results of this study in growing pigs indicated that using naturally contaminated oats at levels up to 4.7 mg DON/kg feed might cause slight immunosuppression, but did not represent a serious health problem.

In a study at low T-2 toxin concentrations, Rafai *et al.* (1995a) fed 7-week-old pigs (~9 kg) a diet with 0.5, 1, 2, 3, 4, 5, 10 and 15 mg/kg of purified T-2 toxin for 3 weeks, with average daily intakes by experimental pigs of T-2 toxin between 0.029 and 0.23 mg T-2 toxin/kg body weight/day. No vomiting or diarrhea was observed in any group, but pigs fed 10 and 15 mg T-2 toxin/kg diet became somnolent and huddled as if chilled. Feed consumption was decreased (not significantly) and serum aspartate aminotransferase activity was significantly increased in pigs by the lowest T-2 toxin concentration.

Pigs fed 3.0 mg T-2 toxin/kg feed had significant decreases in weight gain, but not feed conversion, for 3 weeks. After 9–14 days on 4, 5, 10, or 15 mg T-2 toxin/kg diet, pigs began to show signs of dermatitis and crusting of the skin and the snout, with inflammation becoming more severe with time. Histological examination of affected skin revealed hyperkeratosis, parakeratosis, acanthosis and superficial to deep erosions into the sub-epithelial layer in all groups exposed to T-2 toxin. Pigs at the higher T-2 toxin dosages had involvement of the skin and mucous membranes of the prepuce, tongue and renal pelvis (urothelium). The authors of this study concluded that the no-effect level of T-2 toxin for performance was probably less than 0.5 mg T-2 toxin/kg diet. In contrast, growing crossbred pigs (18 kg) fed 8.0 mg T-2 toxin/kg diet for 30 days showed reduced feed consumption and weight gain but no changes in clinical appearance, as compared with controls (Harvey *et al.*, 1994).

Toxicoses from macrocyclic trichothecenes have occurred in pigs housed on straw litter infected with *Stachybotrys* (Dankó, 1975). The clinical signs included irritation, necrosis and hemorrhages, and are similar to those described for cattle with stachybotryotoxicosis (see Ruminants).

## Horses

Few experimental trichothecene studies using the equine species have been published. Five adult horses (~444 kg) were fed DON-contaminated barley (average range of 36–44 mg DON/kg grain) and consumed approximately 1.27 kg barley/horse/day (44–55 mg DON/horse/day or about 0.099–0.124 mg DON/kg body weight/day) for 40 days (Johnson *et al.*, 1997). The horses had access to free-choice pasture grass. No signs of feed refusal were observed in the horses, and though not weighed, all animals appeared to gain weight and improve body condition according to the authors. No remarkable changes were detected in any hematological or serum biochemical parameters. Both serum IgG and IgA decreased in a linear manner through the trial. The authors attributed decreases in serum total protein, globulin and albumin to changes in the hydration status of the animals and voluntary water consumption during the study. The authors also suggested that gastric microflora detoxified DON prior to absorption. Raymond *et al.* (2003) fed mature, non-exercising mares a blend of naturally contaminated wheat and corn (15.0 mg DON and 0.8 mg 15-ADON/kg diet), with and without 0.2% glucomannan polymer (an adsorbent), for 21 days. Control mares consumed approximately 0.004 mg DON/kg body weight/day, the mycotoxin group 0.029 mg DON/kg body weight/day, and the mycotoxin plus adsorbent group 0.051–0.058 mg DON/kg body weight/day.

Feed intake was significantly reduced in the mycotoxin-fed groups, as compared with the control group. The authors reported that  $\gamma$ -glutamyltransferase activities were increased in mares fed the mycotoxin diet on days 7 and 14, but not on day 21 of the trial. Unfortunately, no serum chemistry analyses were undertaken prior to the experiment on day 0 to establish a common baseline for the horses. Additional serum chemistry parameters and hematology were not affected by the diets. In a subsequent study of exercised horses, mares were fed one of three treatments, a control diet, a mycotoxin diet (11.2mg DON/kg, 0.7mg 15-acetyldeoxynivalenol/kg diet) and a mycotoxin diet (14.15mg DON/kg feed, 0.7mg 15-acetyldeoxynivalenol/kg diet) with 0.2% glucomannan polymer for 21 days (Raymond *et al.*, 2005). Feed intake and weight gains were depressed in horses fed the mycotoxin-contaminated diets, as compared with control mares. No effect of diet was seen on hematology or serum chemistries, which included  $\gamma$ -glutamyltransferase activities, nor were any differences noted in athletic ability measured by time-to-fatigue treadmill step tests. Feeding 2% glucomannan polymer as an adsorbent did not prevent a depression in feed consumption in this study.

Lethal trichothecene mycotoxicoses from *Stachybotrys* have been recognized in field cases involving horses in the former USSR, particularly the Ukraine since the late 1930s (reviewed by Forgacs, 1972; Dankó, 1975; Hintikka, 1978). *Stachybotryotoxicosis* typically occurred during indoor feeding of horses with *S. alternans*-contaminated straw or hay. The horse is very sensitive to *Stachybotrys* toxins, with 1mg of pure *Stachybotrys* toxin considered a lethal dose. Soviet authors described two forms of the disease, "typical" or prolonged disease and "atypical" or acute disease, based on the dose and duration of toxin ingested. The typical form, which is further subdivided into three stages, was more common, and occurred after continuous consumption of sub-lethal quantities of moldy vegetation. The first stage occurred 2 or 3 days following consumption of moldy feed. Irritation, and later necrosis, occurred wherever the toxin(s) contacted tissue, especially the oral, nasal and ocular mucous membranes. Clinical signs of conjunctivitis, lacrimation and profuse salivation, along with spontaneous nosebleeds, hemorrhage of mucous membranes, maxillary lymph node swelling and dysphagia, also occurred. The first stage lasted 2–3 days or could persist for a month. The second stage lasted 15–50 days and was characterized primarily by clinicopathological changes; clinical signs were non-specific. An initial leukocytosis was followed by leukopenia and thrombocytopenia and, in some cases, blood failed to clot. During the third stage, thrombocytopenia and leukopenia worsened, horses became febrile (40–41.5°C), anorexic and prone to colic. Weight loss, recumbency and septicemia were

common. This stage lasted 1–6 days and usually ended in death.

The atypical form of *stachybotryotoxicosis* was peracute (1–3 days) and associated with high concentrations of *Stachybotrys* toxins in the feed. This form was characterized by nervous system irritation or depression, cardiac arrhythmias, pulmonary edema and hemorrhages of serosal and mucosal membranes and muscular tissue, muscle necrosis and oral ulcers. Post-mortem findings were characterized by hemorrhage and necrosis of tissues (Hintikka, 1978). Hemorrhages occurred on serous and mucous membranes and in the spleen, liver, lungs, brain, spinal cord, lymph nodes and most notably in muscle tissue. Clearly circumscribed necrotic foci, yellow to brown-gray in color, were seen on oral mucosa, with the entire digestive tract generally appearing hemorrhagic and necrotic.

In addition to toxicoses involving macrocyclic trichothecenes, historical accounts of equine deaths were reported in horses provided moldy feed in northern Japan. Horses developed clinical signs and died after consuming moldy bean hulls, which were commonly used as fodder and bedding especially in the winter and spring (Ishii *et al.*, 1971). The clinical signs of affected horses were central nervous system disturbances including convulsions and cyclic movements, depressed respiration, icterus and bradycardia. Several trichothecenes, including T-2 toxin, DAS and neosolaniol, were associated with the clinical syndrome, but cause-effect was not established.

## Dogs and cats

Trichothecenes are fairly heat stable compounds and following incorporation into pet food diets, DON remains stable during extrusion and drying (Hughes *et al.*, 1999). The authors reported that DON concentrations (from a naturally contaminated wheat source) greater than  $4.5 \pm 1.7$  or  $7.7 \pm 1.1$ mg DON/kg diet reduced feed intake in dogs and cats, respectively. When DON concentrations reached 8–10mg/kg feed, clinical signs of vomiting and reduced feed intake and body weight occurred in dogs and cats. Dogs that had been previously exposed to DON-contaminated feed preferentially selected uncontaminated dog food; dogs with no previous experience with DON-contaminated dog food consumed equal quantities of DON-contaminated and uncontaminated food.

## Ruminants

During wet growing seasons, DON contamination of cereal grains can be sufficiently high to make grains unsuitable for human food or swine feed. Anderson *et al.* (1996) evaluated the use of naturally scab-infected barley

with elevated DON concentrations (about 35mg/kg) in beef growing/finishing and pregnant heifer rations. The authors fed increasing levels of DON to crossbred steers for 84 days, at 0.9, 3.7, 6.4 and 9.2mg DON/kg diet, during the growing period and for 100 days during the finishing period at 1.1, 5.0, 8.8 and 12.6mg DON/kg diet. No significant differences were found in beef performance including feed intake, feed efficiency, rate of gain, or carcass quality. The authors concluded that DON-contaminated feed could be provided up to 9mg/kg diet during bovine growth and up to 12mg/kg diet during finishing without adverse effects. In a separate study, the authors fed pregnant yearling heifers DON-contaminated barley, 36.8mg/kg at 3.6 or 5.4kg/head/day (about 10.2 or 13mg DON/kg diet, respectively) from mid-gestation through the first 45 days of lactation. No significant changes were noted in feed intake, heifer weight gain, or calf body weights. Calf weight gains were higher for calves nursing heifers fed the DON-contaminated barley during calving and lactation. In a 3-year follow-up of the experimental heifers retained in the herd, all 14 control heifers had been culled for non-pregnancy after 3 years, whereas only eight vomitoxin-fed heifers had been culled for non-pregnancy suggesting feeding DON had no impact on subsequent reproduction (Anderson, 2006). The authors concluded that barley unsuitable for human food could be utilized in beef rations and fed safely at 10–12mg DON/kg diet to pregnant cows.

Trenholm *et al.* (1985) reported an initial slight decrease in feed intake of dry cows fed a wheat–oats-contaminated diet with 6.4mg DON/kg concentrate. The cows returned to normal feed consumption by the end of the sixth week of exposure, with no differences reported in body weight. The only trichothecene mycotoxin apparently tested in the contaminated wheat was DON, so the presence of additional mycotoxins could not be discounted. Charmley *et al.* (1993) fed primiparous Holstein cows DON-contaminated wheat and corn at increasing concentrations of 0.07, 4.95 and 12.09mg DON/kg of dry matter concentrate (daily DON intake of 0.59, 42 and 104mg, respectively) for 10 weeks in a lactation study. The total mixed ration was formulated to support 25kg milk/day and a milk fat level of 3.8%. No changes were observed in total milk output or intake of concentrate or forage. Cows fed 4.9mg DON/kg concentrate had the lowest milk fat content, which the authors did not attribute to DON intake. Similar results were reported by Ingalls (1996) who fed high-producing dairy cows DON-contaminated barley diets up to 14.6mg DON/kg concentrate dry matter (about 8.5ppm in diet, 0.31mg DON/kg body weight) for 3 weeks and found no significant changes in milk production or feed intake between controls and treated cows.

Oral T-2 toxin dosing studies in calves resulted in more severe clinical signs. Pier *et al.* (1976) dosed young Jersey

calves, 35–78kg, with oral gelatin capsules for 30 days at 0.08, 0.16, 0.32 and 0.64mg T-2 toxin/kg body weight (one calf per dose level). The authors estimated that the lower T-2 doses were realistic, as a 50kg calf would have to eat 2kg of corn containing 2mg T-2 toxin/kg to mimic the lowest dose of 0.08mg T-2 toxin/kg feed. All T-2 toxin dosages caused mild enteritis and loose feces in calves. At the higher dosage levels of 0.32 and 0.64mg/kg, bloody feces were apparent, and the calves became anorexic, dehydrated and lost body weight. The calves had elevated serum aspartate aminotransferase activities and prolonged prothrombin times. The high dose calf died on day 20 of the trial. Post-mortem lesions in the highest T-2 toxin dosed calves were ruminal ulcers and abomasitis, while the lower dosed calves had mild enteritis. Abomasal ulcers were described in the calf dosed at 0.16mg T-2 toxin/kg body weight.

Oswailer *et al.* (1981) dosed beef calves (85–200kg) orally with 0.1, 0.3 and 0.6mg purified T-2 toxin/kg body weight/day for 6 weeks, and found that 0.3mg/kg (mimic ~10mg T-2/kg diet) decreased feed consumption with no outwards signs of clinical disease. A clinically effective dose of 0.6mg/kg (mimic ~20mg T-2/kg diet) produced marked differences in body weight gain, as compared with control animals. All calves in the high dose group (0.6mg T-2 toxin/kg body weight) refused to eat the concentrate portion of their diet starting on the second day of the trial and consumed a limited portion of diet provided throughout the entire 6 weeks of T-2 toxin exposure. The high T-2 toxin dosed calves had intermittent diarrhea, soft tan to dark, semi-fluid feces, and became thin with rough hair coats. Calves dosed with 0.3mg/kg generally showed a lack of interest in eating the total amount of feed provided. No coagulopathies were observed in the T-2 toxin-treated calves. The authors questioned whether cattle would consume T-2-toxin-contaminated feed in the range of 10–20mg/kg for a sufficient time to produce clinical signs.

Weaver *et al.* (1977) intubated daily a pregnant Holstein cow (third trimester of gestation) with 182mg of purified T-2 toxin for 15 days. On the fourth day of dosing, the cow delivered a bull calf that was also intubated with T-2 toxin at 0.6mg/kg body weight for 7 consecutive days, and then on alternate days for a total of 16 days of treatment. The calf became severely depressed, with hind-quarter ataxia, knuckling of rear feet and anorexia. Complete blood counts, serum total protein and several liver enzymes were within the normal range for both cow and calf throughout the treatment. Gross and microscopic lesions were seen only in the cow and included congestion of the small intestine mucosa and a ruminal ulcer. Histological changes were congestion of the lamina propria blood vessels of the omasum, rumen, jejunum and ileum, and edema of the submucosa, muscular layers and serosa of the cecum and colon. The bone marrows of both animals were normal.

In a field case, anorexia, periodic elevated temperatures, abortions in mid-gestation and a 20% death loss were associated with feeding moldy, high moisture corn to lactating Holstein dairy cows during a 5-month period in late winter (Hsu *et al.*, 1972). Post-mortem lesions of extensive hemorrhages on serosal surface of internal viscera were reported. Among the fungi cultured from the corn were *F. tricinctum*, *F. roseum* and *F. moniliforme* and various *Penicillium* spp. A sample of feed taken in late May contained 2mg T-2 toxin/kg, which the authors estimated as a low concentration because of losses during analysis. The authors assumed other toxins were also present and contributed to clinical toxicity, but were not analyzed.

Stachybotryotoxicosis in cattle occurred mainly as large outbreaks in young animals (Dankó, 1975; Hintikka, 1978). Clinical signs included lethargy, inappetance, bloody diarrhea and epistaxis. In chronic toxicosis, changes in the hematology appeared to be the initial toxic event. After a leukocytosis of short duration, leukopenia and thrombocytopenia developed. Clinical signs appeared gradually with hematological changes and were similar to those seen in the "typical" form of horses. Cows could abort during the second half of gestation with hemorrhagic lesions apparent in the fetus and fetal membranes. Mortality could be as high as 90–100% in affected cattle. Toxicosis in sheep was similar to cattle. Additionally, sheep exhibited hyperthermia and progressive anemia with marked impairment of the lymphoid system (Schneider *et al.*, 1979) and wool loss with skin hemorrhaging (Hajtós *et al.*, 1983).

Dankó (1975) commented that animals preferred to eat *Stachybotrys*-contaminated straw rather than good-quality hay because of a flavor produced by the mold in the straw, but this observation was not supported in other literature. *Stachybotrys* toxins appeared more toxic in an acidic pH (Dankó, 1975). Therefore, ruminants were considered relatively resistant because of salivation and the higher pH environment of the rumen. Feeding a high carbohydrate diet, which lowers rumen pH, could enhance the toxic effects of *Stachybotrys*. Treatment of animals affected with *Stachybotrys* mycotoxins was generally unrewarding due to severe damage to the lymphoid system. Immunosuppression of both humoral and cellular systems was an important clinical effect from toxins of *Stachybotrys*.

Ovine responses to trichothecene exposure are similar to cattle. Seven crossbred lambs (mean weight of 17.9kg) between 3 and 6 months of age consumed a DON-contaminated wheat ration (15.6mg DON/kg) for 28 days with no significant changes in behavior, clinical signs, feed consumption, hematology, or serum clinical chemistries compared to a control group (Harvey *et al.*, 1986). In an experiment using purified DAS, crossbred ewe lambs (average 38kg) were fed *ad libitum* 5.0mg DAS/kg diet for 34 days (Harvey *et al.*, 1995). The lambs

developed diarrhea during the first week of the study, with a significant decrease in feed intake and weight gains by the end of the exposure period. No dermal or oral lesions were observed in DAS treated lambs, nor were gross lesions observed at necropsy of the lambs. The authors fed lambs a diet contaminated with both aflatoxin at 2.5mg/kg feed and DAS at 5.0mg/kg feed and noted a synergistic response in the marked reductions in feed intake and weight gains.

Friend *et al.* (1983) dosed 6–8-week-old male lambs with purified T-2 toxin in gelatin capsules at 0, 0.3 and 0.6mg/kg body weight for 21 days. All lambs had bouts of diarrhea, but several lambs dosed with 0.6mg T-2 toxin/kg body weight had prolonged periods of diarrhea, appeared unthrifty and started fleece-pulling at the end of 3 weeks of treatment. At necropsy, T-2 treated lambs appeared to have smaller and less active thymic tissue, as compared to the control group, and lesions of focal rumenitis with parakeratosis and infiltration by polymorphonuclear cells.

## Poultry

Poultry are not as sensitive to the effects of trichothecenes as swine, but are probably more sensitive than ruminants. Day-old chickens fed DON-contaminated feed at 9 or 18mg DON/kg diet for 7 weeks had decreased relative and absolute liver weights, but showed no changes in feed intake (Kubena *et al.*, 1985). Chickens fed high DON concentrations in rations (>15mg DON/kg) exhibited feed refusal and weight loss (Kubena *et al.*, 1987; Kubena and Harvey, 1988). DON contamination of rations up to concentrations of 18mg/kg feed provided to laying hens did not affect hatchability of eggs (Lun *et al.*, 1986; Bergsjö *et al.*, 1993b). Bergsjö *et al.* (1993a) fed a naturally contaminated oat diet to White Leghorn laying hens at concentrations of 0.12–4.9mg DON/kg feed for 70 days. Low concentrations of 3-ADON (0–0.63mg/kg) and zearalenone (trace to 0.55mg/kg) were detected in the diets. No significant differences in feed intake, weight gain, egg production, body weight at hatching and viability of the chicks were found between treatment groups.

Purified T-2 toxin added to a commercial laying hen ration at 20mg T-2 toxin/kg diet for 3 weeks caused raised oral lesions, yellowish-white to gray in color, during the first week of T-2 toxin administration on the sublingual and palatine areas, and then on the tongue and corners of the mouth (Wyatt *et al.*, 1975). Feed consumption by hens decreased by about 25% compared with control diet intake during the first week of T-2 toxin exposure, with the treated laying hens showing a significant weight loss after 1 week of the trial. Egg production of the T-2 toxin-treated hens declined by 20% in the second and the third week of exposure; the eggshell

thickness was significantly decreased after 3 weeks of T-2 toxin exposure.

In a study of 27-week-old laying hens fed *ad libitum* diets containing purified T-2 toxin at 0 (control), 0.5, 1, 2, 4 and 8 mg/kg feed for 8 weeks, the highest dosage caused a significant decrease in feed consumption, egg production and shell thickness, as compared with hens fed the control diet (Chi *et al.*, 1977). Fertility and progeny performance were not altered by feeding T-2 toxin, but hatchability of fertile eggs was significantly decreased in hens fed 2 and 8 mg/kg, as compared with hens fed the control diet. Oral lesions, circumscribed and proliferative plaques, were noticed after the second week in hens fed 4 and 8 mg/kg and after the third week in hens fed 0.5 mg/kg. Severity and incidence of lesions were proportional to dietary T-2 toxin concentration. No significant histopathological changes were observed in the liver, heart, kidney, brain, or bone marrow, but necrotic lesions were observed in the gizzard and crop. Diaz *et al.* (1994) fed hens both T-2 toxin and DAS, each at 2 mg/kg feed in the diet. Hens exhibited oral lesions, a significant decrease in feed consumption (decline of about 12%) and egg production (decline of 15%), as compared with controls.

Generally, concentrations of T-2 and HT-2 toxin greater than 1 mg/kg are not common in grains except in wet years in the upper Midwest of the United States; often, HT-2 toxin is found at higher concentrations than T-2 toxin. Rafai *et al.* (2000) evaluated such relatively low levels (0, 0.2, 0.4, 0.6, 0.8, 1, 2, 3 and 4 mg T-2 toxin/kg diet) of exposure for 7 weeks in day-old Pekin ducklings. Within 2 days after starting the experiment, most ducks fed T-2 toxin developed oral lesions. The dermatotoxic lesions gradually disappeared in the ducks fed less than 3 mg T-2 toxin/kg feed. Ducks fed 3 and 4 mg T-2 toxin/kg feed refused the diet in the first week and from weeks 3 to 7. The feed intakes of ducks fed 0.6–4 mg T-2 toxin/kg feed were generally less than that of the control group. No significant dose-related changes were noted in serum chemistry and hematology. Similar dose-related oral lesions were reported in day-old Muscovy ducks within 16 h of exposure to T-2 toxin and DAS at 0.25, 0.5, or 1 mg/kg feed (Shlosberg *et al.*, 1986). Decreased body weights, thymus, spleen and bursa of Fabricius weights were noted in 6-week-old mallards fed 2 mg T-2 toxin/kg feed for 9 days (Neiger *et al.*, 1994). Microscopic lesions were observed in lymphoid organs and included a moderate decrease in thymic cortical lymphocytes.

### New trichothecene concern

In North America during the mid-1990s, interest focused on *Stachybotrys chartarum* or black mold found in damp buildings as a possible cause of idiopathic

pulmonary hemorrhage in infants (Dearborn *et al.*, 1999). Epidemiological investigations of pulmonary hemorrhage in infants found an association with airborne fungi including *Stachybotrys*. *S. chartarum* produces a variety of secondary fungal metabolites, including simple trichothecenes (trichodermol, trichodermin and verrucarol), macrocyclic trichothecenes (verrucarins B and J; roridins D, E, isoE and L-2; the satratoxins F, isoF, G, isoG, H and isoH) and spirocyclic drimanes that are recognized immunosuppressants (Jarvis, 2003). *S. chartarum* appears to divide into two chemotypes, one produces the macrocyclic trichothecenes and the other produces a class of diterpenoids, the atranones that to date have not been shown to possess significant biological activity (Jarvis, 2003). The characterization of natural products from *Stachybotrys* species and any relationship to clinical disease remains a challenge.

## TREATMENT

The first action is to stop exposure to moldy feed. If using screenings or poor-quality grain, cleaning the grain by removing broken, shriveled kernels and washing the grain can lower mycotoxin contamination. Generally, clinical signs of feed refusal will disappear within 7 days after removal of the contaminated feed. Animals return to production within 14 days.

No specific therapies for trichothecene mycotoxicoses are available. Some trichothecenes undergo enterohepatic recirculation and are excreted in the feces. The use of activated charcoal, which binds toxins within the gastrointestinal tract and prevents toxin reabsorption, plus magnesium sulfate, was beneficial as part of a therapeutic protocol for treatment of acute, T-2 toxicosis in swine (Poppenga *et al.*, 1987). Metoclopramide, given intravenously immediately prior to and following T-2 toxin administration, was only partially successful as an anti-emetic (Poppenga *et al.*, 1987). A number of binders, such as clay and zeolitic products, have been suggested for use with trichothecene-contaminated feed to prevent absorption by animals. Their efficacy has not been proven and marked species variations exist. The U.S. Food and Drug Administration has not approved any ingredient for use as a trichothecene mycotoxin binder.

## CONCLUSIONS

Trichothecene mycotoxins occur worldwide; however, both total concentrations and the particular mix of toxins present vary dramatically with environmental

conditions. Proper agricultural practices such as avoiding late harvests, removing overwintered stubble from fields, and avoiding a corn/wheat rotation that favors *Fusarium* growth in residue can reduce trichothecene contamination of grains. Storage of grains at less than 13–14% moisture (less than 0.70  $a_w$ ) and hay/straw at less than 20% moisture are important in preventing trichothecenes production. Once produced, trichothecenes are stable compounds and can remain present at toxic concentrations in feed for years. Field reports of trichothecene toxicity in livestock in North America generally involve DON contamination of feed. Acute, high dose exposures are not common. More typically, chronic to sub-chronic exposure to low dose DON-contaminated feed in swine occurs and leads to nutritional impairment, poor production and possible immune susceptibility to infections.

Due to the vague nature of toxic effects attributed to low concentrations of trichothecenes, a solid link between low level exposure and a specific trichothecene(s) is difficult to establish. Mold identification and determination of fungal spores can indicate feedstuffs of deteriorated quality, but provide no information as to the presence or concentration of mycotoxins that actually cause adverse health effects. Multiple factors, such as nutrition, management and environmental conditions, impact animal health and need to be evaluated with the knowledge of the mycotoxin(s) and concentrations known to cause adverse health effects. Future research evaluating the impact(s) of low level exposure on livestock may clarify the potential impact on immunity.

Trichothecenes are rapidly excreted from animals, and residues in edible tissues, milk, or eggs are likely negligible. In chronic exposures to trichothecenes, once the contaminated feed is removed and exposure stopped, animals generally have an excellent prognosis for recovery (Prelusky *et al.*, 1994).

# Zearalenone

Michelle S. Mostrom

## INTRODUCTION

Zearalenone is a nonsteroidal estrogenic mycotoxin produced by several species of *Fusarium* fungi. The primary producer of zearalenone is *Fusarium graminearum* (teleomorph *Gibberella zeae*). Additional *Fusarium* fungi capable of producing zearalenone include *F. culmorum*, *verticillioides* (*moniliforme*), *sporotrichioides*, *semitectum*, *equiseti* and *oxysporum*. Contamination of cereal grains by zearalenone has been reported worldwide, primarily in temperate climates. Typically, zearalenone concentrations are low in grain contaminated in the field, but increase under storage conditions with moisture greater than 30–40%. Zearalenone has major effects on reproduction that can lead to hyperestrogenism. Prepubertal swine are the most sensitive species. Typical clinical signs of hyperestrogenism are swelling of the vulva, increase in uterine size and secretions, mammary gland hyperplasia and secretion, prolonged estrus, anestrus, increased incidence of pseudopregnancy, infertility, decreased libido, and secondary complications of rectal and vaginal prolapses, stillbirths and small litters. This chapter describes toxicity of zearalenone and its major metabolites in animals.

## BACKGROUND

Estrogenism in swine was reported in the mid-1920s in the Midwest U.S. (McNutt *et al.*, 1928). A condition of swelling and eversion of the vagina in young gilts and swelling of the prepuce in males was associated with

consuming moldy corn. Prolapse of the vagina and occasionally the rectum were noted as secondary effects. With replacement of the moldy corn with clean corn, the animals recovered to normal, but if exposure to moldy corn continued, eversion of the uterus, secondary infections and death occurred. Mirocha *et al.* (1971) noted high death losses in some herds and hypothesized that mortality was related to vaginal and rectal prolapses and subsequent septicemias; however, the presence of additional mycotoxins could not be excluded in causing death. Stob *et al.* (1962) isolated an active metabolite with uterotrophic and anabolic activities from culture of *G. zeae* (*F. graminearum*).

The *Fusarium* compound found in corn with uterotrophic activity was named zearalenone, previously known as F-2, and is chemically described as 6-(10-hydroxy-6-oxo-*trans*-1-undecenyl)- $\beta$ -resorcylic acid lactone (Figure 95.1). At least seven derivatives of zearalenone have been found that naturally occur in corn. Zearalenone and uterotrophic active derivatives were classified as estrogens in the sense that they produce estrus or cornification of the vagina of adult mice (Mirocha and Christensen, 1974). Zearalenone can be produced on numerous substrates, including wheat, barley, corn, corn silage, rice, sorghum and occasionally in forages. Production in soybeans is uncommon. Moisture content and the presence of oxygen are critical factors for zearalenone production. In laboratory cultures, *Fusarium* growth occurs during a 3-week period at moisture levels over 20% and temperatures between 20 and 25°C. If the fungus is stressed by cool temperatures of 8–15°C for several weeks, zearalenone can be produced. Production of zearalenone in the field is similar to that in the laboratory, with alternating moderate and low temperature

FIGURE 95.1 Chemical structure of zearalenone.

weather capable of stimulating zearalenone production. Zearalenone can be produced fairly quickly in the field during wet weather in the late summer or early fall weather following hail damage to corn. Very high concentrations of zearalenone, which can occur naturally in some field samples, generally result from improper storage at high moisture rather than production in the field. Corn stored in a crib and exposed to winter weather was particularly prone to fungal invasion and production of zearalenone. In addition to the co-occurrence of other estrogenic metabolites, such as  $\alpha$ - and  $\beta$ -zearalenol, zearalenone is commonly detected in grains with another *Fusarium* mycotoxin deoxynivalenol. Zearalenone is heat stable, but can be partially destroyed during extrusion cooking of cereals (Castells *et al.*, 2005).

## TOXICOKINETICS

Zearalenone is fairly rapidly absorbed following oral exposure (Dailey *et al.*, 1980). Following a single oral dose of 10mg zearalenone/kg body weight to 15–25kg pigs, the absorption was approximated to be 80–85% (Biehl *et al.*, 1993). Zearalenone and associated metabolites were found in the plasma of a pig in less than 30min after initiating feeding with parent compound. Following zearalenone administration, zearalenone can be localized in reproductive tissues (ovary and uterus), adipose tissue and interstitial cells of the testes (Ueno *et al.*, 1977; Kuiper-Goodman *et al.*, 1987). The reported biological half-life of total plasma zearalenone radioactivity following oral dosage in pigs is 86h (Biehl *et al.*, 1993). Species differences in zearalenone susceptibility might be related to hepatic biotransformation, with the highest amount of  $\alpha$ -zearalenol, which has increased estrogenic activity compared to  $\alpha$ -zearalanol and zearalenone produced by pig hepatic microsomes, whereas chicken microsomes produced the highest amounts of  $\beta$ -zearalenol, which has lower estrogenic activity (Malekinejad *et al.*, 2006). Pigs readily conjugated almost all absorbed zearalenone and  $\alpha$ -zearalenol through glucuronidation.

While the liver plays a major role in glucuronidation, the intestinal mucosa is also active. Zearalenone was reduced to  $\alpha$ - and  $\beta$ -zearalenol in sow intestinal mucosa homogenates (duodenum and jejunum) *in vitro* (Olsen *et al.*, 1987). Gastrointestinal flora can aid in the metabolism of zearalenone. Zearalenone can undergo rumen metabolism, with reduction to mostly  $\alpha$ -zearalenol and to a lower amount of  $\beta$ -zearalenol (Kiessling *et al.*, 1984). Whether rumen metabolism will increase or decrease zearalenone toxicity depends on absorption by the gastrointestinal tract, liver metabolism by hydroxysteroid dehydrogenase and competition at the cytosolic receptor sites in the animal species.

Zearalenone undergoes extensive enterohepatic circulation and biliary excretion in most species. The major route of excretion for most species is through the feces, although rabbits primarily excrete zearalenone in the urine. Most zearalenone administered in a dose is excreted within a 72h period. Approximately 94% of radio-labeled zearalenone, given orally to White Leghorn laying hens at 10mg/kg body weight, was eliminated through the excreta within 72h post-dosing (Dailey *et al.*, 1980). No major retention of radio-labeled activity was found in edible muscle tissue, but lipophilic metabolite(s) were reported in egg yolk (at about 2mg/kg concentration) 72h post-dosing.

Concern has focused on potential residue of zearalenone and its metabolites in milk, eggs and foods, and precocious development of sexual characteristics in young girls (Kuiper-Goodman *et al.*, 1987; JECFA, 2000). Zearalenone and  $\alpha$ - and  $\beta$ -zearalenols can be transmitted into the milk of sheep, cows and pigs administered high doses of zearalenone (Hagler *et al.*, 1980; Mirocha *et al.*, 1981). Hyperestrogenism has been reported in lambs and pigs nursing dams dosed with zearalenone (Hagler *et al.*, 1980; Palyusik *et al.*, 1980). Dairy cows fed rations with purified zearalenone at 50mg zearalenone/day and 165mg zearalenone/day for 21 days had no detectable concentrations of zearalenone or  $\alpha$ - and  $\beta$ -zearalenol in the milk or plasma (Prelusky *et al.*, 1990). One cow dosed with 544.5mg zearalenone/day for 21 days had maximum concentrations of 2.5ng zearalenone/ml and 3.0ng  $\alpha$ -zearalanol/ml in the milk. Cows dosed orally with a 1-day dose of 1.8 or 6g zearalenone had maximum milk levels on day 2 of 4.0 and 6.1ng zearalenone/ml, respectively. This research indicates that minimal transmission of zearalanone occurs into milk and only for a short period of time after exposure to high concentrations of zearalenone.

Following intubations of tritiated-zearalenone into the crops of 7-week-old broiler chickens, the greatest accumulation of radioactivity occurred in the liver 30min post-administration, which became a trace of radioactivity by 48h post-administration (Mirocha *et al.*, 1982). Only zearalenone was detected in muscle tissue at

approximately 4ppb at 48h post-administration, indicating the zearalenone residues in edible tissue are minimal.

## MECHANISM OF ACTION

Zearalenone undergoes reduction of the 6' ketone to a secondary alcohol, which leads to two diastereoisomeric zearalanols ( $\alpha$  and  $\beta$ ), which are naturally occurring fungal metabolites. The  $\alpha$ -zearalanol metabolite, which is less estrogenic than  $\alpha$ -zearalanol but three times more estrogenic than zearalenone, is an anabolic growth-promoting compound, zearanol or Ralgro<sup>®</sup>, used in both cattle and sheep commercially.

Zearalenone and metabolites can interact directly with the cytoplasmic receptor that binds to 17 $\beta$ -estradiol and translocate receptor sites to the nucleus (Katzenellenbogen *et al.*, 1979). In the nucleus, stimulation of RNA leads to protein synthesis and clinical signs of estrogenism. Following subcutaneous injection of the compounds, the zearalanols and zearalenone stimulated production of a specific uterine protein and increased uterine weights. Within the resorcylic acids,  $\alpha$ -zearalenol exhibited the greatest binding affinity for cytosolic estrogen receptors, while zearalenone and  $\beta$ -zearalenol displayed much lower binding affinities (Fitzpatrick *et al.*, 1989). The hydroxylation of zearalenone to  $\alpha$ -zearalenol apparently is an activation process, whereas the production of  $\beta$ -zearalenol would be a deactivation process. The relative binding affinity of  $\alpha$ -zearalenol was greater in the pig than in the rat or chicken. Interspecies variations in sensitivity to zearalenone in the feed could be related to different metabolites produced and the relative binding affinities of zearalenone and metabolites formed.

Zearalenone can also act on the hypothalamic-hypophyseal axis. Using 70-day-old Yorkshire gilts (20–27kg) fed 1.5–2mg zearalenone/kg feed for 45–90 days, Rainey *et al.* (1990) determined that prepubertal exposure to zearalenone affected the hypothalamic-hypophyseal axis and the luteinizing hormone (LH) surges that lasted for at least 44 days post-exposure. However, zearalenone consumption did not delay the onset of pubertal estrus or impair conception rates, ovulation rates, or number of fetuses. Slightly older prepubertal gilts (178 days of age and 94kg) fed 10mg zearalenone daily for 2 weeks had suppressed mean serum concentrations of LH, but the onset of puberty and subsequent reproduction were not adversely affected (Green *et al.*, 1990). Male rats, 70 days old, dosed orally with zearalenone at 20mg/kg body weight for 35 days, had elevated serum prolactin concentrations but showed no changes in serum LH and follicle stimulating hormone concentrations, body and testes weights,

or in spermatogonia, spermatocytes and spermatids (Milano *et al.*, 1995). At relatively high concentrations *in vitro*, approximately 400 $\mu$ M, zearalenone appeared to act directly on interstitial cells of the testes inhibiting steroidogenesis (Fenske and Fink-Gremmels, 1990).

While zearalenone primarily affects reproduction, it may have additional effects. During exposure of *in vitro* cell lines, zearalenone acted as a ligand for human pregnane X receptor (hPXR), which can activate a transcription factor regulating the expression of numerous hepatic drug-metabolizing enzymes, including expression of cytochrome P450 enzymes (Ding *et al.*, 2006). This suggests a potential for zearalenone to induce metabolism of drugs.

At natural contamination levels in feeds, zearalenone does not appear to impact the immune response. Results from *in vitro* studies of zearalenone and metabolites  $\alpha$ - and  $\beta$ -zearalenol and  $\alpha$ - and  $\beta$ -zearalanol and mitogen testing with leukoagglutinin, concanavalin A and pokeweed revealed that these mycotoxins inhibited mitogen-induced proliferation of both B and T lymphocytes (Forsell and Pestka, 1985). No treatment differences were observed in B6C3F1 mice fed a diet with 10mg zearalenone/kg diet for 8 weeks and control mice that were tested with a splenic plaque-forming response to sheep erythrocytes and a delayed hypersensitivity response to keyhole hemocyanin (Pestka *et al.*, 1987).

## TOXICITY

Zearalenone has low acute toxicity in most species. In most natural conditions, concentrations of zearalenone in feed ingredients are less than 20mg/kg (ppm) and generally less than 5mg zearalenone/kg feed (Sundlof and Strickland, 1986). Prepubertal swine are most sensitive to zearalenone, ruminants may exhibit some adverse effects, and poultry appear to be the least sensitive species. Females are more sensitive than males, and cycling female pigs may be more sensitive than pregnant sows. Pregnant swine may abort. Abortions have been associated in field cases with natural *Fusarium* mold exposure, but have not been reproduced with purified zearalenone (Mirocha and Christensen, 1974). Younger male pigs appear to be more sensitive than older males and can undergo atrophy of the testes and enlargement of mammary glands.

### Swine

Gilts fed rations with 0, 3, 6, or 9mg purified zearalenone/kg feed that started the day after they showed the first estrus were bred at subsequent heat periods

(Young and King, 1986a). A majority of gilts fed 6 or 9 mg zearalenone/kg feed became pseudopregnant based on examination of their reproductive tracts or plasma progesterone levels. Gilts fed rations with 3 mg zearalenone/kg feed had no reproductive effects. After removal of zearalenone from the diet, approximately half of the gilts fed 6 or 9 mg zearalenone/kg feed returned to estrus spontaneously. Edwards *et al.* (1987a) reported luteal maintenance and extended inter-estrous intervals in sexually mature gilts fed purified zearalenone at concentrations of 5–10 mg/kg feed from days 5 to 20 of the estrous cycle. Approximately 86% of the retained corpora lutea underwent spontaneous regression and most gilts came into estrus within the next 30 days. In a subsequent study, Edwards *et al.* (1987b) fed prepubertal gilts a diet with 0 or 10 mg zearalenone/kg feed for 30 days from 145 to 193 days of age, switched the gilts to a control diet, and then exposed the gilts to a mature boar. While treated gilts displayed vulvar swelling during the 30-day feeding period and were delayed in showing first estrus, the proportion of gilts showing estrus with exposure to the boar was similar between treatment and control gilts, and subsequent cycling was not affected when the treated feed was removed. Young *et al.* (1990) reported an increased weaning-to-estrus interval and embryonic mortality (measured as a decreased ratio of fetuses to corpora lutea) and a decreased number of fetuses per sow in second parity sows fed 10 mg zearalenone/kg diet. No reproductive effects were observed in prepubertal gilts fed a ration with 0.5 mg zearalenone/kg feed (Friend *et al.*, 1990).

Young gilts (30–35 kg) administered 5 mg of purified zearalenone *per os* daily developed swelling of the vulva on the fourth day of treatment, an approximate daily dose of 0.143–0.167 mg zearalenone/kg body weight (Mirocha and Christensen, 1974). Gilts dosed with 1 mg of purified zearalenone daily for 8 days developed pronounced vulvar swelling. Gilts exposed to higher concentrations of zearalenone may show atrophy of the ovaries along with edema and cellular proliferation of all layers in the uterus. Kuiper-Goodman *et al.* (1987) noted a no adverse effects level for zearalenone in pigs reaching puberty at 0.06 mg zearalenone/kg body weight/day.

Male swine fed a high concentration of zearalenone (30 mg/kg feed) appeared initially to have accelerated maturation of spermatogenesis, which occurred 1.5–2 months earlier than control animals (Ványi and Széky, 1980). Although germinal epithelium damage was limited to several foci initially, with continued zearalenone exposure the damage became widespread with proliferation of the interstitium around seminiferous tubules. Young and King (1986b) fed lower levels of zearalenone in the diet (0, 3, 6 and 9 mg zearalenone/kg feed) to boars from 32 days of age up to 145 or 312 days of age. Feeding up to 9 mg zearalenone/kg feed to the boars

did not affect the libido, but the boars fed the highest dose of zearalenone produced lower total and gel-free volumes of semen with lower total motile sperm. Zearalenone does not appear to affect mature boars. No adverse effects in reproductive parameters, including testicular size, libido, sperm motility and morphology, plasma testosterone and 17 $\beta$ -estradiol concentrations, were reported in mature Yorkshire boars fed increasing concentrations of purified zearalenone at 0, 2, 20 and 200 mg/kg ration for 8 weeks (Ruhr *et al.*, 1983).

The European Union (2006) guidance values for zearalenone in feedstuff (with a moisture content of 12%) for piglets and gilts is 0.1 mg/kg or ppm, for sows and fattening pigs is 0.25 mg/kg, and for calves, dairy cattle, sheep and goats is 0.5 mg/kg.

## Ruminants

Several case reports have associated dairy herd health problems and zearalenone in moldy feed. Young dairy heifers, 6–14 months of age, developed slight enlargement of at least one mammary gland quarter while fed moldy corn in a ration (Bloomquist *et al.*, 1982). Following a change in the ration, the heifers returned to normal 7 weeks later. Zearalenone contamination of the moldy ration was detected by thin-layer chromatography. Roine *et al.* (1971) reported turbid discharge from the vulva, obvious estrous behavior lasting for 1–2 weeks, and infertility in dairy cows and heifers. Strains of *F. graminearum* and *culmorum* were isolated from the feed that caused an increase in uterine weight in rats and were capable of producing between 3 and 9.5 mg zearalenone/kg feed. Ványi *et al.* (1974) reported a drop in milk production, feed intake and swelling of the vulva in dairy cows exposed to varying concentrations of zearalenone, ranging from 5 to 75 mg zearalenone/kg feed. In an experimental study, 18 cycling heifers were dosed with 0 or 250 mg of purified zearalenone daily through one non-breeding estrous cycle and the next two consecutive estrous cycles during which the heifers were bred (Weaver *et al.*, 1986a). The authors calculated that treated heifers were given an average of 250 mg zearalenone/364 kg body weight/day or 0.69 mg zearalenone/kg body weight/day. The control and treated heifers had conception rates of 87 and 62%, respectively, at a statistical probability of  $p < 0.065$ . Eighteen dairy cows (three cows per group) dosed orally with 0, 31.25, 62.5, 125, 250 and 500 mg of purified zearalenone daily for two consecutive estrous cycles had no changes in serum progesterone concentration, erythrocyte and leukocyte blood counts, packed cell volume, estrous cycle length, clinical health, or sexual behavior (Weaver *et al.*, 1986b).

Zearalenone can affect ewe reproduction when ewes are exposed to the mycotoxin prior to mating.

Zearalenone, administered orally at concentrations greater than 3mg/animal/day, given to ewes prior to mating depressed ovulation rates and reduced lambing percentages (Smith *et al.*, 1990). Ewes administered a similar range of oral doses of zearalenone (0, 1.5, 3, 6, 12 and 24mg/ewe/day) for 10 days, starting 5 days after mating, showed no effect of zearalenone exposure after mating on pregnancy rate or embryonic loss. Breeding rams fed a diet containing 12mg zearalenone/kg feed for 8 weeks had no significant adverse effects on semen volume, concentration, motility, or morphology during the trial and for 6 weeks after zearalenone feeding was ceased (Milano *et al.*, 1991).

## Equine

Gimeno and Quintanilla (1983) reported estrogenic signs of edematous vulvas, prolapsed vaginas, oversized uteruses and internal hemorrhage in mares, and severe flaccidity of genitals in two male horses fed corn screenings for 30 days in a field exposure. All sick animals collapsed with respiratory paralysis and sudden blindness, and died quickly. Analysis for zearalenone in the feed detected 2–3mg zearalenone/kg diet. While the authors tested for a variety of mycotoxins by thin-layer chromatography, fumonisins in the corn screenings were not determined because they had not been recognized as mycotoxins and a cause of death in horses. Fumonisin would have to be considered as a primary cause of some of the adverse effects, particularly blindness and death, in these horses.

In a study of six cycling trotter mares, Juhász *et al.* (2001) determined that daily oral administration of 7mg purified zearalenone starting 10 days after ovulation until the subsequent ovulation had no adverse effect on reproduction. Zearalenone had no effect on the length of the interovulatory intervals, luteal and follicular phases of the ovary, and did not significantly affect uterine edema. The authors noted that zearalenone exposure started 10 days after ovulation and the exposure period to zearalenone was short in this study. The dose of purified zearalenone represented a natural contamination of feed of about 1mg zearalenone/kg feed and ranged between 0.013 and 0.010mg zearalenone/kg body weight/day for approximately 8–10 days.

## Poultry

Growing female White Leghorn chickens dosed orally once with 15g zearalenone/kg body weight showed no adverse effects in reproductive tissues (Chi *et al.*, 1980). In a second experiment, chickens dosed orally or intramuscularly with increasing concentrations of zearalenone (0–800mg/kg body weight) for 7 consecutive

days had increased oviduct weights with increasing zearalenone doses. Poultry appear to be fairly resistant to the effects of zearalenone.

## TREATMENT

Quick removal of zearalenone-contaminated feed from the ration and replacement with clean feed is essential. Generally, 3–7 weeks following removal of the contaminated feed, animals will return to normal reproductive status. No zearalenone mycotoxin binder has been proven to be efficacious in any species of livestock by the U.S. Food and Drug Administration.

## CONCLUSIONS

Maintaining moisture concentrations less than 15–16% in feeds should adequately prevent zearalenone production during storage. When naturally contaminated feed must be used, incorporation into rations for less susceptible species, such as feedlot animals or poultry, should be considered. At naturally occurring concentrations of zearalenone in grains, residues in meat, milk and eggs are probably not significant.

# Melamine and cyanuric acid

Karyn Bischoff

## INTRODUCTION

Melamine, or 1,3,5-triazine-2,4,6-triamine, is a small, nitrogen-rich molecule used in the manufacture of plastics, adhesives, cleaners and yellow dye. Though once considered practically non-toxic based on early laboratory animal studies, significant morbidity and mortality related to crystalluria, nephrolithiasis and nephrotoxicity have resulted from pet food contamination.

Beginning in early 2007, reports of renal failure in cats and dogs fed various commercial pet foods led to concerns about possible contamination, and a widespread recall of suspect foods was initiated prior to identification of the toxin. Eventually, >150 pet food products were identified as containing contaminated ingredients and were recalled. Analysis revealed that these products contained up to approximately 3200ppm melamine and 600ppm cyanuric acid (Cianciolo *et al.*, 2008; Skinner *et al.*, 2010). Samples of the imported wheat gluten contained 8.4% melamine as well as the following melamine breakdown products: 5.3% cyanuric acid, 2.3% ammelide and 1.7% ammeline (Rumbeiha *et al.*, 2010). Because melamine is 67% nitrogen based on the molecular weight, its addition to foodstuff increases the nitrogen content and thus the estimated protein content when protein is measured by common methods, such as the Kjeldahl method, which actually measure the nitrogen content.

It was later determined that similar episodes of pet food contamination occurred in Asia and South Africa. An incident in 2004 was estimated to have affected more than 6000 dogs and cats in the Republic of Korea,

Japan, Thailand, Malaysia, Singapore, Taiwan and the Philippines. Earlier in 2007, there was a melamine-associated pet food recall in South Africa (Osborne *et al.*, 2008; Yhee *et al.*, 2009). Aside from pet food, feeds for chickens, hogs and fish were also found to be contaminated (Reimschuessel *et al.*, 2008, 2009). Melamine-contaminated pet food scraps were fed on hog farms in seven U.S. states and contaminated feeds were traced to 38 poultry farms and at 197 fish hatcheries (Acheson, 2007; FDA, 2010). Investigation of renal failure in piglets in Spain between 2003 and 2006 found that the kidneys contained melamine, cyanuric acid and relatively high concentrations of ammelide and ammeline (Gonzalez *et al.*, 2009). Hundreds of fur-bearing raccoon dogs in China died after being fed melamine-contaminated feeds in 2008 (Bhalla *et al.*, 2009).

The 2007 pet food recall was considered a sentinel event by some (Osborne *et al.*, 2008; Lewin-Smith *et al.*, 2009). Indeed 1 year later melamine contamination of milk-based products, particularly baby formula, was detected in China. Chinese authorities detected melamine concentrations between 2.5 and 2563ppm in 13 commercial brands of milk powder and trace contamination in nine others (Bhalla *et al.*, 2009). Approximately 300,000 children could have been affected, more than 52,000 were hospitalized and six died. Children in Taiwan, Hong Kong and Macau could also have been affected (Hau *et al.*, 2009; Reimschuessel *et al.*, 2009; Skinner *et al.*, 2010). Due to global marketing of products and ingredients, melamine-contaminated products were found in almost 70 countries, including the United States.

FIGURE 96.1 Structural formulas of melamine and cyanuric acid.

## SOURCE

Melamine, or 1,3,5-triazine-2,4,6-triamine (Figure 96.1), which contains 3 carbon atoms, 6 nitrogen atoms and 6 hydrogen atoms, was first synthesized in the 1830s and has found numerous uses in manufacturing. Melamine is polymerized with formaldehyde to produce a variety of durable resins, adhesives, cleansers and flame retardants. Melamine is also a major ingredient in the pigment Yellow 150, used in textile dyes and inks. China, the largest melamine producer, produces a quarter of the melamine used in the world.

Cyanuric acid, often found as a co-contaminant with melamine, is an intermediate produced during melamine manufacture and degradation. It is commonly used to stabilize chlorine in swimming pools and in the manufacture of bleach, disinfectant and herbicides (Dalal and Goldfarb, 2011).

## PHARMACOKINETICS/ TOXICOKINETICS

Melamine is minimally, if at all, metabolized in monogastrics, but could be partially metabolized in the rumen of cattle and small ruminants. Melamine does not accumulate over time in the animal body. Renal elimination of unchanged melamine is approximately 90% complete within 24 hours (Qin *et al.*, 2010). The half-life for urinary elimination of melamine is given as 6 hours in dogs (Lipschitz and Stokey, 1945). The elimination half-life in swine is approximately 4 hours (Yang *et al.*, 2011). Therefore, melamine should be almost completely excreted within 2 days of the last exposure in these monogastric species; however, crystals were seen microscopically in feline kidneys 8 weeks after dietary exposure to melamine and cyanuric acid (Cianciolo *et al.*, 2008). The elimination half-life of melamine in small ruminants is 3–6-fold slower than in monogastrics, possibly due to prolonged sequestration in the rumen

(Baynes *et al.*, 2010). Urinary excretion accounted for 54.1% of melamine administered to sheep, and 23.7% was found in the feces (Cruywagen *et al.*, 2011).

Detectable melamine concentrations have been reported in edible tissues from animals. It was estimated that 3.6% of melamine fed to sheep partitioned to muscle (Cruywagen *et al.*, 2011). Melamine concentrations in the kidney were higher than concentrations in the skeletal muscle or liver of lambs, and concentrations decreased below 20 ppb 4 days after cessation of exposure. Addition of cyanuric acid to the diet did not affect melamine deposition (Lv *et al.*, 2010). The highest tissue melamine concentrations in chickens fed melamine-containing diets were found in the kidneys, with lower concentrations in the liver and muscle. Tissue residues were depleted 10 to 20 days after exposure ceased (Bai *et al.*, 2010). Melamine administered to pregnant rats was detected in the placenta and fetuses (Jingbin *et al.*, 2010). However, reproductive and developmental effects have not been attributed to melamine in animal studies (Skinner *et al.*, 2010; Bischoff, 2011).

Melamine concentrations were detected in catfish and trout within 1 day of dosing, and the half-life of melamine in skeletal muscle of fish ranged from 1.5 to 4 days (Reimschuessel *et al.*, 2009). Due to the longer elimination half-life of melamine and cyanuric acid in fish, these compounds do not need to be given together. Melamine can be given 1 to 3 days after cyanuric acid (dependent on fish species) and produce crystals, and cyanuric acid can be given 7 to 14 days (dependent on species) after melamine and produce crystals (Reimschuessel *et al.*, 2010).

Melamine is excreted by dairy cattle into milk, particularly in high-producing cattle, though milk yield and composition are otherwise unaffected. Melamine can be detected in milk within 8 hours of exposure and remains detectable until 4 days after cessation of exposure. Transfer efficiency from feed to cows' milk was calculated to be between 0.66 and 0.95% and was not dependent on melamine dose (Shen *et al.*, 2010). Approximately 0.3% of a melamine dose was excreted in milk in dairy goats, and milk melamine concentrations remained above the level of concern (1.0 µg/mL) until 3 days after cessation of dosing (Baynes *et al.*, 2010).

Melamine fed to chickens is deposited within eggs within a day or 2 days post-exposure (Chen *et al.*, 2010; Bai *et al.*, 2010). The melamine concentration in eggs is proportional to the dietary concentration; a dietary concentration of 164 ppm could produce an actionable melamine concentration in eggs of 2.5 ppm (Chen *et al.*, 2010). A 4-day withdrawal period has been recommended for eggs from melamine-exposed chickens, though trace concentrations of melamine remain detectable in eggs for about 9 days after exposure ceases (Yang *et al.*, 2011).

## MECHANISM OF ACTION

Though previous animal studies found that both melamine and cyanuric acid were relatively nontoxic when given individually, they caused crystal formation in renal tubules when given together (Puschner and Reimschuessel, 2011). Melamine and cyanuric acid crystallize, forming a lattice structure at the molecular level, at a pH of 5.8 (Osborne *et al.*, 2008; Bhalla *et al.*, 2009). Crystals form in the distal convoluted tubules of the kidneys. Crystals recovered from kidneys and urine of cats that ingested melamine-contaminated food contained 70% cyanuric acid and 30% melamine based on infrared spectra results (Osborne *et al.*, 2008; Thompson *et al.*, 2008).

Renal pathology is believed to result from intratubular obstruction causing increased intrarenal pressure. This may be the explanation of the renal hemorrhage and inflammation reported in cats and dogs. Since melamine has diuretic properties, pre-renal azotemia could contribute to the renal pathology (Bhalla *et al.*, 2009).

Cyanuric acid did not contribute to the formation of urinary calculi in children as it did in companion animals (Gao *et al.*, 2010). However, calculi in children were produced by a similar interaction between melamine and uric acid. This interaction has also been reported in poultry (Bai *et al.*, 2010). Humans and most other primates lack the enzyme uricase, which converts uric acid to allantoin (Reimschuessel *et al.*, 2008). Compared to adults, human infants excrete between 5 and 8 times as much uric acid, which may increase their susceptibility to melamine toxicosis (Skinner *et al.*, 2010). Urinary pH <5.5 is associated with the formation of urate crystals and low pH is believed to be involved in melamine/urate crystal formation (Gao *et al.*, 2010). Crystals associated with nephrotoxicosis in these infants contained melamine and uric acid at a molar ratio of 1:1–2, respectively (Skinner *et al.*, 2010; Wen *et al.*, 2010). Birds and reptiles also excrete uric acid; therefore, susceptibility in these species could be similar to those seen in human neonates. Dalmatian dogs, too, have reduced uric acid metabolism, and thus excrete uric acid.

## TOXICITY

Melamine has relatively low toxicity based on animal studies. The oral LD<sub>50</sub> of melamine is 3200mg/kg in male rats, 3800g/kg in female rats, 3300mg/kg in male mice and 7000mg/kg in female mice. Long-term administration of melamine to laboratory rodents at concentrations ranging from 0.225 to 0.9% of the diet produces urolithiasis. Lesions in the urinary bladder, including transitional cell carcinoma, were observed in rats fed diets containing

0.45% melamine (Melnick *et al.*, 1984). The mechanism of carcinogenesis was most likely secondary to epithelial hyperplasia caused by mechanical irritation (Melnick *et al.*, 1984; Hau *et al.*, 2009). Urolithiasis was consistently identified in rats fed diets containing 0.3 to 3.0% melamine (Okumura *et al.*, 1992). Renal cortical fibrosis and lymphoplasmacytic nephritis were reported in female rats fed diets containing 0.45% melamine (Melnick *et al.*, 1984). Among domestic animals, sheep given single (217mg/kg) or multiple (200 to 1351mg/kg/d) doses of melamine had dose-dependent clinical signs of anorexia, anuria and uremia after 5 to 31 days (Clark, 1966). Dogs fed 125mg/kg melamine had crystalluria but no other adverse effects were identified (Lipschitz and Stokey, 1945).

Cyanuric acid has similarly low toxicity when given alone. It produces degenerative renal changes in guinea pigs when given at doses of 30mg/kg body weight for 6 months, in rats fed a diet containing 8% monosodium cyanurate for 20 weeks, and in dogs fed a diet containing 8% monosodium cyanurate. Lesions included ectasia of the distal collecting tubules and multifocal epithelial cell proliferation (Canelli, 1974).

The combination of melamine and cyanuric acid is markedly more toxic to most domestic animals than either compound when given alone. Administration of 50mg/kg melamine or cyanuric acid to rats did not result in adverse effects, but when both were given together at the dose of 50mg/kg, evidence of nephropathy was observed (Puschner and Reimschuessel, 2011). Cats fed diets containing up to 1% melamine or cyanuric acid alone had no evidence of clinical abnormalities. However, cats fed diets containing 0.2% each of melamine and cyanuric acid had evidence of acute renal failure and crystaluria within 48 hours due to renal tubular necrosis. Lesions typical of those associated with the pet food recall were observed (Puschner *et al.*, 2007). A pig fed 400mg/kg melamine and 400mg/kg cyanuric acid daily had bloody diarrhea within 24 hours, which resolved. Necropsy revealed perirenal edema and round golden-brown crystals with radiating striations in the kidneys. Similar lesions were present in tilapia, rainbow trout and catfish dosed with 400mg/kg each of melamine and cyanuric acid per day for 3 days, though most of the fish survived the renal damage (Reimschuessel *et al.*, 2008).

A recent study suggested that melamine is neurotoxic as it impaired synaptic plasticity in hippocampus and thereby learning and memory deficits in rats (An *et al.*, 2011).

## CLINICAL SIGNS

Early clinical signs of vomiting and inappetance were apparent in cats and dogs ingesting contaminated food, followed later by evidence of renal failure. The most

common clinical signs in cats and dogs were inappetence, vomiting, polyuria, polydipsia and lethargy (Cianciolo *et al.*, 2008). The most common symptoms described in children were increased or reduced frequency of urination or anuria, hematuria, stranguria and unexplained crying, but many children were asymptomatic (Hau *et al.*, 2010; Wen *et al.*, 2010; Hu *et al.*, 2010).

## CLINICAL PATHOLOGY

Affected cats had urine specific gravities  $<1.035$  and elevated serum urea nitrogen and creatinine concentrations within 36 hours of exposure, hyperkalemia and hyperphosphatemia (Cianciolo *et al.*, 2008; Puschner and Reimschuessel, 2011). Urinalysis revealed the presence of circular green-brown crystals in urine sediment (Cianciolo *et al.*, 2008). Serum chemistry findings included elevated serum urea nitrogen and creatinine concentrations.

Serum chemistry findings in affected infants included elevated serum potassium, urea nitrogen and creatinine concentrations (Sun *et al.*, 2010). Hematuria and the presence of fan-shaped crystals were reported in urine samples and urine pH ranged from 5.0 to 7.5 (Hau *et al.*, 2009).

## PATHOLOGY

Post-mortem findings from animals that died typically included bilateral renomegaly and evidence of uremia (Thompson *et al.*, 2008; Cianciolo *et al.*, 2008).

Microscopic lesions were found primarily in the kidneys. Renal tubular necrosis with evidence of rupture and regeneration were present. Distal convoluted tubules contained large golden-brown birefringent crystals (15 to 80 micrometers in diameter; Figure 96.2) with centrally radiating striations, sometimes in concentric rings, and smaller amorphous crystals (Cianciolo *et al.*, 2008; Thompson *et al.*, 2008). Crystals were spherical with a hedgehog-like appearance on images from scanning electron microscopy (Figure 96.3). Crystals were still present in distal convoluted tubules 8 weeks after cessation of exposure to contaminated feed (Cianciolo *et al.*, 2008). Perivascular inflammation of subcapsular veins was also reported.

Melamine/cyanuric acid crystals could be differentiated from more common types of urinary crystals based on morphology and histochemistry or special staining. Von Kossa stains calcium oxalate and calcium phosphate crystals and Alizarin red S at pH between 4.1 and 4.3 stains calcium phosphate crystals only, but neither stains melamine/cyanuric acid crystals. Oil red O, usually

**FIGURE 96.2** Renal histology from a cat that ingested melamine and cyanuric acid contaminated food. Typical crystals are present within the renal tubule at the center. (Courtesy of Dr. R. Cianciolo).

**FIGURE 96.3** Scanning electron micrograph of melamine/cyanuric acid crystals from the urine of a cat. (Courtesy of Dr. B. Hoff.)

used to identify lipids, stains melamine/cyanuric acid crystals but not calcium oxalate or calcium phosphate crystals (Cianciolo *et al.*, 2008). Melamine/cyanuric acid crystals dissolve over time when kidney is stored in formalin (Puschner and Reimschuessel, 2011).

A cat that was euthanized 8 weeks after exposure had moderate tubular necrosis with regeneration and severe crystalluria. The finding of severe perivenous fibrosis and venous luminal stenosis in this cat suggested that cats that survived acute renal failure may have been predisposed to chronic renal ischemia leading to chronic renal disease (Cianciolo *et al.*, 2008).

Lesions secondary to uremia were sometimes observed in affected cats and included bilateral white

plaques on the ventral surface of the tongue and gastric mineralization (Cianciolo *et al.*, 2008).

A renal biopsy from an affected child had glomerular sclerosis, swelling and necrosis of renal tubular epithelium, tubular dilation with the presence of material consistent with a crystal, and an interstitial lymphoplasmacytic infiltrate. These changes were hypothesized to be due to urinary tract obstruction (Sun *et al.*, 2010). Stones in the urinary tract ranged in size from 2 to 18 mm in diameter, and approximately half were <5 mm in diameter. Diameter of the stone was dependent on the concentration of melamine in the diet, but not on the duration of exposure (Hu *et al.*, 2010). Renal calculi were usually bilateral, and calculi were also found in the ureter, unilaterally or bilaterally, and in the urinary bladder (Hau *et al.*, 2009; Gao *et al.*, 2010; Wen *et al.*, 2010).

## DIAGNOSIS

Diagnosis of melamine poisoning is based on the presence of melamine and cyanuric acid in samples of urine or kidney from affected animals, or contaminated food or feed. Gas chromatograph/mass spectroscopy (GC/MS) and liquid chromatography/tandem MS are used to analyze for melamine and cyanuric acid (Cianciolo *et al.*, 2008; Hon *et al.*, 2011; Puschner and Reimschuessel, 2011). Infrared spectroscopy or Raman spectrometry can be used to determine the composition of the urine crystals (Puschner and Reimschuessel, 2011). Identification of crystals on histopathology or urinalysis is also helpful in the diagnosis.

## TREATMENT AND PROGNOSIS

The basic treatment regimens for crystalluria and urolithiasis related to melamine ingestion include fluid therapy and supportive care in both veterinary and pediatric patients (Anonymous, 2007; Wen *et al.*, 2010). Increased water intake and fluid therapy were used to increase urine output. Because low urinary pH is associated with crystal formation in infants, alkalization of the urine was used to maintain urine pH between 6.0 and 7.8 in affected children. Sodium bicarbonate or potassium citrate was added to intravenous fluids for this purpose (Gao *et al.*, 2010; Wen *et al.*, 2010).

Antispasmodic drugs such as anisodamine or atropine were given to facilitate excretion of uroliths in children, and pain management was instituted (Bhalla *et al.*, 2009; Wen *et al.*, 2010). Most children recovered with this conservative management (Gao *et al.*, 2010; Wen *et al.*, 2010).

However, hemodialysis was required in some patients, as was surgical intervention (Wen *et al.*, 2010). Most children recovered fully, but 12% were found to have renal abnormalities 6 months after treatment (Liu *et al.*, 2010).

Analysis of 586 cases reported during the pet food recall of 2007 by veterinarians and accredited veterinary diagnostic laboratories found 451 cases matching the case definition of melamine toxicosis, 65.5% were cats and 34.4% were dogs. Older animals and animals with preexisting conditions were less likely to survive, and 73.3% of affected dogs and 61.5% of affected cats died (Rumbeiha *et al.*, 2010). However, >80% of exposed cats during the original feeding trials survived, suggesting that not all exposed cats become severely affected (Cianciolo *et al.*, 2008).

## CONCLUSIONS

Melamine poisoning in small animals and infants was associated with intentional contamination of pet food and milk products to increase the nitrogen concentration, and therefore the apparent protein concentration. Although there are some data on the number of infants affected, there is no way to determine the number of cats and dogs affected by the pet food recalls in 2007 because of a lack of veterinary care for many animals and lack of central reporting of morbidity and mortality for companion animals. Estimates vary depending on the source and have ranged from 571 to 39,000 cats and dogs (Osborne *et al.*, 2008; Puschner and Reimschuessel, 2011). Although many cats and dogs succumbed to melamine toxicosis, others survived with supportive and symptomatic care. There are little data on the long-term effects of melamine on cats and dogs.

# Ionophores

Meliton N. Novilla

## INTRODUCTION

Ionophores are compounds that form lipid soluble, dynamically reversible complexes with cations and by this means facilitate specific ionic transport across biologic membranes (Pressman, 1976; Reed, 1982; Taylor *et al.*, 1982). There are two major subclasses of ionophores, (1) neutral ionophores, which are highly toxic because they form charged complexes that are capable of perturbing biologic membranes and action potentials, and (2) carboxylic ionophores, which form zwitterionic complexes with cations and promote electrically neutral cation exchange diffusion that is tolerated better in intact organisms. The ionophoric activity may alter normal concentration gradients resulting in cellular ion imbalance, pH change, calcium overload, lipid peroxidation and disruption of plasma membranes. The alteration in the membrane transport of ions is the basis for the metabolic, organic and functional effects of this class of compounds. Since their pharmacologic activity is dose related, the usefulness of carboxylic ionophores is based on selective toxicity to protozoan parasites and bacteria and margins of safety in the approved target species. Desirable effects occur when animals are provided feed containing approved dosage ranges, but higher levels may result in adverse effects.

This chapter attempts to provide an overview of ionophores as they relate to veterinary medicine, with emphasis on ionophore-induced toxicity. Large numbers of ionophore safety and toxicity studies have been conducted in support of marketing approval, but results of many studies are unpublished. For this reason, information presented was gleaned from published laboratory and field reports of toxicoses in various species of animals, available reviews and Freedom of Information

summaries obtained from the U.S. FDA. However, due to space limitations, not all information can be included, hence apologies are extended to laboratory scientists and field researchers whose work has been omitted or inadvertently missed.

## BACKGROUND

Presently, seven carboxylic ionophores are approved for the control of coccidiosis and promotion of growth and feed efficiency in several animals of economic importance. Since their introduction carboxylic ionophores have played significant roles in livestock and poultry production systems throughout the world. Monensin, first introduced as Coban<sup>®</sup> in the United States for the control of coccidiosis in chickens in 1971, was later marketed in 1975 as Rumensin<sup>®</sup> to promote growth and/or increase feed efficiency in cattle. Similarly, lasalocid has been marketed since 1977 as Avatec<sup>®</sup> for chickens and since 1982 as Bovatec<sup>®</sup> for cattle. Salinomycin, narasin and maduramicin were approved for chickens, respectively in 1983, 1986 and 1989, while laidlomycin and semduramicin were approved in 1994 for use in cattle and chickens, respectively. (See [Figure 97.1](#).)

Other benefits of ionophore use include (1) reduction of coccidial oocyst discharge in ruminants, (2) prevention of acute bovine pulmonary edema and emphysema, (3) decreased incidence of bloat, (4) prevention of ruminal lactic acidosis, and (5) amelioration of ketosis in lactating dairy cows (Novilla, 2004; Duffield *et al.*, 2002; Heuer *et al.*, 2001; Parker *et al.*, 1986; Nocerini *et al.*, 1985; Potter *et al.*, 1984). The reduction of deaths in some cattle

FIGURE 97.1 Structures of carboxylic ionophores.

herds has been hypothetically related to the reduction of indigestion, metabolic stress, bloat and enterotoxemia associated with monensin feeding.

Potential uses of the ionophores are under experimental investigation in many parts of the world and off-label uses of some ionophores are known to occur. Monensin has been used for the control of toxoplasmosis in pregnant sheep (Buxton *et al.*, 1988), disseminated visceral coccidiosis in cranes (Carpenter and Novilla, 1992), diarrheal disease in swine (Kyriakis *et al.*, 1993), gregarine infections in shrimp (Jones *et al.*, 1994; Fajer-Avila

*et al.*, 2005) and microsporidial gill disease in fish (Becker *et al.*, 2002). The use of monensin to improve efficiency of milk production in dairy cattle has been approved in the U.S. (FDA, 2004). Experimental studies on the use of ionophores for the treatment of malaria (Adovelande and Schrevel, 1996; Gumila *et al.*, 1997), mycobacteriosis (Brumbaugh *et al.*, 2004; Greenstein *et al.*, 2009), lead poisoning (Hamidinia *et al.*, 2002) and as an aid in the potentiation of anti-cancer therapies (Griffin *et al.*, 1993; Shaik *et al.*, 2001) have been conducted. These studies were conducted in cell culture or as challenge studies

TABLE 97.1 General pharmacology studies on monensin

Test system	Species	Monensin dose (mg/kg)	Route	NOEL (mg/kg)
General behavior	Mouse	0, 10 and 30	Oral	10
Coordinating activity of skeletal muscles	Mouse	0, 10 and 30	Oral	10
Anti-electroshock seizures	Mouse	0 and 30	Oral	30

Cardiovascular and respiratory effects	Pig (anesthetized)	0, 0.00069, 0.0014, 0.0035, 0.0069, 0.014, 0.035, 0.069, 0.14, 0.35 and 0.69	Intravenous	0.0035

<sup>a</sup>Based on transient increases in coronary blood flow at doses  $\geq 0.69$  mg/kg.

in laboratory animals and have shown some degree of efficacy. In spite of these encouraging results, there have been no reports of investigational use of ionophores in humans.

## PHARMACOLOGY/ PHARMACOKINETICS

### Pharmacology

Investigational studies were conducted to determine if ionophores had any undesirable pharmacological properties. A series of general pharmacology studies was conducted with monensin (Novilla, 2004). Earlier, Hanley and Slack (1982) reviewed the pharmacology of lasalocid. The studies with monensin assessed its effects on the central, peripheral and autonomic nervous systems and the digestive, respiratory and cardiovascular systems. The test systems with doses and route of administration and no-observed-effect-level (NOEL) are shown in Table 97.1.

In mice, an oral dose of 10 mg monensin/kg produced no significant effects on general behaviors, coordinating activity in skeletal muscles, electroshock seizures and acetic acid writhing. However, slight sedation, decreased sensitivity to tactile stimulation, slight depression of muscular coordination and depressed acetic acid writhing occurred at 30 mg/kg. In cats, immobilized by d-tubocurarine or anaesthetized with urethane and  $\alpha$ -chloralose, an oral dose of 30 mg/kg produced no effect on the electroencephalogram and the spinal

reflex. At the same dose in anaesthetized cats, the heart rate, electrocardiogram, respiration and blood pressure responses to epinephrine, acetylcholine, histamine and contractions of the nictitating membrane in response to electrical stimulation of the cervical sympathetic ganglion were not affected. Charcoal meal transit in mice was not affected by an oral dose of 10 mg/kg while 30 mg/kg significantly depressed the transit rate. Gastric secretion was not affected by an oral dose of 30 mg/kg in rats. In isolated guinea pig illegal preparations, monensin in a bath concentration of  $10^{-5}$  g/mL had no antagonistic effects on contractures induced by acetylcholine, histamine and barium chloride. In the rat anti-carrageenan edema test, monensin given orally at 30 mg/kg did not significantly inhibit carrageenan-induced edema of the hind paw.

The studies targeting specific organ systems of laboratory animals indicated that monensin at a dose of 10 mg/kg orally produced no effect on the central, peripheral and autonomic nervous systems or the respiratory and digestive systems. However, striated (heart and skeletal) muscle has been identified as the primary targets of toxicity in laboratory animals and domestic livestock given large doses of monensin and other ionophores by oral or parenteral routes (Todd *et al.*, 1984; Novilla and Folkerts, 1986; Van Vleet *et al.*, 1991; Novilla and Todd, 1991; Dowling, 1992).

The cardiovascular effects of oral and intravenous administration of monensin were evaluated in conscious dogs (Holland, 1978). In the oral study, doses of 0, 0.138, 0.345, 0.69 or 1.38 mg monensin/kg body weight in 15 mL of 10% acacia were given by gavage to four or six dogs. Effects were limited to increased coronary

blood flow at doses  $\geq 0.69$  mg monensin/kg. At the 0.69 mg/kg dose, coronary flow increased from 24 mL/minute before dosing to a maximum of 40 mL/minute 17.5 minutes after dosing. At the 1.38 mg/kg dose, coronary flow increased from 18 mL/minute pre-dosing to a maximum of 49 mL/minute 13 minutes after dosing. In both cases, coronary blood flow had returned to normal levels by 30 minutes after dosing. Heart rate and mean blood pressure of monensin-treated dogs did not change significantly from the controls at any dose level. Coronary artery flow did not increase following doses of 0.138 and 0.345 mg monensin/kg. In the intravenous (IV) study, coronary blood flow, blood pressure and heart rate were measured in each of six dogs given total cumulative doses of 0.0069, 0.0138, 0.0345, 0.069 and 0.138 mg monensin/kg body weight. Four control dogs were given dextrose alone. Coronary artery flow significantly increased at 0.069 and 0.138 mg/kg and mean blood pressure increased significantly at 0.138 mg/kg. Coronary artery flow did not change significantly following doses  $\leq 0.0345$  mg/kg while heart rate did not change significantly from the controls at any dose level. Mean blood pressure also did not change significantly at dose levels of 0.0069, 0.0345 and 0.069 mg/kg. Based on the transient increases in coronary blood flow observed in these studies, the no observed effect levels (NOELs) were 0.345 and 0.0345 mg monensin/kg following oral and intravenous dosing, respectively.

The cardiovascular effects of monensin are similar to those observed for lasalocid. Hypothetically, based on their inotropic and chronotropic properties, ionophores were considered as potential therapies for human cardiac disease (Pressman, 1976; Hanley and Slack, 1982).

These pharmacology studies are considered relevant to the overall safety of ionophores as they provide insight into the secondary pharmacological actions and support the margins of safety for exposure in humans during the manufacturing processes or in the mixing or handling of the premixes in preparing feeds for the target species. In regard to the dog cardiovascular studies, monensin-induced increases in coronary blood flow observed at oral doses of 0.69 and 1.38 mg/kg were transient and considered not to be toxicologically important. At these doses, the respective increases of 67 and 172% in blood flow are in the physiologic range by virtue of the autoregulatory coronary flow reserve. Further, the phenomenon was not considered to be deleterious because recognized indicators of cardiovascular toxicity, such as increased blood pressure and/or heart rate, were not observed concurrently in the oral study. If it can be assumed that the relative potency of IV dosing to produce increased blood pressure is 11 times greater than by oral dosing (Holland, 1978), then the equivalent dose of 1.52 mg monensin/kg given orally by capsule would be expected to produce this change. According to Pressman

and Fahim (1983), a single oral dose of 2.0 mg/kg in dogs produced increased heart rate and arterial pressure for up to 2 hours after dosing, hence the lower dose of 1.38 mg monensin/kg may be considered as the no observed adverse effect level (NOAEL). If one takes 0.69 mg monensin/kg as a pharmacologically significant oral dose and 0.345 mg/kg as a NOEL for humans, then a 60 kg person would require 41.4 mg of monensin to manifest a transient effect on coronary blood flow while 20.7 mg monensin will have no effect (Donoho, 1984).

Human exposure to systemic levels of monensin and other ionophores high enough to produce any toxicological effects is very unlikely. With the use of safety equipment and close adherence to good manufacturing practices (GMPs) and label instructions, personnel manufacturing and handling ionophore products should not be subjected to undue risk. Furthermore, it is highly unlikely for these exposures to occur in humans consuming meat and milk products from animals fed a complete feed formulated with ionophores because residues are extremely low (Novilla, 2004).

## Pharmacokinetics

Tissue residue and metabolism studies were required to be conducted on all marketed ionophores to support human safety. For monensin, several studies with both  $^{14}\text{C}$ -monensin and unlabeled compound have shown that following oral administration in cattle and other species, monensin is rapidly absorbed and extensively metabolized by the liver and that most of the administered monensin and its metabolites are excreted in the bile. Results of biochemical studies on the metabolic fate of monensin in animals have been published (Davison, 1984; Donoho, 1984; Atef *et al.*, 1993; Nebbia *et al.*, 2001). The metabolite pattern for monensin is similar in cattle, chickens, rats, turkeys, sheep and pigs. Metabolite characterization studies indicated that hydroxylation (*o*-demethylation and oxidation) is the primary metabolic pathway of monensin resulting in low concentrations of a large number of polar metabolites in the feces of  $^{14}\text{C}$ -monensin-dosed animals. The pattern of metabolites in cattle and rats is similar. Based on radiolabeled studies in steers and dairy cows, the liver had the highest total monensin residue following zero withdrawal (Davison, 1984; Donoho, 1984; Kennington *et al.*, 1995). Parent monensin and five metabolites were identified in liver, bile and/or feces from monensin-treated steers and dairy cows. Studies have shown that metabolite M-1 (*o*-desmethyl monensin) was 20 times less active than parent monensin, the marker residue. Hence, the suspected first step in monensin metabolism appears to eliminate most of the biological activity. Plasma levels of monensin are low and decline rapidly in cattle treated with monensin. In cattle administered

$^{14}\text{C}$ -monensin, residues of radioactivity depleted rapidly from the tissues. In a recent tissue residue study, no monensin was detected in extracted fat, liver, kidney and muscle tissues from cattle given feed containing 100 ppm to provide a dose of 0.9 mg monensin/kg body weight/day for 28 days (Coyle and Walker, 2005). Feeding of muscle, liver and other viscera from cattle provided dietary levels of 165 ppm monensin (five times the approved use level) to rats and dogs for 3 months produced no adverse effects. Moreover, monensin does not accumulate in tissues of animals even when given intoxicating doses (Donoho, 1984; Atef *et al.*, 1993). Thus, exposure of humans to residues of monensin in meat or milk from animals treated according to the label instructions will be very limited and will be due primarily to the parent compound. Furthermore, when residues, primarily the parent compound, are present in animal products intended for human consumption, they will be at minimal levels for which a sufficient margin of safety has been demonstrated in the toxicology studies (Novilla, 2004).

Pharmacokinetic studies with other marketed ionophores generated data similar to that of monensin. Results of these studies in the FOI summaries facilitated determination of the safe residue concentration, acceptable daily intake, marker residue and tolerance, and withdrawal time by the U.S. FDA.

## MECHANISM OF ACTION

Carboxylic ionophores are known to form cationic ( $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Ca}^{++}$ ) complexes that enhance their transport across bimolecular lipid membranes (Pressman, 1976; Pressman and Fahim, 1982, 1983; Taylor *et al.*, 1982; Reed, 1982; Mollenhauer *et al.*, 1990). However, ion proclivities differ and evidence gathered in various laboratories indicates that carboxylic ionophores may have multiple effects at the cellular level. (See Figure 97.2.)

In this diagram, monensin, classified as an  $\text{Na}^+$  selective ionophore, binds to  $\text{Na}^+$  outside the cell, carries it into the cell and produces higher intracellular concentrations of  $\text{Na}^+$ . Influx of  $\text{Na}^+$  is counterbalanced by an efflux of  $\text{K}^+$  but, since  $\text{K}^+$  efflux is slow, an initial efflux of proton ( $\text{H}^+$ ) occurs, which may result in intracellular alkalosis. With salinomycin and narasin and others that show  $\text{K}^+$  selectivity, the  $\text{K}^+$  egress is countered by an initial  $\text{H}^+$  ingress, which could result in intracellular acidification. Salinomycin and narasin preferentially complex  $\text{K}^+$  over  $\text{Na}^+$  at a ratio of 4:1. An ionophore-mediated rise in intracellular  $\text{Na}^+$  is known to increase the intracellular levels of  $\text{Ca}^{++}$  due to an ATPase-driven exchange mechanism at the cell membrane. Monensin was reported to shorten the duration of the action

**FIGURE 97.2** Diagram of cation ion exchange diffusion across plasma membranes facilitated by monensin. Large arrows indicate major transport activity.

**FIGURE 97.3** Effect of ionophores on ion and water dynamics in the coccidia. M = monensin. From [Thomas et al. \(1985\)](#) Elanco Animal Health.

potential and suppressed the pacemaker potential in cardiac tissue ([Novilla, 2004](#)). These membrane current effects were related to transmembrane alterations in the gradients of  $\text{Na}^+$  and  $\text{K}^+$  ions and to increased intracellular  $\text{Ca}^{++}$  following the increase in cytoplasmic  $\text{Na}^+$  concentration, probably via an  $\text{Na}^+/\text{Ca}^{++}$  exchange mechanism. Lasalocid directly translocates  $\text{Ca}^{++}$  because it forms complexes with divalent cations with a range of complexing and transport capabilities including primary amines, e.g., catecholamines ([Hanley and Slack, 1982](#)). Monensin also causes release of catecholamines from cultured adrenal chromaffin cells, and salinomycin causes a multifold augmentation of plasma catecholamines in animals. Catecholamines and toxic oxidation products have been implicated in myocardial necrosis through greater influx of  $\text{Ca}^{++}$  and formation of free radicals.

By special immunohistochemistry staining, monensin treatment was shown to increase  $\text{Na}^+\text{K}^+$ -ATPase and  $\text{Ca}^{++}$ -ATPase and NO synthase activities in the heart of chickens ([Calo et al., 2002, 2003](#)). Nitric oxide, the product of NO synthases, is recognized as a regulator of calcium homeostasis. Alterations in the concentrations of  $\text{Ca}^{++}$  and other cations extracellularly as well as changes in their intracellular distribution have been associated with changes in subcellular organelles and cell damage ([Shier and DuBourdieu, 1992; Calo et al., 2002, 2003; Sandercock and Mitchell, 2004](#)).

Carboxylic ionophores directly affect the asexual and sexual developmental stages of *Eimerian* coccidia by causing the normal transport of  $\text{Na}^+$  and  $\text{K}^+$  ions to fail ([Smith and Galloway, 1983](#)). In studies with free *Eimerian* sporozoites, monensin causes increased  $\text{Na}^+$  levels in the parasite, increased activity of the sodium pump,

decreased intra-sporozoite ATP and stimulation of glycolysis ([Smith et al., 1981](#)). Continuous exposure to monensin results in an increased osmotic gradient within the developing sporozoan parasite. Water follows and the organisms utilize energy to maintain intracellular homeostasis. When energy is exhausted the parasite swells with damage to organelles and death ensues ([Smith et al., 1981; Mehlhorn et al., 1983](#)). While most ionophores target free coccidial stages in the intestinal lumen (sporozoites and merozoites), the first intracellular generation (trophozoites) was most sensitive to lasalocid ([Long and Jeffers, 1982](#)). (See [Figure 97.3](#).)

Similar events occur in susceptible bacteria. By reducing acetic and butyric acid producing (Gram-positive) bacteria and promoting growth of propionic acid producing (Gram-negative) bacteria, ionophores improve the efficiency of rumen fermentation resulting in a greater retention of feed energy in metabolizable nutrients ([Bergen and Bates, 1984; Russell and Strobel, 1989](#)). Monensin, lasalocid and laidlomycin have been shown to alter the molar ratios of volatile fatty acids (VFAs) such that there is increased propionate and decreased acetate and butyrate without altering total VFA concentration.

## TOXICITY

### Pathogenesis

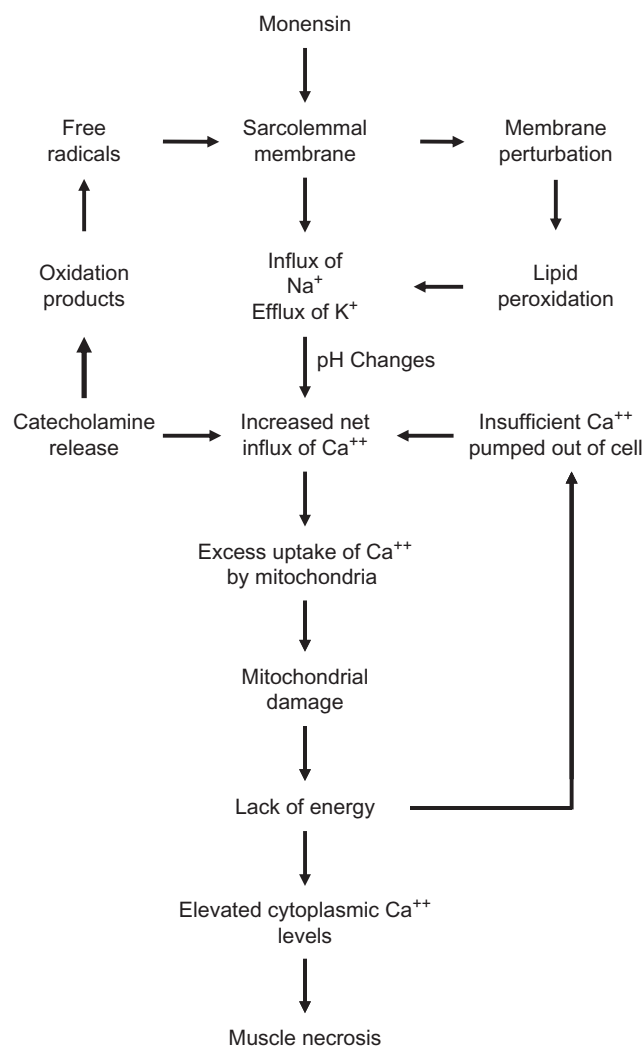

The exact mechanism of the toxicity induced by ionophores is not known. However, reasonable hypotheses have been generated based on their inherent ionophoric

activity (Van Vleet *et al.*, 1983c, 1991; Novilla and Folkerts, 1986). All ionophores facilitate transmembrane ion fluxes and dissipation of ion gradients, which are exaggerated at toxic levels. Cells respond to the metabolic insult by expending energy to maintain homeostasis. When homeostatic mechanisms are exceeded, toxicity ensues from excessive influxes of  $\text{Na}^+$  and  $\text{Ca}^{++}$  leading to degeneration and necrosis of cardiac and skeletal muscle cells. Although the ionophore mode of action is simple, four biochemical changes, including intracellular pH effects, calcium overloading, catecholamine release and lipid peroxidation, probably occur during ionophore toxicoses. (See Figure 97.4.)

In the diagram, monensin facilitates cation exchange diffusion as it intercalates with plasma membranes (Pressman, 1976; Reed, 1982). The exaggerated pharmacologic activity at toxic levels disrupts not only osmotic gradients but the intracellular pH as well. Since drastic changes in acid-base balance are incompatible with life, the pH shifts may be responsible for the peracute deaths observed with very high toxic levels of ionophores (Novilla and Folkerts, 1986). The monensin-induced entry of  $\text{Na}^+$  is followed by entry of calcium, due to an ATPase-driven exchange mechanism at the cell membrane. A calcium ionophore like lasalocid or A23817 promotes  $\text{Ca}^{++}$  entry directly. Ionophores are known to trigger the release of  $\text{Ca}^{++}$  from intracellular stores further increasing  $\text{Ca}^{++}$  levels in the cytoplasm.

Two other mechanisms contribute to calcium overloading: exaggerated release of neurotransmitters like catecholamines and increased peroxidation of lipids. Monensin, lasalocid and salinomycin have been reported, respectively, to release catecholamines from adrenal chromaffin cells, transport catecholamines directly, or augment catecholamine plasma levels. The degradation products of catecholamines have been implicated in myocardial necrosis, through the formation of free radicals and calcium influx (Reichenback and Benditt, 1982). Since ionophores are lipophilic and have detergent properties, dose-related perturbations of plasma membranes can promote increased lipid peroxidation. It is known that lipid peroxidation promotes membrane damage, and consequently increases  $\text{Ca}^{++}$  influx.

Since they are not mutually exclusive, one or more of the above pathogenic mechanisms may increase calcium concentrations in the cell. The rise in intracellular calcium can be buffered by calcium pumps in the plasma membrane, mitochondria and sarcoplasmic reticulum. However, toxicity overwhelms this buffering mechanism and a vicious cycle ensues, resulting in calcium overloading. Elevated calcium levels then activate muscle proteases and phospholipases which initiate degradative processes (disassembly of myofilaments and membrane damage) in striated muscle and ultimately cell death (Van Vleet *et al.*, 1983c, 1991; Sandercock and Mitchell, 2004).

**FIGURE 97.4** Probable sequence of events induced by monensin in muscle cells. Adapted from Novilla and Folkerts (1986).

## Occurrence

Generally, the marketed ionophore products have been found to be safe and effective in the target species provided the approved dosage ranges. However, excessive ionophore feed concentrations have resulted in the ionophore toxic syndrome (Novilla, 1992). Toxic syndromes have occurred from the following: (1) feed mixing errors or ingestion of premix concentrates with unsafe amounts of ionophores; (2) extra label use, either accidental or intentional, have resulted in adverse reactions in horses, dogs, rabbits, adult poultry, ostriches, camels, deer, water buffaloes and humans; and (3) drug incompatibilities with other compounds such as tiamulin, chloramphenicol and macrolides such as triacetyloleandomycin have also resulted in toxicity (Novilla and Muller, 2003).

Feed mixing errors have caused the most toxicity problems in animals for which ionophore use has been approved. Reports of toxicity in the target species have

been reviewed (Potter *et al.*, 1984; Novilla and Folkerts, 1986; Dowling, 1992). Among the non-target species, horses appear to be the most susceptible and fish the most tolerant to high levels of ionophores. Except for a direct exposure to a monensin premix following a barn break-in, horse toxicity cases have resulted from feed contamination at the mill. Similarly, feed mill contamination of commercial dog food, cat food and concentrate ration for ostriches have resulted in toxicoses.

In humans, there are two publications of intentional exposure to monensin. According to Kouyoumdjian and associates (2001), a 17-year-old Brazilian male admitted ingesting monensin premix (Rumensin<sup>®</sup>, exact amount unknown), probably to develop muscle. Instead he fell ill, was hospitalized and died from acute rhabdomyolysis with renal failure. Although the amount of monensin ingested in this case was not estimated, in another case cited, two deaths among six people that consumed baked goods made with premix were attributed to monensin exposure of at least 10 times the optimum daily dose fed to cattle. In another report from Brazil, a 16-year-old farm worker who ingested approximately 500mg of monensin (5 grams of Rumensin<sup>®</sup> 100 premix) "to become stronger" developed an early and severe rhabdomyolysis followed by acute renal failure, heart failure and death (Caldeira *et al.*, 2001).

In target species, culprit feeds usually contained five times the maximum approved ionophore use level in the total mix ration provided to the affected animals, with two exceptions. Toxic episodes have occurred from amending cattle and sheep rations with poultry litter (30% or above) containing maduramicin residues and incompatibilities with drugs concurrently administered via feed or drinking water (Van Vleet, 1986; Dowling, 1992; Anadon and Reeve-Johnson, 1996; Novilla and Muller, 2003). Poultry litter contained levels of maduramicin which proved to be toxic to cattle and sheep. Various antibiotics, including tiamulin, chloramphenicol, macrolides and sulfa drugs, such as sulfachlorpyrazine, have been reported to potentiate ionophore toxicity. Among drug combinations that resulted in adverse effects in cattle, chickens (Frigg *et al.*, 1983), turkeys (Weisman *et al.*, 1983) and swine (Van Vleet, 1986), the most frequently reported drug interaction is with the pleuromotilin derivative, tiamulin. According to Meingassner *et al.* (1979), tiamulin interferes with the metabolic degradation of monensin in the liver, causing the ionophore to accumulate to toxic levels. The primary step in monensin metabolism is *o*-demethylation (Donoho, 1984) which is catalyzed by several P450 enzymes (Ceppa *et al.*, 1997; Nebbia *et al.*, 2001). Witkamp *et al.* (1996) considered the formation of tiamulin metabolite inhibitory (MI) complexes with P450 enzymes to be the basis of the toxic interaction, similar to that reported with macrolide antibiotics (see review

by Anadon and Reeve-Johnson, 1999). However, Szücs *et al.* (2004) reported no evidence of tiamulin MI complexes and that tiamulin directly inhibited CYP3A and two other enzymes, CYP1A2 and CYP2E1, involved in monensin-*o*-demethylation. Whether similar alterations in ionophore metabolism occur with other drugs are not clear but is an active area of research.

The incidence of ionophore toxicity in all species appears to be low (Novilla and Folkerts, 1986). This is based on periodic reviews of product complaints submitted to the U.S. FDA, as well as from a perusal of the literature. For instance, from 1976 to June 30, 1992, Elanco Animal Health received information about 168 complaints of cattle mortality involving 2045 head where Rumensin<sup>®</sup> was being fed and suspected as a cause of death. Other causes of death were ultimately found for all but 1532 head. Of the 1532 head, most deaths were believed to have been caused by mixing errors. Approximately one-half of the deaths occurred when there were mixing errors of greater than five times the intended dose. When compared to approximately 334 million head of beef cattle that received Rumensin<sup>®</sup> during this time period, the prevalence rate of toxicity would be less than 0.0005% (Novilla and Laudert, 2009). This is remarkable considering the widespread use of ionophore products. In the U.S., more than 90% of broiler chickens and about 75% of cattle marketed yearly have consumed ionophores at least part of their lifetime. More information and reports of adverse reactions are available on monensin than for the other ionophores because of monensin's long-standing and widespread use in food animals. However, all the other ionophores can produce a similar toxic syndrome following overdose, misuse and drug interaction.

Over the years, several acute toxicity (LD<sub>50</sub>) studies have been conducted in laboratory and domestic animals with monensin, lasalocid, salinomycin and narasin. Due to a change in FDA regulations, there are limited or no LD<sub>50</sub> data for the other marketed ionophores. Available data for most species are shown in Table 97.2.

The LD<sub>50</sub> of monensin varies from 214mg/kg in broiler chickens to 1.4mg/kg in horses, the most sensitive domestic animal species to ionophore toxicoses. In ionophore toxicoses, there is a progression of events from ingestion of a particular product. Dose and time factors influence the outcome. The greatest risk of intoxication is upon initial exposure, since animals will not consume highly contaminated feed. After an overdose, repeated daily intake of high levels of ionophores is not possible when anorexia occurs (Potter *et al.*, 1984; Matsuoaka *et al.*, 1996).

Laboratory and field studies have shown that there is a threshold dose for individual ionophores below which no adverse effects are observed. Safety studies have shown that consumption by horses of complete feed

containing the maximum approved level of monensin for cattle is harmless. This is probably true for lasalocid and laidlomycin as well since there are no confirmed reports of ionophore toxicoses in horses used in cattle feedlots.

Results of acute toxicity studies with ionophores in domestic animals indicate that the horse is the most sensitive species; the chicken least sensitive; and cattle intermediate. From studies in ponies given toxic doses of monensin, Amend *et al.* (1981) found that the death pattern from single, high toxic doses by gavage varied from peracute death in less than 24 hours; acute death in 24 to 96 hours; subacute death in 4 to 14 days; and chronic death after 14 days. The latter is not a chronic toxicity by definition, but delayed death secondary to congestive heart failure (CHF), a recognized consequence of ionophore toxicoses. Death from CHF may occur in some animals that survive the acute toxic episode depending on the affected area in the heart and the cardiac reserve. In cattle, peracute death from monensin toxicity has not occurred. In fact, no deaths have been recorded earlier than 3 days even after high-level (LD<sub>50</sub>) toxic exposure (Potter *et al.*, 1984).

Blood-level studies suggest that horses, compared to cattle, are not able to clear monensin rapidly from the blood (Donoho, 1984). This was probably related to the oxidative efficiency of P450 demethylating enzymes in the liver. Working with liver microsomes from horses, pigs, broiler chicks, rats and cattle, Nebbia and associates (2001) found that horses had the lowest catalytic

TABLE 97.3 Effect of feeding monensin in complete feed to horses for 28 days

Monensin level	Effect
33 ppm (cattle use level)	Transient anorexia <sup>a</sup>
121 ppm (broiler use level)	May be toxic
330 ppm (10 × cattle use level)	Lethal

From Matsuoka *et al.* (1996).

<sup>a</sup>Occurred in week 2 and 3 of the study.

efficiency which may explain the greater susceptibility of horses to the ionophore-induced toxicosis, relative to the other species. However, not all levels of monensin are toxic to horses (Matsuoka *et al.*, 1996). In a sub-chronic feeding study in horses, all three horses provided a complete ration containing 330 ppm monensin (or 300 grams/ton, 10 times the maximum cleared level of monensin in complete feeds for feedlot cattle) and one out of three horses given 121 ppm monensin died during the 1-month feeding period. However, three horses provided 33 ppm monensin maintained typical levels of feed intake and suffered no ill effects attributable to treatment (see Table 97.3).

After evaluating the effects of monensin in either supplements or blocks in pasture horses, Matsuoka and co-workers (1996) made the following conclusions that may apply to other marketed ionophores as well: (1) horses on pasture may consume, at initial exposure, enough supplement containing high levels of monensin to be

toxic and/or lethal; (2) following an initial high-level monensin exposure, consumption of treated feed, supplement or block is negligible; and (3) horses can consume certain levels of monensin without suffering any ill effect indicative of toxicity.

## Clinical signs

Physical signs reported for ionophore toxicoses across several animal species are as follows: anorexia, diarrhea, depression, hypoactivity/reluctance to move, dyspnea, leg weakness, ataxia and recumbency. Most of these clinical signs occur in all animals studied but variations in their occurrence have been observed. For instance, diarrhea is commonly observed with monensin toxicity in cattle and poultry but has not been reported in either horses or dogs. The most consistent clinical sign in animals that have ingested toxic levels of ionophores is partial to complete anorexia (Novilla and Folkerts, 1986).

In chickens, anorexia is associated with diarrhea, drowsiness, extreme weakness and sternal recumbency with legs extended posteriorly. In target animal safety and toxicity studies, depression of growth and feed conversion as well as higher mortality occur in broilers fed five times the recommended level of monensin for 8 weeks (Novilla, 2004). Broiler breeders exposed to high levels of ionophores manifest severe drops in egg production, anorexia, depression, paralysis and death in sternal recumbency. Similar signs were reported in turkeys with toxicity induced by monensin, salinomycin and narasin (Salyi *et al.*, 1988). Mortality was variable but high death losses (up to 96.7%) were recorded with salinomycin (Halvorson *et al.*, 1982).

In cattle, clinical signs of monensin toxicosis include anorexia, diarrhea, ataxia, recumbency, depression and non-responsiveness to visual stimuli (Van Vleet *et al.*, 1983c; Potter *et al.*, 1984; Novilla and Muller, 2003). There is a definite correlation between onset of clinical signs and amount of monensin consumed. All intoxicated cattle manifest partial to complete anorexia. Severely intoxicated animals develop anorexia within 24 h. Animals exposed to lower levels may take up to 48 h to develop anorexia. Diarrhea usually is evident in 24 to 48 h in animals receiving high doses of monensin. Exposure to low doses may result in a delay of up to 5 days in the onset of diarrhea. Onset of depression follows a similar pattern, being observed by day 3 in animals receiving excessive monensin overdoses while being observed after 1 week in animals receiving less than excessive overdoses. Rapid breathing and ataxia may be present only in animals that have consumed extremely high levels. In cattle, death occurs without any manifestations of struggle.

Galitzer and coworkers (1982) found that lasalocid-intoxicated cattle manifested early signs of forced watery

diarrhea, muscle tremors and greater cardiac and respiratory rates followed by or concurrent with anorexia. Delayed signs of cardiac insufficiency were evident 7 to 10 days after administration of the toxic dose. The temporal occurrence of clinical signs and mortality from ionophore toxicity was clearly documented by Potter *et al.* (1984) in a multiple bolus dosing trial with monensin in cattle (see Table 97.4).

The onset and severity of toxic effects induced by monensin were dose related. In the study, anorexia was the most consistent clinical sign of toxicity and no deaths occurred earlier than 4 days after exposure to high toxic doses of monensin. However, multiple bolus dosing does not simulate actual field conditions since repeated exposure to toxic levels is not possible when anorexia occurs. Further, the onset and severity of toxicity from bolus dosing is different than that via feed (Buck *et al.*, 1976).

Sheep and goats have clinical signs similar to cattle (anorexia, diarrhea, ataxia) but affected lambs frequently exhibit labored breathing, frothing at the mouth and kicking at the abdomen (Agaoglu *et al.*, 2002; Novilla and Muller, 2003). Dogs with ionophore toxicoses become weak and develop a rapid onset of paresis progressing to flaccid paralysis of the anterior and posterior limbs, tongue laxity and dyspnea (Safran *et al.*, 1993; Condon and McKenzie, 2002; Novilla and Muller, 2003; Segev *et al.*, 2004). In pigs, anorexia, diarrhea, lethargy, dyspnea, ataxia, knuckling at the fetlock and myoglobinuria were present prior to lateral recumbency and death from ionophore toxicoses (Van Vleet *et al.*, 1983a,b; Plumlee *et al.*, 1995).

As in cattle and other species, anorexia is the first and most consistent clinical sign finding in the horse with ionophore toxicoses (see Table 97.5).

Diarrhea has not been observed with either monensin or lasalocid but was reported with salinomycin and narasin (Whitlock *et al.*, 1978; Novilla and Folkerts, 1986; Matsuoka *et al.*, 1996; Novilla and Muller, 2003). Profuse sweating was also observed with monensin, salinomycin, narasin and laidlomycin but not with lasalocid toxicity. Horses with leg weakness and ataxia generally progress to recumbency. Once recumbent, horses frequently attempt to rise with thrashing of the limbs until death supervenes. This is in contrast to cattle that die without signs of struggling.

## Post-mortem findings

Necropsy findings in animals with ionophore toxicoses include hemorrhages and pale areas in the heart, pale areas in some limb muscles, pulmonary edema, hydrothorax, ascites and inflammation of the stomach and intestines (Van Vleet *et al.*, 1983a,b,c; Galitzer *et al.*, 1986a,b; Novilla and Muller, 2003). Animals that die

soon after exposure often will have no lesions, since they had not had time to develop or they may be masked by post-mortem changes. Those with lethal doses surviving longer than a week may have hydropericardium, pulmonary edema, hydrothorax, ascites, reddish-mottled liver and subcutaneous edema of the abdomen and limbs. (See Figures 97.5 and 97.6.)

At necropsy, cutting the ventricular and thigh muscles transversely often shows the diffuse pallor of myonecrosis induced by toxic levels of ionophores. Skeletal muscle lesions may be quite severe in sheep, pigs and dogs, moderate in cattle and minimal to slight in horses. For this reason, myoglobinuria, evidenced by red urine, has been observed in pigs, sheep and dogs but not in cattle or horses.

## Histopathologic findings

Target organs damaged by toxic doses of monensin and other ionophores were identified to include the heart and skeletal muscles in all species studied (Todd *et al.*, 1984; Novilla and Folkerts, 1986; Van Vleet *et al.*, 1991; Dowling, 1992; Novilla and Muller, 2003). In addition, neurotoxic effects have been reported for lasalocid (Shlosberg *et al.*, 1985; Safran *et al.*, 1993), narasin (Novilla *et al.*, 1994) and salinomycin (Van der

Linde-Sipman, 1999). The development of muscle lesions varies among species. The heart is primarily affected in horses, skeletal muscle in pigs and dogs, and there is about equal tissue predilection in rats, chickens and cattle. Morphologic effects include degeneration, necrosis and repair of cardiac and skeletal muscle fibers with a variable inflammatory component and secondary lesions of congestive heart failure. Neuropathic changes occurred in peripheral nerves and the spinal cord. Focal swelling, fragmentation, loss of axons and formation of digestion chambers filled with macrophages were observed in both sensory and motor nerves, and there was vacuolation with swelling, degeneration and fragmentation of myelin sheaths and axons in the spinal cord.

The most important change is a toxic myopathy characterized by focal areas of degeneration, necrosis and repair in cardiac and skeletal muscles with a variable inflammatory component (Novilla and Folkerts, 1986; Van Vleet *et al.*, 1991). Muscle lesions are similar to those described for compound A204, the first polyether antibiotic tested at Lilly Research Laboratories (Todd *et al.*, 1984). Doses and time factors influence the severity and distribution of lesions in ionophore toxicoses. (See Figures 97.7 and 97.8.)

Generally, no significant lesions are seen by light microscopy in animals that die immediately, and animals

**FIGURE 97.5** Thoracic and abdominal viscera from a mare that died 7 days following a single gavage dose of 1.65 mg monensin/kg body weight. Note the fluid accumulation in the body cavities and the pale areas and epicardial hemorrhages on the heart.

**FIGURE 97.7** Early necrotic focus in the left ventricle of a gelding that died 20 hours following gavage with 2.5 mg monensin/kg body weight. Necrotic muscle fibers have sparse infiltration of neutrophils and lymphocytes. H&E. Original magnification  $\times 64$ .

**FIGURE 97.6** Diffuse pallor in cross-sections of the heart from the same mare described in [Figure 97.5](#) legend.

**FIGURE 97.8** Larger foci of myofiber necrosis with contraction bands in the interventricular septum from a horse euthanized 72 hours following a single oral dose of 1.65 mg monensin/kg body weight given by gavage. More cellular infiltrates with lymphocytes, macrophages and few eosinophils are present. H&E. Original magnification  $\times 10$ .

that die after an acute course may have only a few scattered degenerated fibers in the heart and highly active muscles, such as the diaphragm. Lesions are most pronounced within 7 to 14 days following ingestion of a toxic dose and are accompanied by profound attempts at repair. Skeletal muscle fibers regenerate rapidly, and

lesions are completely healed in about a month. Heart muscle fibers do not regenerate, but repair takes place by replacement fibrosis. Secondary lesions of congestive heart failure, including heart dilatation and hydropericardium, lung edema, liver necrosis and fluid accumulation in the thoracic and abdominal cavities, may be present, depending upon the severity of heart damage and the potential cardiac reserve. (See [Figures 97.9](#) and [97.10](#).)

Observations to date indicate that in horses the heart suffers the greatest damage from monensin toxicoses with little or no involvement of skeletal muscles. This finding is in contrast to dogs and pigs in which

**FIGURE 97.9** Skeletal muscle from a steer that died 6 days after a gavage dose of 39.8mg monensin/kg body weight. Notice the fragmented and regenerating fibers. H&E. Original magnification  $\times 80$ .

**FIGURE 97.10** Hearts from animals that survived acute ionophore toxicity. (Left panel) Section of left ventricle with focal interstitial fibrosis from another steer, cohort of that described in Figure 97.9 legend, euthanized 28 days after a gavage dose of 39.8mg monensin/kg body weight. H&E. Original magnification  $\times 20$ . (Right panel) Interstitial fibrosis in the left ventricle from a gelding that survived a gavage dose of 2mg monensin/kg body weight for 4 months. Masson's trichrome. Original magnification  $\times 32$ .

the lesions are most pronounced in skeletal muscles. Chickens, cattle and rodents have about equal predilection for cardiac and skeletal muscle lesions.

### Other laboratory findings

Mitochondrial swelling, myelin figures and lipid vesicles were observed ultrastructurally in cardiac and skeletal muscles of ponies given monensin at 4mg/kg and observed for 79h (Mollenhauer *et al.*, 1981). Early

**TABLE 97.6** Some biomarkers of ionophore toxicity

Bilirubin	

degenerative changes of sarcoplasmic vacuolation from swollen mitochondria and accumulation of lipid were described in cattle and pigs with monensin toxicosis (Van Vleet *et al.*, 1991). Severely injured mitochondria had marked swelling, disrupted cristae and dense matrical granules. Scattered myelin figures were present in muscle cells with numerous disrupted mitochondria. Subsequently necrosis occurred in degenerated myocytes and was characterized by dense fibers with intact sarcomeres or disrupted fibers with hypercontraction bands. Necrosis was followed rapidly by extensive macrophage infiltration with lysis of disrupted organelles and contractile material. Similar ultrastructural findings were observed in hearts and skeletal muscles of sheep given monensin and in skeletal muscles of broilers simultaneously given triacetyloleandomycin in the drinking water and monensin in the feed (Dowling, 1992). Regeneration as evidenced by myoblast proliferation was observed as early as 4 days post-treatment in pigs and sheep.

Hematologic parameters are not significantly affected by ionophore toxicosis (Van Vleet *et al.*, 1983a,b,c; Condon and McKenzie, 2002; Segev *et al.*, 2004). Elevation of serum enzymes, notably creatine kinase, lactate dehydrogenase and aspartate transaminase, may indicate damage to cardiac and skeletal muscles (Amend *et al.*, 1981; Van Vleet *et al.*, 1983b,c; Galitzer *et al.*, 1986b; Wilson, 1990). Alkaline phosphatase, inorganic phosphorus and total bilirubin levels are also higher, while serum levels of calcium and potassium are lower. (See Table 97.6.)

The progressive hypokalemia and attendant cardiac conduction disturbances demonstrated in ponies were considered the life threatening events in early acute monensin toxicosis (Amend *et al.*, 1981).

### Diagnosis and differential diagnosis

Since all ionophores in the market place are likely to produce a similar toxic syndrome in overdosage and misuse situations, six important criteria must be considered before a diagnosis of toxicity is given (Novilla and Muller, 2003). These include (1) history of feed-related problem, usually affecting a group of animals; (2) ionophore laboratory assays; (3) clinical signs manifested during the toxicity episode; (4) gross post-mortem

lesions; (5) microscopic pathology; and (6) exclusion of nutritional, infectious and other toxic factors.

History assumes great significance when the problem is connected to the introduction of newly formulated feed or supplement to the herd or flock. Since clinical signs and lesions are not pathognomonic, feed analysis for the amount and type of ionophore in the ration is necessary for diagnosis. With the availability of seven ionophores in the market place, the use of an efficient and highly selective laboratory assay is indicated. Newer methods have been developed to determine one or more ionophores in feeds and tissues (Bertini *et al.*, 2003; Ebel *et al.*, 2004). Several samples of the feed should be submitted for analysis, including residual material from the feeder, trough, auger, or feed bin. Feed assays may prove exposure to a particular product but significantly higher than the recommended levels must be found for a confirmatory diagnosis. Otherwise, concurrent use of an incompatible drug must be documented. Absent proof of a gross feed mixing error, a wide list of differential diagnoses need to be excluded in order to return a presumptive diagnosis.

Initially, ionophore toxicoses may be suspected when there is a history of a feed-related problem in a group of animals; clinical signs of anorexia, diarrhea, labored breathing, depression, locomotory disorder, recumbency and death; lesions affecting heart and skeletal muscles; or congestive heart failure. The clinical signs and lesions induced by toxic levels of ionophores are not pathognomonic. However, recent introduction of newly formulated feed or supplement to a flock or herd in which signs and lesions are present may cause one to suspect that acute intoxication has occurred. Dose and time factors influence the severity and distribution of lesions. Animals that die soon after exposure may not have muscle lesions discernible by light microscopy. Lesions are likely to be found in animals that survived longer than a week. The most active skeletal muscles may be involved when the heart is not affected or is only slightly affected. Since changes can be missed because of their focal distribution, more intense tissue sampling to include one section each of the atria, ventricles and interventricular septum of the heart, the diaphragm and muscles of the abdomen and thigh is desirable. Some animals with substantive heart damage from very high levels of monensin and other ionophores may later develop congestive heart failure.

Although a presumptive diagnosis of ionophore toxicosis can be made based on history, clinical signs, lesions and considerations of differential diagnosis, specific assays are needed for confirmatory diagnosis. With seven ionophores currently in use, the need for confirmatory laboratory assays cannot be overemphasized. In monensin toxicosis, values greater than five times the recommended use level in the feed provided affected animals are usually confirmatory. Assays on stomach contents from per acute and acute cases of toxicity can prove

exposure but values obtained have been low. Only minimal residues of monensin have been detected in target tissues of cattle and chickens given monensin (Donoho, 1984; Atef *et al.*, 1993). Further, blood levels of monensin are low or undetectable even in intoxicated animals and accumulation in target tissues does not occur.

Ionophore toxicosis may be confused with acute infectious diseases, deficiencies and other intoxications (Van Vleet *et al.*, 1983a,b,c; Novilla and Folkerts, 1986; Dowling, 1992; Novilla and Muller, 2003). In the differential diagnosis of monensin toxicosis, myopathic conditions should be considered first. In cattle, these would include (1) ionophore toxicoses, (2) vitamin E and selenium deficiencies, (3) poisonous plant ingestion, e.g., senna, coyotillo, white snakeroot, vetch, and (4) the common, yet puzzling, sudden death syndrome with myocardial necrosis. Ionophore toxicosis usually involves an accompanying history of feed supplementation or feed change and usually involves many animals. Clinical signs are anorexia, diarrhea, lethargy, ataxia and the suggestion of damage to striated muscles. Vitamin E and selenium deficiency occurs sporadically and produces prominent degeneration and necrosis with calcification of cardiac and skeletal muscles. Plant poisonings are usually localized to areas where the toxic plants are indigenous. For instance, coffee senna (*Cassia occidentalis*) poisoning occurs in the southeastern United States. It may cause anorexia, diarrhea and the production of dark urine, but generally causes more pronounced lesions in skeletal muscles than in the heart. The coyotillo plant (*Karwinskia huntholtiana*) in southwest Texas and Mexico produces limberleg in sheep and goats characterized by progressive weakness of the legs, muscular incoordination, recumbency, respiratory distress and death. Lesions are observed both in cardiac and skeletal muscles as well as peripheral nerves and the liver. White snakeroot (*Eupatorium rugosum*), a plant indigenous to much of eastern Canada and the United States, causes "trembles" in goats, sheep, cattle, horses and swine. Cardiac and skeletal muscle lesions may be present in animals that ingested this plant. However, with trembles there is constipation, blood in feces, an odor of acetone in the breath and severe fatty degeneration in the liver and kidney that are not seen in ionophore toxicities. Hairy vetch (*Vicia villosa*) also produces myocardial necrosis but, unlike monensin toxicosis, it produces dermatitis, conjunctivitis and abortion as well as lesions in the kidneys, adrenal glands, lymph nodes and thyroid gland. The syndrome of sudden death with myocardial necrosis in cattle, especially calves, is common but sporadic in occurrence and is associated with lesions in cardiac but not skeletal muscle (Bradley *et al.*, 1981). Hence, clinical history and detailed pathologic studies will help distinguish among ionophore toxicosis, acute infectious diseases, deficiencies and other intoxications.

From a clinical standpoint, respiratory diseases, particularly infectious bovine rhinotracheitis and the shipping fever complex, are initially considered in the differential diagnosis for cattle because of the respiratory difficulties that occur with ionophore toxicosis. At necropsy, however, pneumonic lesions are consistent with these diseases. Animals with acute bovine pulmonary edema and emphysema or fog fever, nitrogen dioxide intoxication, or rape, turnip, or kale poisoning also exhibit respiratory difficulties; but, in these conditions, gross lesions will include severe interstitial and interlobular emphysema or pneumonia or both rather than edema. The incoordination, stiff wobbly gait and loss of visual reflexes may lead one to suspect polioencephalomalacia and thromboembolic meningoencephalitis but, in these conditions, histologic lesions present in the brain are confirmatory. Unequivocal central nervous system lesions have not been found in cases of monensin toxicity in any species. However, lesions in the spinal cord and peripheral nerves occurred with lasalocid toxicosis in chickens (Shlosberg *et al.*, 1985). Peripheral neuropathic changes have also been reported in cats exposed to salinomycin-contaminated feed (Van der Linde-Sipman *et al.*, 1999) and in dogs given narasin (Novilla *et al.*, 1994). Salt poisoning will cause nervous signs, paralysis and diarrhea, but knowledge that insufficient amounts of water were available to the animals will also point to this problem. Eosinophilic meningoencephalitis is pathognomonic for salt poisoning in pigs, but this lesion does not occur in other species. Laboratory procedures used to confirm a diagnosis include assays of serum, cerebrospinal fluid and brain tissue for sodium concentrations (Buck *et al.*, 1976). In cattle, urea toxicosis must be considered when sudden collapse, bloat, violent convulsions, terminal tetanic spasms and high death losses occur within 10 min to 4 h from exposure to newly formulated feed. Deaths occurring earlier than 72 h have not been reported in cattle gavaged with high doses of monensin (Potter *et al.*, 1984).

In poultry, differential diagnoses should include nutritional (focal) myopathy, coffee senna toxicity, botulism, sodium chloride (salt) toxicity, mycotoxicosis by cyclopiazonic acid and other myopathic mycotoxins, round heart disease and, in the turkey, the knockdown (downer) syndrome. Although no striated muscle lesions are produced in botulism and sodium chloride toxicity, clinical signs of limber neck and lesions of "water belly" may be confused with ionophore toxicoses. On the other hand, birds affected with salt poisoning may have enlarged hearts or have enlarged pale kidneys from urate nephrosis. Monensin *per se* does not produce "barebacks" in broiler chickens, and downers among replacement birds may be suffering from viral arthritis. Therefore, this common reovirus infection must be excluded as a cause of the problem in chicken flocks. In commercial turkeys reared in confinement, focal myopathy has been attributed to

deficiencies in vitamin E or selenium associated with rapid growth (Wilson *et al.*, 1990). Nutritional myopathy may mimic skeletal muscle lesions induced by ionophore toxicoses; but unlike those of nutritional myopathy, ionophore-induced lesions are monophasic and polyfocal with little or no mineralization. Muscle lesions also occur in deep pectoral myopathy, coffee senna toxicity and toxicoses from the mold toxins, cyclopiazonic acid and moniliformin. Their clinical presentation and presence of other lesions will help distinguish these conditions.

Round heart disease, also known as round heart-edema-ascites syndrome or spontaneous cardiomyopathy, occurs sporadically in turkeys and other fowl (Czarnecki, 1984). Clinical signs indicate the presence of heart failure but the exact cause has not been determined. A genetic predisposition has been suggested because it is more common in certain lines of turkeys, particularly those having a rapid rate of early muscle development. Some of the predisposing factors include low levels of oxygen and high levels of carbon dioxide in the incubator, poor brooder house ventilation and overcrowding during transport. Exposure to these factors may occur days or weeks prior to onset of illness. In contrast, monensin toxicity occurs as a sudden outbreak in a flock of birds accidentally provided toxic levels due to a feed mixing error. Among birds that survive the acute toxic episode, a few, depending upon the extent and location of heart damage and the potential cardiac reserve, may subsequently develop dilatation of the heart and secondary signs of congestive heart failure.

Another condition that needs to be distinguished from monensin toxicity is the turkey knockdown syndrome. Turkey knockdown has been defined as any condition affecting the neuromuscular system to the extent that a bird is unable to stand or walk (Wages, 1993). A necrotizing myopathy, particularly of the rear limbs, has been reported in turkeys with the knockdown syndrome (Cardona *et al.*, 1993). Unfortunately, striated muscles have limited responses to injury (Van Vleet *et al.*, 1991) and lesions induced by any ionophore, including monensin, are not pathognomonic (Novilla, 1992). Although monensin feed inclusion rates in knockdown cases are within or slightly above the maximum recommended level of 99 ppm (Wages, 1993; Cardona *et al.*, 1993) monensin has been implicated as a causative factor because the clinical and pathologic findings are similar to those induced by monensin toxicity. However, unlike monensin toxicity, the turkey knockdown syndrome is characterized by: (1) low incidence and fatality rates; (2) acute onset of paresis/paralysis; (3) no anorexia, birds will eat if able to reach feeders; (4) no diarrhea; (5) affected birds are alert; (6) unable to vocalize; (7) presence of widespread skeletal muscle lesions that are subacute to chronic in character, generally no heart lesions; and (8) rapid recovery following change of feed. These

observations were confirmed in an epidemiological, case controlled study of knockdown cases in the Shenandoah Valley of Virginia that evaluated various factors, including management, environment, health, feed, water, pathology and clinical pathology analytes (Evans *et al.*, 2000). Serum vitamin E levels were significantly lower in affected birds (Meldrum *et al.*, 2000). Feed and/or water intake alterations were highly correlated with the incidence of turkey knockdown and modification of practices affecting feed/water intake reduced the incidence of knockdown in one farm from 6 in 1999 to 0 in 2000.

In pigs, vitamin E and selenium deficiency, gossypol poisoning and porcine stress syndrome (PSS) should be considered in the differential diagnosis since skeletal or cardiac lesions may be found in these conditions (Van Vleet *et al.*, 1983b, 1986). In monensin toxicosis, the striated muscle lesions appear more frequently and are more severe in skeletal muscle than in cardiac muscle. Myoglobinuria may also be present. Widespread cardiac and skeletal muscle lesions, vascular damage, dietetic hepatitis and gastric ulceration may be found in vitamin E and selenium deficiency. With PSS, cardiac and skeletal muscle lesions may or may not be observed following a history of stress.

For horses, the exertional myopathies, such as equine rhabdomyolysis (Monday morning disease) and hyperkalemic periodic paralysis, plant poisoning from coffee senna and white snakeroot, should be excluded along with blister beetle intoxication, colic and laminitis (Whitlock *et al.*, 1978; Amend *et al.*, 1981; Novilla and Folkerts, 1986). Complete herd history, clinical examination, successful supportive treatment and necropsy may help differentiate these conditions from ionophore toxicoses.

## TREATMENT

When ionophore toxicity is suspected, a feed change to a non-ionophore medicated ration must be made immediately and the affected group(s) of animals maintained on this ration until all diagnostic procedures are completed. In cattle presumably diagnosed with monensin toxicity, it is advisable to replace the suspected culprit feed with feed known to contain the approved concentration of monensin. This allows the rumen microbes of unaffected cattle to remain adapted to monensin and will promote overall herd performance (Novilla and Laudert, 2009). At the present time, there is no known antidote or treatment for ionophore toxicity. Although previous antidotal trials failed, the search continues (Mitema *et al.*, 1988). Nonetheless, it may be difficult to find a drug that can block up to four pathogenic mechanisms, acting singly or in concert, that are involved in the toxicoses.

Therapeutic interventions have been largely supportive. For horses, Amend *et al.* (1981) recommended supportive treatment with mineral oil, activated charcoal and aggressive fluid and electrolyte replacement with potassium and phosphorus supplementation, including means to reduce cardiac work. However, supportive therapy may not be practical on a herd or flock basis.

Van Vleet and coworkers (1983a, 1986, 1987) obtained protection against the development of *clinical* monensin toxicity in pigs treated with selenium and vitamin E (selenium as selenite at 0.25mg/kg and vitamin E as  $\alpha$ -tocopherol acetate at 17IU/kg) prior to a single oral dose of 50mg monensin/kg ( $LD_{50}$   $16.7 \pm 3.57$  mg/kg). A similar regimen in cattle administered toxic doses of monensin provided only partial protection but clinical signs in pigs with tiamulin-induced salinomycin toxicity were ameliorated following administration of vitamin E. The protection against the toxicoses was theorized to be produced by stabilization of cellular membranes since selenium and vitamin E are known to prevent and control peroxidation-mediated cellular injury (Tappel, 1981; Van Vleet, 1986). Similarly, the antioxidant property of zinc prevented adverse effects of salinomycin in chickens (Kamashi *et al.*, 2004). Monensin, like all polyether carboxylic ionophores, is lipophilic and may produce dose-dependent membrane perturbations and increased lipid peroxidation, which could lead to degradative processes. Further studies are needed to determine whether antioxidants, such as vitamin E and selenium, or zinc administration may have important roles in the prevention and treatment of ionophore toxicoses.

Until proper and effective therapy is available, prevention of ionophore toxicoses by (1) proper use from the implementation of good feed manufacturing and feeding practices at the feed mill and farm level; (2) avoidance of overdosing of feeds for approved species, which may carry over to feeds for non-target species; and (3) adherence to species restrictions will help prevent the adverse effects associated with this class of compounds.

## CONCLUSIONS

Seven ionophores – monensin, lasalocid, salinomycin, narasin, maduramicin, laidlomycin and semduramicin – are marketed globally for use as anticoccidial drugs for poultry and/or growth promotants in ruminants. Off-label usage of ionophore products is known to occur since other uses continue to be investigated and applied in many countries. It is likely that basic and applied research on these versatile compounds could lead in the future to product line extensions to other target species and potential development of novel therapeutics for unmet needs in veterinary and human medicine.

Generally, these feed additives have been found to be safe and effective in target animal species, but toxic syndromes have resulted from overdosage, misuse and drug interaction. Among the domestic species, horses are the most sensitive to ionophore toxicoses, poultry the least sensitive, and cattle intermediate. However, even for the horse, there is a threshold level of exposure below which no adverse effects are observed. Consumption of complete feed containing the maximum approved use levels of monensin, lasalocid, or laidlomycin is harmless. Dose and time factors influence the severity and outcome of the toxic exposure. Results of controlled studies and confirmed field reports of toxicity indicate that the greatest risk of intoxication is upon initial exposure to ionophore-containing feed or supplement. Following sublethal exposure, consumption of culprit feed or supplement is negligible because of anorexia. Animals that die acutely after high levels of exposure often will have few or no lesions. Those that die later have profound striated (cardiac and/or skeletal) muscle lesions and changes secondary to congestive heart failure in some animals that survive the acute toxic episode.

Confirmatory diagnosis requires efficient laboratory assays to determine the identity and amounts of the ionophore involved and a thorough consideration of differential diagnosis. These cannot be overemphasized. There is no known antidote or specific treatment for ionophore toxicoses and treatment is largely supportive. Judicious use, avoidance of overdosing and adherence to species recommendation will enhance livestock production and help prevent the occurrence of adverse effects associated with this class of compounds.

## Nonprotein nitrogen (urea) and hyperammonemia

*Rhian Cope*

### INTRODUCTION AND BACKGROUND

Nonprotein nitrogen (NPN) intoxication is not a common occurrence in ruminants. It has long been recognized that ruminal microbes of cattle and sheep can utilize NPN to synthesize proteins that can replace a portion of their total dietary protein requirements. Given that feeding NPN sources are typically cheaper than feeding expensive true protein, the practice of adding NPN to ruminants' diets is relatively commonplace. Feed grade urea ( $\text{CO}[\text{NH}_2]_2$ ) is the cheapest, most effective and most available nitrogen source. Other NPN compounds, which may be less readily available and more expensive, include ammonium acetate ( $\text{CH}_3\text{CO}_2\text{NH}_4$ ), ammonium bicarbonate ( $\text{NH}_4\text{HCO}_3$ ), ammonium carbamate ( $\text{NH}_2\text{CO}_2\text{NH}_4$ ), ammonium lactate ( $\text{CH}_3\text{CHOHCO}_2\text{NH}_4$ ), ammonium sulfate ( $[\text{NH}_4]_2\text{SO}_4$ ), monoammonium phosphate ( $\text{NH}_4\text{H}_2\text{PO}_4$ ), biuret ( $\text{NH}_2\text{CONHCONH}_2$ ), dicyanodiamide ( $\text{NH}_2\text{C}[\text{NH}]\text{NHCN}$ ) and diammonium phosphate ( $[\text{NH}_4]_2\text{HPO}_4$ ). All these NPN sources consist of varying nitrogen content and protein equivalent; so addition of these products into the diet requires stringent nutritional dietary examination. Many of these supplements are solids and can be directly mixed into the mineral or grain component of the diet. Some, such as urea, can be added to molasses-based liquid products or into solid mineral blocks. Ammoniated beet pulp, citrus pulp, straw, silage, molasses and rice hulls have also been used to supplement the protein content of a ruminant's diet. Ruminants can also be poisoned by gaining access to some fertilizers that can contain over 40% urea.

### TOXICITY

All mammalian species are potentially susceptible to NPN poisoning via the consumption of ammonium-containing feeds, if the dose is high enough. When urea is added to the ruminant's diet, it is rapidly broken down by bacterial urease in the rumen to ammonia. The ammonia is then utilized by the rumen bacteria, along with soluble carbohydrates, to synthesize amino acids and proteins (hence the name "nonprotein nitrogen"). Most of the excess ammonia produced is protonated to the ammonium ( $\text{NH}_4$ ) ion and is trapped in the rumen. If this excess ammonia production continues, the rumen pH increases. When ammonia concentrations become too high too quickly, significant amounts get absorbed systemically. In the bloodstream, ammonia travels via the portal circulation to the liver where it is incorporated into the urea cycle and urea is then excreted in the urine via the kidneys or secreted into the saliva. Toxicities occur when this entire system becomes overwhelmed resulting in a clinically significant hyperammonemia. Excess ammonia has been shown to inhibit the citric acid cycle ([Hatch, 1977](#)), to cause a lactic acidosis and to interfere with cerebral energy metabolism and the sodium-potassium ATPase pump. The systemic metabolic acidosis is thought to be related to a hyperkalemia, and it is this abnormality that can ultimately lead to cardiac arrest.

Factors that potentially can predispose ruminants to poisonings with these compounds include low energy diets, high rumen pH (e.g., rumen impaction), elevations in body

temperature (enhances urease activity), dehydration, stress, concurrent disease, alterations in rumen microflora and hepatic insufficiency. The lack of a readily available supply of soluble carbohydrates markedly affects the rumen bacteria's ability to utilize the ammonia. It is generally recommended to slowly introduce increasing levels of NPN in the diet over a period of several days to allow the rumen bacteria to adapt to the ammonia source. Most poisonings in ruminants occur as a result of inadequate implementation of an adaptation period, improper mixing of the supplement into the diet and unlimited/unrestricted access to palatable liquid NPN supplements. NPN poisoning in monogastrics is not common.

Toxic and lethal doses are difficult to establish in ruminants due to all the predisposing factors that can enhance or decrease their sensitivity to these compounds. The oral lethal dose for urea in horses is 4.0g/kg body weight and the oral lethal dose for ammonia salts is 1.5g/kg body weight (Hintz *et al.*, 1970). A reported oral toxic dose for urea in nonacclimated cattle is 0.44g/kg body weight (Word *et al.*, 1960), whereas a lethal dose is in the 1.0–1.5g/kg body weight range (Osweiler *et al.*, 1985). Urea is recommended in ruminant rations at a rate of approximately 3% of the grain ration or 1% of the total ration. Adapted cattle can tolerate much higher levels in their diets. Biuret is considered one of the safest of NPN compounds, and a reported lethal dose in cattle is 8.0g/kg body weight (Haliburton and Morgan, 1989). A single dose of 116g of urea caused clinical signs of toxicity in cattle, whereas a dose of 57g did not (Dinning *et al.*, 1948). Davis and Roberts (1959) reported that 0.3g/kg body weight urea was toxic to unacclimated cattle.

## CLINICAL SIGNS

The onset of clinical signs following introduction of a toxic NPN source into an animal's diet can be extremely quick; frequently within 30 min. A delay in the onset of clinical signs can be due to a wide variety of factors, including dose, method of introduction and degree of adaptation. In general, most cases of NPN poisoning in ruminants involve some history of some type of "recent" feed change. Commonly reported clinical signs include uneasiness and ataxia, muscle tremors, excessive salivation, weakness, labored breathing, abdominal pain and bloat. The progression of clinical signs is generally quite rapid and recumbency, convulsions and death typically ensue within 4 h. Hyperthermia, marked jugular pulse, cardiac arrhythmias, vomiting/regurgitation and cyanosis have also been reported (Haliburton and Morgan, 1989). Rarely do animals survive once clinical signs start without some type of rapid treatment intervention.

## DIAGNOSTIC CRITERIA

The diagnosis of NPN intoxication rests mainly on a compatible history of exposure to an NPN source, compatible clinical signs with rapid progression to death and clinical diagnostic laboratory data. Rarely do you find significant post-mortem changes. Common findings at necropsy include generalized congestion of visceral organs, evidence of bloat and mild to moderate pulmonary edema. Subepicardial and myocardial hemorrhages have also been reported. There are several diagnostic aids that can assist the veterinarian in confirming an NPN poisoning.

First, assessing the rumen pH either ante-mortem or shortly after death is a very useful tool. In animals succumbing to NPN intoxication, rumen pH is typically greater than 8–10. A markedly elevated rumen pH post-mortem will gradually revert to normal over time due to continuous microbial activity post-mortem. Other causes of excessive rumen pH can include rumen impactions or other problems leading to a "dead" rumen, or excessive salivary secretions.

Elevated ammonia concentrations in various biological specimens (e.g., serum, plasma, ocular fluid and abomasal or rumen fluid) can be analytically confirmed by various methods. All samples should be collected and frozen immediately for delivery to the diagnostic laboratory, to prevent loss of the highly volatile ammonia. Samples collected post-mortem should be retrieved shortly after death; decomposition of tissues can cause either increases or decreases in ammonia levels which can muddle the interpretation. Ammonia concentrations typically greater than 1.0 mg/dl in serum or plasma and greater than 80 mg/dl in rumen or abomasum contents are diagnostically significant.

Lastly, ammonia, nitrogen, or urea levels can be assessed in the "suspect" feed source. These analyses should be quantitative, and should assist the veterinarian in determining whether a mixing error was responsible for the clinical problem.

## TREATMENT

Rapid intervention is necessary in order for affected animals to survive. This is rarely possible except in experimental settings. Poisonings generally occur on a large scale (rarely a single animal problem) and in a setting (e.g., feedlots, pastures typically located in more rural settings) where it is nearly impossible to implement appropriate rapid therapies. Treatments are generally thought to be effective if initiated within 20 min after the onset of clinical signs, and prognosis is poor for recumbent animals.

Five percent acetic acid (i.e., vinegar) should be orally infused into the affected animal; 2–6 l in cattle and 0.5–1.0 l in sheep and goats (Lloyd, 1981). This should be immediately followed by a large volume (5–10 gallons) of cold water. The acetic acid will lower the rumen pH and shift the concentrations of ammonia to the ammonium ion, which will slow down the systemic absorption of  $\text{NH}_3$ . The cold water will lower the rumen temperatures and slow down the urease enzyme, responsible for the hydrolysis of urea to ammonia. Animals that respond to this treatment may relapse. If this should occur, the drench should be cut in half. Recumbent and convulsing animals respond poorly to this treatment. Other nonspecific, supportive therapies may include anticonvulsant therapy (e.g., phenobarbital, pentobarbital) and intravenous fluid therapy to correct fluid deficits and any existing elemental or electrolyte abnormalities.

Animals that do recover from the acute insult do not appear to suffer any recognizable long-term effects, though abortions have been reported to occur in pregnant animals.

## AMMONIA

NPN poisonings resulting in hyperammonemia should not be confused with ammonia poisoning. Synonyms include ammonia gas, anhydrous ammonia and liquid ammonia. Livestock can be poisoned by ammonia, either through inhalation or ingestion, through its use as a fertilizer. Ammonia readily dissolves in water to form ammonium hydroxide. Anhydrous ammonia is colorless, highly irritating and causes corrosive injury to the mucous membranes of the eyes, lungs and skin. Inhalation of ammonia can lead to severe bronchiolar and alveolar edema, and airway destruction that can result in respiratory failure and death. Dermal contact or oral exposures lead to corrosive skin lesions and corrosive damage to the mucosal lining of the oral cavity, esophagus and stomach.

## CONCLUSIONS

All mammalian species are susceptible to urea/ammonia poisoning, although poisoning occurs with a greatest frequency in cattle by consumption of the contaminated feed. Diagnosis is based on clinical signs and analysis of the body tissues/fluids and feed for urea and ammonia levels. Treatment includes oral administration of acetic acid (vinegar) and symptomatic and supportive therapies.

# Water quality and contaminants

Michael P. Carlson

## INTRODUCTION

Water is essential for all forms of life. The availability of adequate quantities and quality of water dictates the types of life and numbers of individuals that an environment can sustain and may be a limiting factor for livestock production systems. Less water may become available for animal production and what is available may be of poorer quality as water supplies for human use become limited, too. Large-scale animal production practices and emphasis on animal performance may increase the demands on water delivery systems and increase concern about water quality. Water quality generally refers the suitability of water for some purpose. Parameters used to assess water quality vary depending upon its proposed use and may include color, odor, taste, bacterial content, mineral content, salinity and the amounts of inorganic or organic compounds it contains.

The intention of this chapter is to provide the reader with information about water to aid in the assessment of water quality for use by companion and production animals. Some of the more readily accessible water quality standards applicable to drinking water for animals are highlighted. Detailed discussions of the mechanisms by which those chemicals cause adverse effects may be found elsewhere in this book. Information about the daily amounts of water required by animals is also provided to help assess cases of possible exposure of animals to water-borne poisons. Lastly, the risk assessment of blue-green algae poisoning is discussed.

## THE ASSESSMENT OF WATER QUALITY

Water quality for animals may be assessed for several reasons: to determine if the available water is suitable for a particular purpose, to determine if there has been a significant change in water quality, or to determine if adverse health effects that are occurring may be attributable to water contamination. Numerous commercial, governmental and academic laboratories offer water quality analytical services. The assessment of the analytical results from such laboratories requires standards against which to compare the results. National, state or provincial, or local governments may regulate water quality and water quality standards may be established by any or all of those governmental bodies. The quality of drinking water intended for consumption by humans is almost always more extensively regulated than for any other water use.

Reports of results of water quality analyses often include water quality standard ranges against which to assess the reported results. They may include graphical comparisons of the results to the water quality standards, making identification of parameters that fall outside of the standard limits easily identifiable. Such reports often use water quality standards intended for human drinking water, so the user of the report must also assess the suitability of the reported standards for the intended use of the water.

Assessment of the results of water quality analyses must be done using standards that are applicable for the intended use of the water and which are in force for the venue at which the water is to be used. The suitability of

water intended for use as drinking water by animals is better assessed using drinking water standards for animals instead of standards for humans. For example, the U.S. human drinking water standard for nitrate + nitrite is  $10 \text{ mg NO}_3^- + \text{NO}_2^- - \text{N/L}$  (U.S. EPA, 2009a), whereas the livestock Canadian standard for nitrate + nitrite is  $100 \text{ mg NO}_3^- + \text{NO}_2^- - \text{N/L}$  (CCME, 2005a,b). That 10-fold difference can have a significant effect on water quality assessment. Animal owners may take unnecessary and costly actions to mitigate what are erroneously believed to be unacceptably high risk of some sort of adverse health effect.

Raisbeck *et al.* (2011) list several factors that need to be considered when assessing water quality for livestock or wildlife if the following question is posed by an animal owner or manager: "What will <chemical name> present in the water at <concentration> do to my animals?"

- 1 Many chemicals in water interact additively with the same chemicals in feedstuffs. In such circumstances, it is not the water concentration that is singly important but the total dietary content for those chemicals. For example, nitrate ingested from forage is usually much greater than that ingested from water.
- 2 Water quality analytical methods do not necessarily measure the specific chemical form of the chemical present in the water. For example, selenium is usually reported as total selenium and not as the chemical form present, such as selenite or selenate.
- 3 Reports of water quality do not usually differentiate between animal species. The toxicity of chemicals can differ significantly between species. This point has already been highlighted in the previous paragraph of this chapter.
- 4 Many chemical substances in the diet interact with each other. Those chemicals may be either nutrients or potential toxicants. For example, the absorption of copper depends upon dietary molybdenum and sulfur-containing compounds.
- 5 Rate of exposure influences the rate at which adverse health effects may become evident. For example, the ingestion of nitrate-fertilizer-contaminated water usually produces adverse effects much more rapidly than does ingestion of high-nitrate-containing fresh forage.

## WATER QUALITY STANDARDS FOR ANIMALS

Water quality standards for animals are not the same as nor are they enforced with the same authority as those for humans. Water quality recommendations for animals

have been made by the U.S. EPA in 1973 (U.S. EPA, 1973), the National Academy of Sciences (NAS) in 1974 (NAS, 1974) and Canada (CCME, 2005a,b). Table 99.1 lists water quality recommendations for livestock taken from each of those sources for selected chemicals.

Those publications include recommendations for water use by animals other than livestock. Recommendations for other animals are listed in Table 99.2. Readers may find them to be more applicable than the livestock recommendations in certain circumstances.

### U.S. EPA water quality criteria for animals

The U.S. EPA published proposed water quality standards for irrigation, livestock, aquatic life, wildlife, public freshwater, marine aquatic life and recreational water in 1973 (U.S. EPA, 1973). The criteria were formulated and published by the U.S. EPA pursuant to the Federal Water Pollution Control Act Amendments of 1972 and the Water Quality Act of 1965. The report states: "Almost all of the criteria are taken from the recommendations of the National Academy of Science's report on Water Quality Criteria (in press) developed under contract to the Environmental Protection Agency." Those recommendations do not appear to have been revised since their publication.

### National Academy of Sciences recommended limits in drinking water for livestock and poultry

The NAS report published in 1974 (NAS, 1974) summarizes what was known at the time of publication about effects of nutrient and toxic substances that were found in water consumed by domesticated animals. It also contains information about water requirements and the percentages of recommended intake of various substances provided by normal daily water consumption, and toxic concentrations for various species. The publication includes a table summarizing the effects of toxic concentrations of various chemicals in water for various domestic and laboratory animals. The information included in those tables is too extensive to reproduce in this chapter. Readers are urged to consult them as needed.

An ad hoc committee of the National Research Council's Committee on Animal Nutrition reviewed the scientific literature related to minerals and toxic substances in the diets and water for animals. Its findings and recommendations were published as a second revision of mineral tolerances of animals (Committee on Minerals, 2005). Drinking water standards cited in that revision still refer to the 1974 NAS publication (NAS, 1974).

TABLE 99.1 Water quality recommendations for selected chemicals for livestock

Chemical	Upper concentration limit (mg/L)			Microorganisms	U.S. EPA (1973)	NAS (1974)	CCME (2005a)
	U.S. EPA (1973)	NAS (1974)	Canadian (CCME, 2005a)

\*Recommended concentration limits are expressed as the fraction of either lethal concentration – 50 (LC<sub>50</sub>) – or lethal dose – 50 (LD<sub>50</sub>). The concentration listed thereafter is the maximum concentration considered acceptable.

\*\*Equation from reference calculates concentration in units of µg/L; dividing that concentration by 1000 gives concentration in units of mg/L; website has capability of calculating concentration with input of water hardness as CaCO<sub>3</sub>.

## Canadian environmental quality guidelines

Canadian water quality standards for agricultural use, including livestock, were first published in a document titled *Canadian Water Quality Guidelines* in 1987 by the Canadian Council of Resource and Environment Ministers (CCREM). That organization was later renamed the Canadian Council of Ministers of the Environment (CCME). In April 1996, CCME began work that consolidated national environmental quality guidelines for water, soil, sediment, tissue residues and air into one document, which was published as the *Canadian Environmental Quality Guidelines* by CCME. The guidelines are continually reviewed and updated as deemed necessary.

Water quality standards have continued to be revised and current information is readily available on the CCME Canadian Environmental Guidelines Summary Table website at <http://st-ts.ccme.ca/>. The site is designed to produce a listing of the chemicals and the guidelines of interest to the user.

## Organic contaminants

There are numerous organic chemicals, including many used in modern agricultural production, that are also included in various water quality tables. Such chemicals do not seem to be an issue for the quality of water for animals.

Drinking water quality does not appear to be an issue with organic production standards. The USDA National Organic Program's Organic Production and Handling Standards (USDA, 2002) do not include water quality among its livestock standards. The standards contain the following about water (bold font added to identify the mention of water):

Year-round access for all animals to the outdoors, shade, shelter, exercise areas, fresh air, **clean water for drinking**, and direct sunlight, suitable to the species, its stage of life, the climate, and the environment: Except, that, animals may be temporarily denied access to the outdoors in accordance with §§205.239(b) and (c).

European Union legislation has the following mention of water quality (bold font added to identify the mention of water) (Council Regulation 834/2007):

husbandry practices, including feeding, design of installations, stocking densities and **water quality** shall ensure that the developmental, physiological and behavioral needs of animals are met;

## DRINKING WATER QUALITY STANDARDS FOR HUMANS

Drinking water quality standards for selected chemicals that are published by the U.S. EPA (U.S. EPA, 2009a,b,c,d), Canada (Health Canada, 2010) and the World Health Organization (WHO, 2004) are listed in Table 99.3. They are included in this chapter to allow readers to compare standards for animals and humans. The adverse health effects listed in U.S. EPA documents for each chemical are also listed in the table.

In the U.S., legal limits called maximum contaminant levels (MCLs) have been established for about 90 contaminants. If contaminant concentrations in public water supplies and certain private supplies are found to be above applicable MCLs, then the water supplier must take action to bring the contaminant concentration down below the MCL. Meanwhile, an alternate source of water that meets the standards must be provided.

In the U.S., there are primary and secondary water standards for human drinking water (U.S. EPA, 2009b,c). Primary drinking water standards are legally enforceable and water providers cannot provide water containing contaminants higher than their respective MCLs. Secondary standards are non-enforceable guidelines for contaminants that may cause cosmetic effects, such as skin or tooth discoloration, or unacceptable aesthetic effects, such as unacceptable taste or odor from or discoloration of the water.

Primary standards are established considering the adverse health effect caused by the contaminant and

TABLE 99.3 Water quality recommendations for human drinking water: selected contaminants

Agency	Canadian			Potential health effects from exposure above maximum acceptable concentration (U.S. EPA, 2005b)
	U.S. EPA (2005a)	(Health Canada, 2010)	WHO (2004)	
Chemical	Maximum acceptable concentration (mg/L)			
Arsenic	0.010	0.01	0.01 (provisional)	Increased risk of cancer
Cadmium	0.005	0.005	0.003	Kidney damage
Calcium	—	—	—	—

(Continued)

TABLE 99.3 (Continued)

Agency	U.S. EPA (2005a)	Canadian (Health Canada, 2010)	WHO (2004)	Potential health effects from exposure above maximum acceptable concentration (U.S. EPA, 2005b)
Chemical	Maximum acceptable concentration (mg/L)			
Chloride	250 (secondary)	≤250 (aesthetic objective)	No health concerns at usual concentrations	–
Chromium	0.1 (total)	0.005	0.05 (provisional)	Allergic dermatitis
Copper	1.3 (at tap)	≤1.0 (aesthetic objective)	2	Short-term exposure: gastrointestinal distress Long-term exposure: liver or kidney damage; in cases of Wilson's disease consult physician if water Cu concentration exceeds MCL
Cyanobacterial toxins (microcystin-LR)	–	0.0015	–	
Fluoride	4.0	1.5	1.5	Bone disease; pain and tenderness of the bones; mottled teeth in children
Hardness	–	–	–	–
Iron	0.3 (secondary)	≤0.3 (aesthetic objective)	No health concerns at usual concentrations	–
Lead	0.015 (at tap)	0.010 (thoroughly flush faucet before water is taken for consumption or analysis)	0.01	Infants and children: physical or mental development delays, slight attention span deficits and learning disabilities
Mercury	0.002 (inorganic)	0.001	0.001 (total)	Adults: kidney problems, hypertension Kidney damage
Nitrate (as N)	10	10	–	Infants <6 months old: blue-baby syndrome
(as NO <sub>3</sub> <sup>-</sup> )	45	45	50 (short term)	
Nitrite (as N)	1	–	–	Infants <6 months old: blue-baby syndrome
(as NO <sub>2</sub> <sup>-</sup> )	3.3	<3.2, where nitrite is measured in addition to nitrate		
Selenium	0.05	0.01	0.01	Hair or fingernail loss; numbness in extremities; circulatory problems
Sulfate	250 (secondary)	≤500 (aesthetic objective)	No health concerns at usual concentrations	–
Total dissolved solids	500 (secondary)	≤500 (aesthetic objective)	No health concerns at usual concentrations	–
Zinc	5 (secondary)	≤5.0 (aesthetic objective)	No health concerns at usual concentrations	–
Microbes	U.S. EPA	Canadian	WHO	
Total coliforms	≤5% positive samples in a month; positives must be analyzed for fecal coliforms	0 per 100 mL		Presence indicates that potentially harmful bacteria may be present; see fecal coliforms, <i>E. coli</i>
Fecal coliforms	Repeat positive sample is considered in violation	–		Presence indicates water may be contaminated with human or animal wastes; short-term effect: diarrhea, cramps, nausea, headaches, or other symptoms; special health risks for infants, young children, people with severely compromised immune system
<i>E. coli</i>	Repeat positive sample is considered in violation	0 per 100 mL		See fecal coliforms

the dose at which such effects occur. A reference dose (RFD or RfD) is estimated based upon the amount of the contaminant to which a person may be exposed *on a daily basis that is not anticipated to cause the adverse health effect over a person's lifetime*. Consequently, the standards may not reflect the risk of adverse health effects in animals, and care should be used applying them to water intended for consumption by animals. A complete listing of drinking water standards and health advisories applicable to humans is compiled as needed by the U.S. EPA Office of Water. The latest available at the time this chapter was written was published in 2009 and may be accessed on the U.S. EPA website (U.S. EPA, 2009a).

## WATER CONSUMPTION TABLES

The dose of a water-borne contaminate may have to be estimated in cases of suspected toxicoses and may be calculated if the contaminant's concentration in the water and the amount of water consumed by the victims are known. Contaminant concentration in the water may be determined by analysis, but water consumption by the victims is rarely known with certainty.

Water consumption varies by species, weather condition, diet and state of health. All of those factors and their interactions make the determination or estimation of minimal water requirements difficult if not impossible. Additionally, daily water requirements are not necessarily met solely by drinking water consumption.

Use water consumption data to calculate doses of water-borne poisons, if such data are available. If not, use the data in Table 99.4, which was taken from the NAS publication (NAS, 1974), to estimate water consumption. Those data should be modified for situations falling outside of the defining parameters listed in the title.

**TABLE 99.4** Anticipated water consumption of various adult animals of medium weight in temperate climates

Animal	Expected consumption (L/day)
Beef cattle	26–66
Dairy cattle	38–110
Horses	30–45
Swine	11–19
Sheep, goats	4–15
Chickens	0.2–0.4
Turkeys	0.4–0.6

Data are from NAS (1974).

## RATIONALE FOR LIVESTOCK RECOMMENDATIONS

The rationales for the chemicals included in Table 99.1 livestock recommendations included in the U.S. EPA Proposed Criteria for Water Quality Volume 1 (U.S. EPA, 1973) are summarized below. Information listed was what was known at the time the recommendations were formulated and may not reflect current knowledge of the effects of the chemicals. Our addenda are so noted.

The EPA writes in its introduction to the document:

Acceptable limits specified in the recommendations were derived by the application of scientific judgment to lethal dose or lethal concentration data in a manner that provides a margin of safety to test organisms. For those substances whose effects are more aptly described as undesirable such as impairing aquatic habitats, causing taste and odor problems in water supplies, or reducing the aesthetic or recreational quality of a water body, limits which minimize these effects were established on the basis of field and laboratory investigations. Acceptable levels of toxic materials for which specific numerical maximum acceptable concentrations are not prescribed are determined by applying an application factor to locally derived LC<sub>50</sub> data. By basing criteria on effects on the most sensitive important species, a desirable degree of regional and local variation is introduced, allowing water quality standards to depend on local conditions.

An "important species" in the criteria is defined as an organism that: (1) is commercially or recreationally valuable; (2) is rare or endangered; (3) affects the well-being of some species within (1) and (2); or (4) is critical to the structure and function of the ecological system. A "rare or endangered" species is any species so officially designated by the U.S. Fish and Wildlife Service.

### Arsenic

Toxicity of arsenic depends upon its chemical form, relating primarily to rate of excretion. Inorganic oxides are generally more toxic than are organic forms of arsenic. Acute toxicities for farm animals are given in Table 99.5.

Arsenic acid fed to lactating cows at up to 1.25 mg/kg body weight for 8 weeks, equivalent to an intake of 60 L of water containing 5.5 mg arsenic/L daily by a 500 kg animal, was absorbed and rapidly excreted in the urine with no increase of arsenic content of milk. No toxicity was observed.

TABLE 99.5 Acute toxicity of inorganic arsenic by species

Species	Toxicity (g/animal)
Poultry	0.05–0.10
Swine	0.15–1.0
Sheep and goats	10.0–15.0
Horses	10.0–15.0
Cattle	15.0–30.0

Wadsworth 1952 as cited by U.S. EPA (1973).

TABLE 99.6 Effects of cadmium in various species

Species	Amount and source	Effect
Human	15 mg/L in popsicles	Sickening
Male rats	4.5 mg Cd/kg bw	Permanent sterility
Rats or mice	5 mg/L in drinking water	Reduced longevity
Pregnant hamsters	2 mg/kg bw of CdSO <sub>4</sub> by i.v. injection	Dose on day 8 of gestation caused fetal malformations

Data are from U.S. EPA (1973).

Cadmium

Effects of cadmium in various species are listed in Table 99.6.

A small fraction of cadmium is absorbed in ruminants, with most of what is absorbed going to the kidneys and liver. The cow is “found to be very efficient in keeping cadmium out of its milk.” Most major animal products, including beef and milk, seem “quite well protected against cadmium accumulation.”

Chromium

Chromium is not readily absorbed by animals. Most of what is ingested is excreted in the feces. It does not appear to concentrate in mammalian tissue nor does its concentration increase with age. It is concluded that up to 5 mg/L of chromium II or VI in drinking water should not be harmful to livestock. That level may be unnecessarily high and the 1.0 mg/L level is recommended to provide a “suitable margin of safety.”

Copper

Copper is an essential trace element, so some is required in the diet to maintain good health. Swine appear to be more tolerant to copper with dietary concentrations of 250 mg/kg or higher improving live weight gains and feed efficiency. Copper does not appear to accumulate in tissues. But in sheep, copper accumulates in the liver, followed by its sudden release in circulation causing hemolysis. Therefore, sheep are very susceptible to copper toxicosis.

A diet containing 25 mg/kg fed to sheep is considered toxic. About 9 mg per animal per day is considered safe.

Fluorine (Author’s addendum: fluorine and fluoride seem to be used synonymously)

Consumption of drinking water with 2.0 mg/L may produce some tooth mottling, but it is not excessive with respect to animal health or deposition in meat, milk or eggs. Chronic fluorosis of livestock has occurred with water content of 10–15 mg fluoride/L. Total ration content of 30–50 mg fluoride/L (sic) for dairy cattle is considered a safe upper limit. Transfer to milk occurs to a very small extent and to a greater degree in eggs. Fluoride at 1.0 mg/L in drinking water does not harm livestock.

Hardness (Authors’ addendum)

Hard water does not appear to have a deleterious effect on animals, but it often is reported as part of water quality analysis. Hardness is a measure of the calcium and magnesium ions present in the drinking water. Water with high TDS or salinity may or may not be hard water. Hardness of water may be measured as grains/gallon or in ppm. One grain per gallon is equivalent to 17 mg calcium and magnesium per liter. Water is classified according to calcium and magnesium salt content as follows: soft water ranges from 0 to 60 ppm, hard water varies from 120 to 180 ppm and very hard water is greater than 180 ppm.

Iron

In small quantity, iron is essential to animal life, while in excessive quantity it is considered toxic. Due to its involvement in Fenton reaction, iron is known to produce excessive free radicals causing oxidative stress. Brain, lungs and liver are the major sites of iron toxicity. Maximum recommended levels of iron in water for humans, livestock and poultry are <0.3, <0.4 and <0.4 ppm, respectively. Maximum tolerable concentrations of dietary iron have been set at 500 mg/kg for cattle, sheep and poultry, and 300 mg/kg for swine. Elevated dietary iron may antagonize copper, manganese and sulfur in lactating dairy cattle.

Lead

The toxicity of lead has not been clearly established quantitatively. Daily intake of 6–7 mg/kg body weight had been suggested as a threshold dosage in cattle, but that is

difficult to establish. A concentration of 0.5mg/L in drinking water is considered safe. Drinking water containing 5mg/L consumed by rats and mice over the course of their lifetimes produced toxic effects. Death rates of older animals increased, especially in males. Death was not caused by overt lead toxicosis, but was due to an increased susceptibility to "spontaneous infections."

## Mercury

Mercury content in surface water was found to usually be <5µg/L, but methylation of mercury in bottom sediments bordering mercury deposits resulted in the continuous presence of mercury in solution. The relative stability of methylmercury and its high absorption from the gut contributes to its oral toxicity. It had been suggested that livestock blood and tissue lead content be kept below 0.1 and 0.5mg/kg, respectively, to protect humans who might consume those tissues. The safe contamination level for fish consumed by humans had been set at 0.5mg/kg by the U.S. FDA. However, that did not take into consideration other possible sources of dietary mercury. "In view of these facts the limits prescribed herein are reduced by a factor of ten to reduce the significance of levels from meat products in comparison with those of fish" (U.S. EPA, 1973).

## Nitrate and nitrite

Nitrite is more toxic to livestock than is nitrate. Usually nitrite is produced by the reduction of nitrate to nitrite, which occurs in the rumen; in moistened feeds, such as freshly chopped green forage; or water containing sufficient organic matter to sustain microbes. Natural waters may contain "high levels" of nitrate, but they usually contain very low concentrations of nitrite. Nitrate in cattle feed did not seem to pose a hazard to humans consuming dairy products or meat produced from cattle eating the nitrate-containing feed. "Animals fed nitrate continuously develop some degree of adaptation (sic) to it." "Assuming maximum water consumption by dairy cattle of 3–4 times the dry matter intake, the concentration of nitrate to be tolerated in water should be about one fourth of that tolerated in the feed. This would amount to about 300mg/l of nitrate." Effects of nitrate and nitrite at various concentrations given to non-ruminants are summarized in Table 99.7.

It appeared that ingestion of water containing up to 300mg/L nitrate or 100mg/L nitrite was well tolerated by all classes of livestock and poultry studied under controlled experimental conditions.

Authors' addendum: Crowley *et al.* (1974) conducted a 35-month study in Wisconsin comparing reproductive

efficiency and lactational performance for a 54 cow Holstein herd that consumed drinking water containing either 19 or 374ppm nitrate. During the last 15 months of the study, cattle drinking the elevated nitrate containing water had the highest services per conception and lowest first service conception rates. The average milk yield was not significantly different between the two groups but the total milk yield for the entire 35-month study was lower in the elevated water nitrate group. This small difference in milk yield in the elevated nitrate containing drinking water was thought to be due to an increased dry period due to lower conception rates.

The author has never encountered a case of acute nitrate or nitrite toxicosis due to the consumption of drinking water, unless the water had been hauled to the animals in a fertilizer tank. Such cases have always involved cattle and occur when the availability of drinking water is disrupted and drinking water must be hauled to the animals from elsewhere. Such circumstances may occur when water freezes during stretches of very cold weather or the water pump fails and cannot be rapidly repaired. Deaths often occur relatively rapidly; owners often report finding dead victims within a few meters of the contaminated water tank. Ocular fluid collected from dead victims usually contains nitrate in excess of 100µg nitrate/mL and nitrite in excess of 2µg nitrite/mL. Ocular fluid collected from dead victims of forage nitrate toxicosis usually contains less nitrate than ocular fluid from dead victims of water nitrate toxicosis. If the fertilizer tank contained ammonium nitrate, then death may be the result of either excessive ammonia or nitrate exposure, and the determination of the exact cause of death is mostly academic. Under no circumstances do we recommend that a tank that has contained fertilizer be used to haul drinking water to animals, even if it has been "thoroughly washed out." Theoretically, a

TABLE 99.7 Effects of nitrate and nitrite administered to non-ruminants

Species	Concentration, dosage or dose	Observed effect(s)
Gilts from weaning through two farrowing seasons	330mg/L (nitrate)	No adverse effects
Growing pigs	330mg/L (nitrate)	No adverse effects
Chicks and laying hens	Up to 300mg/L (nitrite)	No effects on growth or production
Chicks and laying hens	Up to 200mg/L (nitrite)	No effects on growth or production
Turkey pullets	200mg/L (nitrite)	Decreased growth
Turkeys, laying hens and turkeys	200mg/L (nitrite)	Reduced liver vitamin A stores
	50mg/L (nitrite)	No adverse effects observed

Data are from U.S. EPA (1973).

fertilizer tank may be cleaned sufficiently to haul drinking water, but not practically.

Total dissolved solids (TDS)

“Total dissolved solids” is defined in the NAS publication (NAS, 1974) as the concentration of all dissolved constituents in water. “Salinity” is often used synonymously with “total dissolved solids,” although that assumes that all of the dissolved solids are saline. Salinity is more than a measurement of the total amount of sodium and chloride present in water. Salinity also includes anions such as carbonates expressed as oxides, bromide and iodine expressed as chlorine, and cations such as calcium, magnesium, bicarbonate and sulfate, but does not include organic matter.

The U.S. EPA does not include recommendations for TDS, but the NAS provides criteria for classification of water based upon TDS content established for the U.S. Geological Society. Criteria for two classification systems are listed in Table 99.8. Note the differences in the classification and the use of brine in both, but with different criteria for inclusion in that classification. It has been our experience that those classifications contribute little to the assessment of water quality for animals as we have never encountered an instance where those water classifications have been used to describe the TDS content. Nevertheless, they are included here. More useful information about the use of saline waters for livestock is provided under the section titled “A Guide to the Use of Saline Waters for Livestock” in the NAS publication, starting on p. 48 (NAS, 1974).

Several factors need to be considered in assessing the suitability of saline water for livestock use, including kind, age and sex of the animals; pregnancy or lactation status; physical exertion; climatic conditions;

TABLE 99.8 Water classifications based upon total dissolved solid content

DeWiest classification (1966)		Robinove <i>et al.</i> classification (1958)	
Water classification	TDS content (mg/L)	Water classification	TDS content (mg/l)
Fresh water	<1000		
Brackish water	1000–10,000	Slightly saline	1000–3000
		Moderately saline	3000–10,000
Salty water	10,000–100,000	Very saline	10,000–35,000
		Brine	>35,000
Brine	>100,000		

Data are from U.S. EPA (1974).

diet and its moisture and mineral content; production expectations; water salt content; access to other water sources; and the adaptation to available water sources. Weight given to those factors is largely a matter of judgment, but TDS is the single most reliable factor that can be determined.

The NAS did not recommend the use of highly saline water for livestock but acknowledged that circumstances may arise such that saline water may be all that is readily available. Table 99.9 lists the guidelines for use of saline water for livestock and poultry. If high-TDS water is to be used, the following points should be considered, too:

- 1 Alkalinities and nitrate should be considered whenever water containing >3000mg TDS/L is to be used. Alkalinities of 2000mg CaCO<sub>3</sub> detract from the suitability of water. Hydroxide is more harmful than carbonate, which is more harmful than bicarbonate.

TABLE 99.9 Guide to use of saline waters for livestock and poultry

Water TDS content (mg/L)	Expected health or performance effects
< 1000	None expected for any livestock class
1000–2999	None expected for any livestock class. May cause temporary diarrhea or watery droppings in animals unaccustomed to the water
3000–4999	Should be none. May cause temporary diarrhea or be refused at first by animals unaccustomed to the water. Poor water for poultry, often causing watery droppings, increased mortality and decreased growth, especially in turkeys
5000–6999	Reasonably safe for dairy and beef cattle, sheep, swine and horses. Avoid use of water approaching the higher limit for pregnant or lactating animals. Unacceptable for poultry; use for poultry will almost always be accompanied by some type of problem, especially near the upper limit, such as reduced growth or production
7000–10,000	Unfit for poultry and probably swine. Considerable risk may exist for pregnant or lactating cows, horses, sheep and the young of those species. Considerable risk for animals subject to heavy heat stress or water loss. Generally use of such water should be avoided, although older ruminants, horses and even poultry and swine may subsist on it for long periods of low stress
>10,000	Unacceptable risks for any livestock class

Taken from NAS (1974).

- 2 If offered the choice between two water sources, one highly saline and one less saline, they will choose the less saline source.
- 3 Animals can tolerate high saline water for a few days if they are then given low saline water.
- 4 Water intake usually increases with soluble salt content, except in cases of extremely high saline content, which animals may refuse to drink.
- 5 Abrupt changes from a low to high saline water will likely cause more problems than a gradual change.
- 6 Decreased water intake is very likely accompanied by decreased feed intake. So, animals with high production expectations may not produce as well showing "deleterious effects from waters of lower salts content than animals on a maintenance regimen."
- 7 Highly saline water may furnish enough minerals to be considered in dietary mineral formulations. And salt content of the diet may contribute to the toxicity of saline water, particularly if salt is added to control feed intake. Generally, water should not normally be relied upon as a source on essential inorganic minerals.

## Selenium

At the time that the U.S. EPA formulated its recommendations, no substantiated case of livestock poisoning by selenium in waters had been found. However, selenium toxicosis was found in wildlife exposed to high selenium-containing irrigation runoff water. Agricultural drainage water entering Kesterson Reservoir in California ranged from 0.140 to 1.40 mg/L (140 to 1400 ppb) during 1983–1985.

## Sulfate

No recommendation for sulfate was made by the U.S. EPA probably because the association between sulfate exposure and polioencephalomalacia in ruminants had not yet been discovered. The Canadian recommendation is 1000 mg/L. Exposure to elevated sulfates in drinking water can result in a transient diarrhea. Animals usually acclimate to an elevated level of drinking water sulfate in 3 to 7 days and no longer exhibit diarrhea. Methemoglobin was increased 450% in cattle consuming drinking water containing sulfates at 3493 ppm.

## Zinc

Zinc is relatively less toxic. The findings cited in the EPA document are summarized in Table 99.10. Increased zinc intake increased the zinc content of body tissue, but its accumulation was not great and tissue content fell rapidly after zinc intake was reduced.

## HEALTH EFFECTS OF CYANOTOXINS FROM WATER

The effects of cyanotoxins from water on humans are discussed by Kuiper-Goodman *et al.* (1999) and serve as the basis for risk assessment for exposure from drinking and recreational water by the World Health Organization (WHO, 2004). Relevant information from their chapter is summarized here. A more detailed discussion of cyanotoxins may be found elsewhere in this book (Chapter 72).

## Cyanotoxins

Toxic effects after exposure to cyanobacteria are evidenced by retrospective epidemiological studies of human disease, factual and anecdotal reports of disease in animals, and toxicological studies of cyanotoxins. Cyclic peptides, like microcystins, are specifically toxic to the liver in mammals and of particular concern to human health. Acute toxicoses cause liver hemorrhage and death from liver failure. Chronic toxicoses may promote liver and other cancers.

Alkaloid neurotoxins, like anatoxins and saxitoxins/paralytic shellfish poison (PSP), have shown only acute toxicoses in mammals. Information about anatoxins is sparse. Some of the alkaloid toxins, especially PSP, accumulate in marine and freshwater biota, which may place animals and humans consuming such biota at risk of exposure after consuming them.

Cyanobacterial lipopolysaccharides (LPS) can elicit allergic and toxic responses in humans, although little is known about their acute or chronic effects. They should be considered whenever gastrointestinal and respiratory signs are reported or observed.

## Adverse health effects in humans

Drinking water has been associated with gastrointestinal (GI) illness throughout history. Pathogenic bacteria and viruses are common causes of such illness, and evidence for GI illness caused by cyanotoxin exposure needs to

TABLE 99.10 Zinc toxicity in diets for various animals

Dietary per water Zn content	Species and effect(s)
1000 mg/kg in diet; >2000 2320 mg/L in water	Swine tolerated it; Swine: toxic Chickens: reduced water consumption, egg production, body weight
>500 mg/kg in diet, as oxide	Ruminants: toxic

Data are from U.S. EPA (1973).

take such etiologies into account. Cases of GI and hepatic illness that can be reliably attributed to cyanotoxins have all been coincidental with lysis of cyanobacterial blooms, either natural or artificial. Lysis releases cyanotoxins from the cells into the water.

Artificial lysis occurs after water treatment with copper sulfate to destroy blooms in water reservoirs, and poisonings subsequent to such treatment have been reported in the U.S. and Australia. Water filtration after the treatment can remove cell fragments, but not dissolved cyanotoxins.

Individuals at greater risk of cyanotoxicoses are the young, who drink a higher volume of water than adults in proportion to their body weights, and subjects with liver disease or kidney damage. Chronic effects in humans are of great concern because of the potential of exposure to low concentrations of cyanotoxins in drinking water over the course of a lifetime. Results of animal experiments have indicated chronic exposure to microcystins may promote tumor growth.

Epidemiological studies of the incidence of human hepatocellular carcinoma in China have identified three risk factors: hepatitis B viral infection, exposure to aflatoxin B<sub>1</sub> in food and the source of drinking water. Cancer mortality is lower when the source of drinking water is from deep well than when it is from surface waters. Cyanobacteria are abundant in the same areas where the incidence of hepatic carcinoma is highest.

There have been repeated reports of adverse effects in swimmers exposed to cyanobacterial blooms, such as skin irritation and GI symptoms. Deep blisters on skin under bathing suits have been reported, particularly after contact with the marine cyanobacterium *Lyngbya majuscula*, which is believed to occur when the organism becomes trapped against the skin under the bathing suit. Effects may be due to allergic reactions to cyanobacterial pigments or direct contact with the cyanotoxins. Individual sensitivity to cyanotoxins varies significantly.

Health effects in humans exposed to cyanobacteria in recreational waters include headache, nausea, vomiting, muscular pain, painful diarrhea, abdominal pain, blistering of the lips, sore throats, skin rashes, fever and eye or ear irritation, usually within 7 days of exposure. Severity of symptoms appears to be related to full-body immersion, the amount of water ingested, and the duration of exposure. Severe pneumonia attributed to aspiration of a *Microcystis* toxin was reported to have occurred in two British army recruits after they swam in and underwent canoe training in water containing a dense bloom of *Microcystis* spp.

## Effects in animals

Deaths due to cyanotoxicoses have been reported for cattle, sheep, dogs, horses, pigs, coots, ducks, skunks and

mink exposed to water containing cyanobacteria. Animals consuming food in which cyanotoxins may accumulate may also suffer from cyanotoxicoses. Secondary photosensitization may occur in animals exposed to hepatotoxic cyanotoxins. Post-mortem examination may find evidence of cyanobacteria in stomach content, or liver injury. However, in cases of neurotoxin cyanotoxins, no post-mortem lesions are usually found.

## Cyanotoxins in drinking water

Falconer *et al.* (1999) describe how guideline values for cyanotoxins in water were derived. Information from that chapter that can assist in the assessment of risk from such exposure is summarized here. The World Health Organization has established a provisional guideline for human drinking water of 0.001 mg/L of microcystin-LR (total cell-bound and extracellular) (WHO, 2004). Canada has established a cyanobacterial toxin maximum acceptable concentration of 0.0015 mg/L (as microcystin-LR) (Health Canada, 2010). Australia has established a standard of 0.0013 mg/L of total microcystins as microcystin-LR toxicity equivalents (TE) (ANHMRC, 2004). The U.S. EPA has not yet established a standard. Potential carcinogenicity is the effect upon which those standards are based.

Standards for drinking water for animals have not been established.

## Recreational water exposure

Routes of exposure to cyanotoxins for people and animals from recreational waters include: direct contact with the skin (most important for sensitive areas such as the mouth, ears, eyes and throat, and the area covered by bathing suits worn by humans), swallowing and inhalation of water.

Absorption of cyanotoxins after swallowing, contact with nasal mucosa, or inhalation is likely to be important during water-contact activities. Absorption through nasal and pharyngeal mucosa is more likely to occur when activities involve submersion of the head or inhalation of aerosols produced by water spray. Cumulative liver damage may occur by repeated microcystin intake during periods of daily water activities, especially if the activities take place in areas where scums are or have been present.

## Safe practices for drinking water

Draw drinking water from sources that do not harbor cyanobacteria, such as groundwater or surface water not supporting cyanobacterial growth.

**TABLE 99.11** Critical control points for assessing the safety of drinking water

Control point	Remarks
Water source	Groundwater less risky than surface waters. Water sources contaminated by surface runoff pose higher risks
Presence of cyanobacteria; tendency of bloom formation	Bloom formation less likely during periods of high flow or deep vertical mixing, and are more likely during periods of low flow or stagnation. Historical evidence of algal blooms increases risk; blooms may be cyclic. Nutrient input, especially nitrogen and phosphorus, increases risk. Absence of cyanobacteria reduces risk
Cell lysis	Most cyanotoxins are cell-bound and may be removed with the cells. Lysis may occur naturally as the bloom dies, or artificially by treatment, pumping or transport
Water treatment systems	Cyanotoxins may be removed by filtration through activated charcoal or by oxidation, but effectiveness of treatment should be monitored

Adapted from Table 5.1 in Falconer *et al.* (1999).

Cyanobacterial-contaminated water may be used for drinking water if the cyanobacterial cells are removed without lysing them because most cyanotoxins are cell bound. Removal of released cyanotoxins from the water may be possible, but it may also be difficult and expensive. Risk of cyanotoxicosis should be considered high after algae-infested water is treated with copper sulfate. Critical control points for assessing the safety of drinking water are listed in Table 99.11.

All animals should be denied access to bodies of water containing visible discoloration that cannot be attributed to some source other than algae or cyanobacteria. Areas in which scum has formed should be considered very high risk for acute cyanotoxicosis, regardless of the color of the scum. Identification of the microbial components of the scum may help with the risk assessment.

### Safe practices for recreational waters

Surveillance of recreational waters for algal blooms can be effective in minimizing or preventing exposure, but adequate surveillance of such waters for blooms may be difficult. Governmental agencies may not be able to survey all recreational waters within their jurisdiction adequately, so the burden of surveying recreational waters for the presence of blooms may rest with the users of the waters. Once blooms have been detected in public waters, provision of information to the public is usually the responsibility of public authorities.

Algal blooms are usually regarded as more of a nuisance than a toxic hazard. They are often associated

with unpleasant odors and offensive appearances. They may be regarded as normal in areas where they occur frequently or regularly, and their toxic potential may be unknown or disregarded. The presence of any algal bloom, regardless of its color, location, or time of occurrence, should be considered to pose a high risk of cyanotoxicosis and all animals should be denied access to such areas, whether it is in the water or on the shore. The detection of algal scum formation is problematic if routine monitoring is carried out at 1- to 2-week intervals. Scum formation may occur in a matter of hours to days. Daily inspection for scum formation after cyanobacteria are found to be present is recommended.

The availability of ELISA kits for the detection of microcystins makes it easier to monitor recreational waters for the presence of microcystins. Chorus and Cavalieri (2000) do not recommend risk assessment for cyanotoxicoses be based upon chemical analysis for specific cyanotoxins for two reasons: (1) only some of the substances causing health outcomes are known and can be detected; and (2) epidemiological studies indicate some health effects are not due to known cyanotoxins. They recommend that a monitoring program focus surveillance efforts on sites that are likely to present a risk.

### Monitoring strategy for freshwater cyanobacteria

Kuiper-Goodman *et al.* (1999) recommend the following strategy for monitoring freshwater for cyanobacteria, consisting of the three steps listed below. Each will be briefly discussed and serve as a prerequisite for the following step.

- 1 Determine the carrying capacity of the ecosystem for cyanobacteria: Algal and cyanobacterial growth requires nitrogen and phosphorus and the availability of those nutrients limits the numbers of algae and cyanobacteria that can grow in a body of water. Phosphorus is usually the limiting factor of the two and total phosphorus, not ortho-phosphorus, should be measured because algae and cyanobacteria can store sufficient phosphorus to support their growth. If total phosphorus is found to be  $>0.02$  mg/L, then Step 2 monitoring activities should commence. Inspect the water body area to determine if a source or sources of phosphorus or nitrogen input are present, like sewage, fertilization near the water body, or erosion.
- 2 Inspect the site to detect biomass developments: The frequency of monitoring should be no longer than every 2 weeks and should be concentrated in areas in which a biomass most likely will appear, i.e., leeward shorelines. Visual inspections should include the following activities, each serving as its predecessor's prerequisite.

TABLE 99.12 Guidelines for use of recreational waters

Situation	Health risk	Recommended action
Scum is present	High for acute poisoning and short-term health effects (skin irritation, GI illness). Humans are not likely to ingest scum mats or scum-contaminated water, but animals may. Animals may also be exposed when they groom themselves after contact with scum. Young animals or children playing with, in or around scum are at risk	Prevent contact with scum; prohibit water-contact activities
100,000 cyanobacterial cells/mL; 50 µg chlorophyll <i>a</i> /L with dominance of cyanobacteria	Moderate to high for short-term adverse health effects, potential for chronic effects	Watch for scums. Restrict water-contact activities; continue to monitor the situation, post on-site risk advisory signs
20,000 cyanobacterial cells/mL; 10 µg chlorophyll <i>a</i> /L with dominance of cyanobacteria	Low to moderate for short-term irritative or allergenic effects	Post on-site risk advisory signs

Adapted from Falconer *et al.* (1999).

- A Determine water transparency: If the lake bottom cannot be seen at 50cm depth along the shoreline, or if the Secchi transparency is < 1m, then go to Step B.
  - B Determine if greenish discolorations of the water are present along or near the shoreline, indicating the presence of algal or cyanobacterial masses. If so, go to Step C.
  - C Determine if greenish discolorations of the water are present on the surface anywhere on the body of water.
- 3 Quantitatively assess the biomass as the basis for risk assessment when biomass developments occur: Either of two quantitative measurements may be performed: (1) microscopic examination of samples collected from the biomass to identify if cyanobacteria are present, and if so, what kind; (2) quantitate the concentration of chlorophyll *a* present.

Guidelines for the use of recreational waters based upon those measurements are detailed by Falconer *et al.* (1999) and are summarized in Table 99.12.

Falconer *et al.* (1999) do associate microcystin concentrations with numbers of cyanobacteria cells present in water, which may be valuable as an additional risk assessment variable if microcystin-producing cyanobacteria predominate in the biomass. The association is listed in Table 99.13.

Once algal blooms have occurred in a body of water, they should be considered to pose a high risk of cyanobacterial toxicosis until the microorganisms in them have been reliably identified. There are numerous publications on cyanobacteria that describe cyanobacterial blooms as being blue-green in color, but the absence of blue-green coloration in a bloom does not necessarily lessen its toxic hazard. The safest course of action is to deny access by animals to the bloom area.

The single most effective action that animal owners can take to protect their animals from cyanotoxicoses is to

TABLE 99.13 Expected microcystin content of water based upon the amount of microcystin-producing cyanobacteria present

Number of cyanobacterial cells	Expected microcystin concentration
100,000 cyanobacterial cells/mL	Associated with about 20 µg/L of microcystins, if microcystin-producing cyanobacterial predominate
20,000 cyanobacterial cells/mL	Associated with 2–4 µg/L of microcystins, if microcystin-producing cyanobacterial predominate

Falconer *et al.* (1999).

prevent their animals from making any contact with any scum or biomass in the water or on shorelines. It is not usually possible to determine if the scum or biomass is or is not cyanotoxicogenic by visual inspection alone, so any biomass or scum should be considered potentially toxic.

Once an animal has been exposed to a bloom, it is advisable to monitor the animal closely for signs of cyanotoxicoses. Algal scum may be visible on its coat or around its mouth or muzzle and is a good indicator that dermal exposure to cyanobacteria may have occurred and is suggestive that algae may have been ingested. It is not usually possible to determine how much of the scum might have been ingested. It is expected that human swimmers involuntarily swallow 100–200 chlorophyll *a* per mL of water in one session; water skiers and sail-board riders may ingest significantly more.

### CONCLUSIONS

The assessment of the quality of water must be done in the context of its intended use using standards appropriate for the use. The use of quality standards established

for the consumption of water by humans is not as good as use of standards specifically for animals. Quality standards for water consumption by animals have not received as much attention as quality standards for consumption by humans. Nevertheless, several authorities have made recommendations and those standards are likely more appropriate for water quality assessments than are quality standards for humans.

The assessment of risk of adverse health effects upon exposure to water containing cyanotoxins depends upon the use of the water. Standards for drinking water have been published by several authoritative bodies. Such standards are not directly applicable to instances of incidental contact with or the recreational use of bodies of water that may be contaminated with cyanobacteria or their toxins. Measurement of microcystin content for recreational waters may not be comprehensive enough because there are other toxins that can pose a risk that would not be detected by such analytical methods. Assessment is potentially slower as the specimens must be collected, shipped to a laboratory and then tested for the presence of the toxin. Assessment of the presence of algal blooms either by visual criteria or chlorophyll measurement is not dependent upon detection of the presence of an algal toxin, but may restrict water use in the absence of toxin presence. Results based on visual criteria may be faster than those depending upon chemical analysis. Practical advice to animal owners to minimize the risk: deny animal access if any visible presence of an algal bloom either in the water or on its surface or along its bank is detected.

# Basic concepts of analytical toxicology

Anant V. Jain and Beverly S. Arnold

## INTRODUCTION

Veterinary analytical toxicology deals with the chemical analysis of ante-mortem, post-mortem and environmental specimens to assist the veterinary practitioner in the diagnosis of poisoning. The chemical analytical data reported to the veterinarian is of utmost importance. The correct data will lead to correct diagnosis. The erroneous data may lead to disaster; the client may lose large numbers of animals. The erroneous data may also lead to legal ramifications. Thus, correctness of analytical data is of paramount importance for veterinary analytical toxicology. Chemical measurements are based on the principles of analytical chemistry. In practice, the analytical chemist-toxicologist uses analytical methods to achieve the final results. It should be pointed out that by nature, analytical results are variable. The science of trace analysis (analysis at parts per million (ppm) or parts per billion (ppb)) is not as precise as most layman and many scientists view it to be (Rogers, 1986). Analytical methods once devised are, like life forms, subject to evolution. Natural selection as mediated by analytical chemists ensures that only the fittest analytical methods survive. Therefore, an analytical method must be fit for purpose. It should be pointed out that most of the advancements and improvements in the analytical methods have been by making necessary changes and improvements in various steps used in an analytical method. The papers by Sawyer (1988) and Seiber (1988) clearly demonstrate this point for pesticide analysis. The important steps in chemical analytical measurements are (1) decomposition or extraction of the sample, (2) clean up and separation of analyte from bulk impurities (sample matrix), (3) pre-concentration of analyte, (4) detection and measurement

of the analyte, and (5) the generation of the report. The purpose of this chapter is to provide the analytical chemist/toxicologist an overview of the brief history of early and recent developments in chemical measurements, and above all the basis for scientifically sound chemical analytical measurements.

## HISTORY OF CHEMICAL ANALYSIS

### Early history of chemical analysis

Chemical analysis began on the 8th day (McCrone, 1987). Adam, recovering after cooperating with God in creating Eve, felt the first pangs of hunger. He went around and harvested different kinds of colorful berries, and set down for dinner with Eve. Eve rejected some berries due to foul smell (nose as detector). The bitter tasting ones were rejected next (taste as detector), and the delicious ones were consumed. Thus, the first chemical detectors were nose, tongue and eye; *the five senses were used as chemical detectors for a long time.*

The alchemists, in their futile attempts to make gold from base metals, introduced the techniques of filtration, decantation and distillation. Alchemist's zeal, however unsuccessful, leads to a reservoir of observations.

Observations followed observations, and when a large body of knowledge was available, it was named *chemistry*. Those observations that dealt with the production of substances were termed chemical synthesis, and those related to determining what the substances were called were named chemical analysis. The analysis could be carried out in solution as well as in dry state. The

solution methods were termed “wet” methods, and were further divided into volumetric and gravimetric. These methods used sight (visual observation) as detection device. The dry methods also used sight as the detector.

Archimedes, while running naked through the street and shouting *eureka, eureka*, introduced the use of numerical properties for chemical analysis in the concept of specific gravity (density).

The volumetric and gravimetric methods were used for chemical analysis for a long time. These were the principal chemical analytical methods up to the 19th century.

## Recent history of chemical analysis

In recent years, research in analytical chemistry has focused mainly on the development and application of physical and physicochemical analytical methods – instrumental methods of analysis. Instrumental chemical analysis began with Bunsen (Bunsen burner flame) in 1860, who introduced flame emissive spectrometry, and discovered the metals rubidium and cesium. There are a large number of instruments available today for chemical analysis. The most important of these, which have found routine use in veterinary analytical toxicology laboratories, are (1) chromatographic techniques coupled with a large number of detectors, (2) spectrometry and spectrophotometry, both for the visible and ultraviolet range of the light spectrum, (3) atomic absorption spectrophotometry, (4) inductively coupled plasma spectrometry, and (5) mass spectrometry.

Chromatographic methods in general are the most common methods used at the determinative step for the organic compounds. Chromatography is a separation technique, which separates the impurities in the sample solution from analyte. According to International Union of Pure and Applied Chemistry (IUPAC), chromatography is a method used primarily for the separation of the components of a sample in which the components are *distributed* between *two phases*, one of which is stationary while the other moves. The stationary phase may be a *solid*, or a *liquid supported on a solid*, or a *gel*. The stationary phase may be *packed in a column*, *spread as a layer*, or *distributed as a film*, etc. The mobile phase may be gaseous or liquid. Thus there are two movements in chromatographic system, the mobile phase movement – which is usually at a constant rate – and the movement of the components of the sample. The movement of the component depends upon its relative distribution between the stationary phase and the mobile phase. This results in the separation of the components. This separation process coupled with the detection and measuring device completes the chromatographic system. Chromatography can be conducted in gas phase, known as gas chromatography (GC), liquid phase, known as

liquid chromatography (LC), and on a glass or paper coated with solid adsorbent, known as thin layer chromatography (TLC). A variation of LC is known as high-pressure liquid chromatography (HPLC), since high pressure is used to force the solvent through the chromatographic column. Gas chromatographic equipment can be interfaced with large numbers of detectors such as flame ionization (FID), electron capture (ECD), nitrogen phosphorus (NPD), flame photometric (FPD) (responds to phosphorus and sulfur only), Hall electrolytic conductivity (HECD) (responds to halogens only) and mass spectrometer. HPLC can also be coupled with various detectors such as UV/VIS spectrophotometric detector, fluorescence detector, electrochemical detector, refractive index detector and mass spectrometric detector. Chromatographic techniques coupled with a detector are represented by hyphenated abbreviations. For example, a gas chromatograph equipped with FPD is known as GC-FPD. Sometimes this is also represented as GLC-FPD, due to the nature of the stationary phase of the chromatographic column used. Most of the time, a liquid phase is coated on a solid support and packed in a glass column. Recently, silica columns of very small diameter are used in GC, and are known as capillary columns. In these columns, the liquid phase is usually bonded to the inner surface of the silica capillary.

Instrumental methods have surpassed the traditional gravimetric and volumetric analysis in speed and sensitivity.

## TRUENESS (ACCURACY) OF CHEMICAL ANALYTICAL RESULTS

With all the furious activity in the development of various analytical instruments, the question still remains, how good are your results? One can use the most expensive and sophisticated instrument on the market, but still have to prove that the analytical results so obtained are indeed accurate. As mentioned in the introduction, the analytical results by nature are variable; it is more essential to prove the correctness of the results. Let me give a brief history of why this is important.

After the Civil War (1861–1865), American agriculture had been on the march, and farmers had been trying to produce more and more per unit of land. Synthetic fertilizers were used extensively. Various state governments were trying to verify the claims made by the fertilizer manufacturers to protect the consumer (farmer). The problem was that different laboratories got widely different results for the same ingredient in the fertilizers. There were no uniform methods for fertilizer analysis. In order to control this chaos, Mr. J.T. Henderson,

Agriculture Commissioner of Georgia, called a meeting of various interested parties. On May 15, 1884 the meeting took place at the Senate Chambers at the Capitol in Atlanta (Helrich, 1984).

Dr. Charles Shepard, a commercial chemist from Charleston, South Carolina, addressed the meeting and stressed the need for uniform and validated methods for the analysis. He dramatized the effect that nonuniform methods of analysis were having on the monetary value of fertilizers. He told the convention "a 1% difference in the analysis of phosphoric acid made a difference of \$50,000 in the annual production of a 'good-sized factory'." This presentation had a lasting effect on the attendees and it was decided that the group meet again at AAAS, American Association for the Advancement of Science, in Philadelphia, on September 4–10, 1884. The Philadelphia meeting became the first meeting of the "Association of Official Agricultural Chemists," then known as AOAC. This association is now known as AOAC International. Over the past 122 years, AOAC International has developed a process for validating and harmonizing analytical methods. Method validation is the key for determining the performance of analytical methods, and the reliability of the results obtained. AOAC International is committed to analytical excellence and worldwide confidence in analytical results using a defined method validation process.

## ANALYTICAL METHOD VALIDATION

There are several types of validation for analytical methods. AOAC International (Fredrick Ave, Gaithersburg, MD, USA) is the leading organization that conducts methods validation under its auspices. AOAC International conducts the following types of method validation:

- 1 Performance tested method (PTM)
- 2 Peer-verified method (PVM)
- 3 Official methods of analysis (OMA)

AOAC *Official Methods* are referenced in the U.S. Code of Federal Regulations (CFR) and are used worldwide by regulated industry, product testing laboratories and academic institutions. AOAC International is an independent association devoted to promoting methods validation and quality measurements in analytical sciences. It provides full review and validation of approved standard methods of analysis, promotes uniformity and reliability in statements of results, and develops and promotes criteria useful for laboratory accreditation and analyst certification.

### Performance tested methods

There are a large number of rapid test kits available for chemical and biological analysis. In order to verify the claims made by the kit manufacturer about the performance of test kits, AOAC International introduced the concept of PMT. The applicant (kit manufacturer) submits the performance data of the test kit along with the application fee. AOAC International appoints a panel of experts to review the performance data. If the review of performance data is satisfactory, an expert laboratory is selected to check the performance of the test kit. If the performance is as claimed, the test kit is awarded the status of PMT.

### Peer-verified programs

The AOAC® *Peer-Verified Methods*<sup>SM</sup> Program (PVM) is intended to provide a class of tested methods which have not been the subject of a full collaborative study. Through a less intensive process, the program provides a rapid entry point for methods, which are recognized by AOAC at a level of validation for methods not otherwise evaluated. The distinguishing aspect of an AOAC *Peer-Verified Methods*<sup>SM</sup> is that its performance has been checked in at least one other independent laboratory. Eventually, it is expected that most PVMs will undergo full interlaboratory collaborative studies and obtain *Official Methods*<sup>SM</sup> status. An explanation of the PMT, PVT and OMA is available at [www.aoac.org](http://www.aoac.org).

### Single laboratory validation

In order for a method to be validated as PTM, PVM and finally as *Official Method* it must first be validated in a single laboratory. In international trade and regulatory affairs, only validated methods are acceptable. The method need not to be validated under the auspices of AOAC International, but evidence is required that the method is suitable for the intended purpose such that similar results are obtainable from other competent laboratories. In order to gather this information, single laboratory validation (SLV) is essential. Various standards setting organizations such as International Standards Organization (ISO) and AOAC International (AOAC) have established standards for SLV of methods of analysis. AOAC has more than 120 years of experience in collaboratively validating methods of analysis. These standards require that certain performance characteristics (attributes) of an analytical method must meet specified standards. Many analytical methods published in the scientific literature may not meet the criteria specified in the above standards. They usually lack the essential attributes required for the recognized validation process.

The performance characteristics include: the specificity (the ability to distinguish the analyte from other substances); applicability (as the matrices and the concentration range) and reliability. Reliability is the most important characteristic of an analytical method and is expressed in terms of % recovery, repeatability and reproducibility. Repeatability and reproducibility are expressed in terms of relative standard deviation within laboratory and between laboratories, respectively ( $RSD_r$ ,  $RSD_R$ ). Intermediate precision, another term, which is important for SLV, is the intermediate repeatability relative standard deviation ( $RSD_{ri}$ ). It is also very important that the analytical method is fit for its intended purpose. For example, a method intended for the determination of lead (Pb) in drinking water at ppm or ppb level is not fit for the analysis of lead ore (% composition level). If such a method is used for the determination of lead in an ore, the error and the variability will be too large, and the analysis may not serve its purpose, i.e., whether to mine or not to mine a certain location. Thus fitness for purpose is very important.

There are only a few methods that have been validated for use in veterinary analytical toxicology. These methods are listed in the *Official Methods of AOAC International* (AOAC, 2000). An online version of OMA is available as the membership benefit for members of AOAC International. Thus, it is important that any method used in veterinary analytical toxicology is at least validated within the laboratory.

The American Association of Veterinary Laboratory Diagnosticians (AAVLD) is also an accrediting organization for veterinary diagnostic laboratories in the U.S. AAVLD has been emphasizing the use of validated methods in diagnostic laboratories. It should be pointed out that any method from the scientific literature does not become a validated method by simply rewriting it in ISO format. In order to be validated, the laboratory must prove that the method has acceptable performance characteristics of required attributes. If the laboratory hires a new analyst, the analyst should show that he (she) could get results consistent with the performance characteristics of the method. Many federal laboratories such as the Food Safety and Inspection Service (FSIS) and the United States Department of Agriculture (USDA) (FSIS-USDA, 1995) require this.

### AN EXAMPLE OF AN SLV FOR THE GAS CHROMATOGRAPHIC DETERMINATION OF SELENIUM (Se) IN BLOOD AND LIVER

An illustrated example of the SLV for the determination of selenium in liver and whole blood is given here. In our laboratory, there was a need for the determination

of selenium (Se) in fresh liver and whole blood. The literature survey showed a large number of methods for the determination of Se using widely differing techniques such as fluorometry, AA and GLC with electron capture detector (GLC-ECD). Due to the limitation in appropriate instrumentation, and a conversation with another colleague, we decided on the GLC-ECD method. The method of Poole *et al.* (1977) as modified by Ross and Lund (1982) was selected. The method involves the wet digestion of the sample (0.1–1 g) in concentrated nitric acid with magnesium nitrate; the mixture is heated on a hot plate below 100°C until all the liquid evaporates; afterwards, the temperature is raised to remove the brown fumes of nitric acid. The residual nitric acid is removed by placing the sample in a muffle furnace at 500°C for 30 min. After cooling the sample, the ash is dissolved in concentrated hydrochloric acid for 10 min at 100°C. To the solution, 10 ml of 20% urea is added and the mixture is allowed to cool; 4 ml of 1% solution of 1,2-diamino-4-nitrobenzene is added. The solution is transferred to a 50 ml stoppered polyethylene centrifuge tube quantitatively with the aid of 5 ml water. The contents of the tube are mixed, 5 ml of toluene is added to the tube and vigorously shaken for 30 s, and the phases are allowed to separate. About 2 ml layer of toluene is passed through a column of anhydrous sodium sulfate packed in a pasture pipette. The toluene layer is collected in a Pyrex screw cap tube, and 1  $\mu$ l of the toluene (containing Se derivative) is injected in the gas chromatograph fitted with ECD. A Tracor (MT 222) gas chromatograph fitted with a 6 ft glass column with 1/n. internal diameter packed with 1.5% OV-17 and 0.95% OV-225 was used. The oven temperature was 200°C and the detector temperature was 300°C. The carrier gas nitrogen flow was maintained at 60 ml/min. The Se retention time was about 3 min.

### CALIBRATION CURVE: HOW TO MEASURE A QUANTITY OF INTEREST

The modern chemical analytical instruments use physical properties for the measurement of analyte concentration. Thus, analytical instruments have to be optimized and calibrated to detect and report the information about concentration of an unknown. Instruments are calibrated to test the response against a series of known standards of the analyte. The result of this experiment is a plot of response versus concentration, known as calibration curve. Calibration curves are functions of an instrument's response to a range of known concentration levels of reference material. In some cases, the concentration level may be too low to be detected by the particular instrument in use; in other cases, it may be too high and overload the detector. The optimal range

TABLE 100.1 Se calibration curve data

Concentration	Response
$x_i$	$y_i$
0	0
0.1	2.1
0.25	5.8
0.5	10.9
0.75	17
0.99951739	$r$
$b$	$a$
22.5308311	20.049865952

of concentration level for detection is usually narrow. Ideally, this narrow range represents a linear response. The analytical chemist prefers to work in this linear range, since data analysis is comparatively easy in this range. The calibration standards from the reference material should be made with utmost care and accuracy. The concentration of the analyte in the unknown sample is calculated by using a mathematical relationship between concentration and response, known as the regression equation for the calibration curve. The regression equation takes the form response ( $y$ ) = slope of the curve ( $b$ ) +  $y$  intercept.

$$y = bx + a \quad (100.1)$$

We can determine the value of  $b$  and  $a$  from the calibration curve data, and the concentration of analyte in the sample,  $x$ , can be calculated according to Eqn (100.2)

$$x = \frac{y - a}{b} = \frac{\text{Response} - \text{Intercept}}{\text{Slope}} \quad (100.2)$$

The response is read from the instrument, and the slope and intercept are obtained from the calibration curve.

## GOODNESS OF LINEARITY OF CALIBRATION CURVE

The degree of linearity of the calibration curve is determined by the correlation coefficient,  $r$ , the detector response is plotted on the  $y$ -axis and the concentration of the reference standards is plotted on the  $x$ -axis. The value of  $r$  varies from  $-1.0$  to  $+1.0$ . A value of 1 indicates that there is positive linear relationship between the detector response and the standard concentration. The data for a typical calibration curve for Se is shown in Table 100.1. The data in Table 100.1 show a linear relationship, and the calibration curve shows a straight line, shown in Figure 100.1.

The value of  $r$  is calculated on an Excel spreadsheet using the function, =correl(array  $y$ , array  $x$ ). The values

FIGURE 100.1 Se calibration curve.

of the slope  $b$  and intercept  $a$  are calculated by using the function =linest(array  $y$ , array  $x$ ). In order to get both values ( $b$  and  $a$ ), place the data for concentration,  $x$ , and the response,  $y$ , columns as shown in Table 100.1. Run the "linest" function in a column just below, marked  $b$ . Hold the shift and ctrl key and hit enter, both values will appear on the spreadsheet.

The correlation coefficient, slope and the intercept can also be calculated with the aid of Eqns (100.3–100.5) given below (Miller and Miller, 1992):

$$r = \frac{\sum_i \{(x_i - \bar{x})(y_i - \bar{y})\}}{\sqrt{\left[ \sum_i (x_i - \bar{x})^2 \right] \left[ \sum_i (y_i - \bar{y})^2 \right]}} \quad (100.3)$$

$$b = \frac{\sum_i \{(x_i - \bar{x})(y_i - \bar{y})\}}{\sum_i (x_i - \bar{x})^2} \quad (100.4)$$

$$a = \bar{y} - b\bar{x} \quad (100.5)$$

The regression equation for the calibration is as follows:

$$y = 22.53x + (-0.0499)$$

The numbers are referenced in the text. Those without numbers are referred to by other means.

## Recovery and accuracy

The recovery and accuracy was determined with the use of standard reference bovine liver (1577a) from the National Institute of Standards and Technology (NIST), Gaithersburg, MD. The mean value of Se in the NIST standard 1577a was reported to be  $0.71 \pm 0.07$  ppm. Duplicate samples of NIST bovine liver sample were run on 10 different days. A new calibration curve was made

TABLE 100.2 Se recovery data

Replicate	Day 1	Day 2	Day 3	Day 4	Day 5	Day 6	Day 7	Day 8	Day 9	Day 10	Mean
1	0.754	0.678	0.614	0.517	0.696	0.769	0.662	0.690	0.560	0.740	0.668
2	0.804	0.753	0.709	0.663	0.691	0.772	0.663	0.619	0.560	0.790	0.7024
Mean											0.6852

TABLE 100.3 Acceptable recovery values for various analyte concentrations

Concentration	Recovery limits (%)
100%	98–101
10%	95–102
1%	92–105
0.1%	90–108
0.01%	85–110
0.001% (10 ppm)	80–115
0.0001% (1 ppm)	75–120
1 ppb	70–125

each day with new Se standards (obtained from Perkin Elmer). The results of Se concentration in NIST bovine liver are shown in Table 100.2.

The mean recovery from NIST 1577a bovine liver is 0.6852 ppm. Thus, recovery % is:

$$\begin{aligned}\% \text{ Recovery} &= (\text{Laboratory mean recovery} / \\ &\quad \text{NIST value}) \times 100 \\ \% \text{ Recovery} &= 0.6852/0.71 = 96.5\%\end{aligned}$$

The % recovery is well within the values recommended in AOAC guidelines (AOAC, 2003) that are shown in Table 100.3.

### Precision

The precision of an analytical method is represented by the standard deviation for the method for replicate measurements. There are two kinds of standard deviations that can be computed for the laboratory method. One is the standard deviation for within day run, i.e., the standard deviation for replicate samples that are analyzed on a given day; the other is the standard deviation for among days analysis. Since the routine samples are analyzed on days when the laboratory receives them, the standard deviation for “among days” applies for the routine samples. The manual calculations for this standard deviation are complex. Fortunately, AOAC International has the software for calculating these standard deviations, which is available from Dr. Joanna Lynch (jl72@cornell.edu), Cornell University, Ithaca, NY. This software is developed for evaluating interlaboratory (collaborative) studies. However, this is also applicable for the determination of within day and among days standard deviation.

This software can also determine the % recovery for the method.

The within day standard deviation ( $s_r$ ), also known as repeatability, is calculated from the software as 0.0480 ppm, and the relative standard deviation,  $RSD_r$ , which is represented by the relationship

$$\%RSD_r = \frac{s_r}{\bar{x}} \times 100 = 7\% \quad (100.6)$$

But our true standard deviation for repeatability is among days standard deviation, thus the true repeatability relative standard deviation is calculated by using  $s_R$  (0.082) (from AOAC software). For replicate measurements made on different days within a laboratory, it is also known as intermediate precision. For the purposes of clarity, this relative standard deviation is represented as %  $RSD_{ri}$ . The true repeatability relative standard deviation (among days) is:

$$\%RSD_{ri} = \frac{s_R}{\bar{x}} \times 100 = 11.97\% \quad (100.7)$$

Although the recovery is within AOAC International guidelines, does it belong to the same population as the NIST bovine liver 1577a? The answer to this question is obvious. The 95% confidence limit for the NIST bovine liver is given in the certificate of analysis as  $0.71 \pm 0.07$  ppm. The laboratory mean recovery of 0.69 ppm (0.6852 rounded to two decimal places) is within the confidence limit as provided by NIST certificate of analysis. Thus, it can be concluded that there is no significant difference between two means. At this point, the only thing to be answered is how good the laboratory relative standard deviation ( $RSD_{ri}$ ) is. This is determined by the use of HorRat values.

### HorRat values

For SLV work, the HorRat value is given by the relationship,

$$HorRat_r = RSD_{ri}/PRSD_R \quad (100.8)$$

where  $RSD_{ri}$  is the relative standard deviation for among days analysis (Eqn 100.8), and  $PRSD_R$  is the predicted relative standard deviation for between laboratories analysis. How do we find  $PRSD_R$ ? It can be predicted based

on the concentration of the analyte (Horwitz *et al.*, 1980; Horwitz, 1982). Based on the data from 100 years' worth of interlaboratory method validation studies conducted under AOAC International auspices, Horwitz determined that relative standard deviation between laboratories and within laboratory is dependent on the analyte concentration. The relationship is expressed by the equation:

$$PRSD_R \% = 2C^{-0.15} \quad (100.9)$$

where  $C$  is expressed as the mass fraction. The above equation can be expressed in spreadsheet notation:  $PRSD_R \% = 2 \times C^{(-0.15)}$ . For example, a concentration of 1 ppm is expressed as  $1.000E-6$  ( $1 \mu\text{g/g}$ ). Thus for an analyte concentration of 1 ppm the calculated:

$$PRSD_R \% = 2 \times (1.000E-07)^{(-0.15)} = 16\% \quad (100.10)$$

Another observation of Horwitz that was confirmed by Thompson and Lowthian (1997) is that the precision of analytical methods at any given concentration does not improve with time, despite the advances in analytical technology. The mean value of selenium in NIST bovine liver is 0.71 ppm, thus, the predicted relative standard deviation for between laboratories is

$$PRSD_R \% = 2 \times (7.1E-7)^{(0.15)} = 16.7\%$$

Thus, the HorRat value for our method for the determination of selenium is:

$$HorRat = 11.97/16.7 = 0.71$$

The accepted HorRat values for single laboratory method validation are from 0.5 to 1.3. Thus, the relative standard deviation for our method is well within the accepted limit. The linearity of the calibration curve, the percent recovery, the relative standard deviation and HorRat value clearly show that the method meets the validation criteria.

## Shewhart chart

The basic concept behind Shewhart's control chart is the distinction between two categories of variation. A process will either display "controlled variation" or it will display "uncontrolled variation." When a process displays controlled variation, its behavior is indiscernible from what might be generated by a "random" or "chance" process. On the other hand, when a process displays uncontrolled variation, then something markedly different has occurred from what would have been expected from a random or chance process, and therefore an "assignable cause" can be attributed to that occurrence. Also, as its

FIGURE 100.2 Shewhart chart – Se assay.

effect has been large enough to notice, it is surely worth the effort to try to identify this assignable cause.

Given this distinction, the control chart is a technique for detecting which type of variation is displayed by a given process. The objective is to give the user a guide for taking appropriate action – to look for assignable causes when the data display uncontrolled variation, and to avoid looking for assignable causes when the data display controlled variation.

Shewhart looked upon the control chart as the voice of the process – one can use the chart to understand how a process is behaving. Therefore, a process is said to be "in control" only when it has demonstrated, by means of a reasonable amount of data, that it is performing consistently and predictably. Moreover, from a practical perspective, such a process is, in essence, performing as consistently as possible. Therefore, any process that is not performing "as consistently as possible" may be said to be "out of control." Thus, the control chart is a procedure for characterizing the behavior of a process.

Figure 100.2 shows the Shewhart control chart for our GC method for selenium determination in NIST bovine liver 1577a. In normal distribution, two standard deviations of the mean consist of 95% of the values, and three standard deviations comprise 99% of all the values, which can result from random variation in the process. Thus, for each run, if we plot the difference from the mean on the  $y$ -axis, and number of runs on the  $x$ -axis, it provides us with a pictorial view of the variation in the process. If our values fall within two standard deviations from the mean, the process is statistically under control. Thus, two standard deviations in either a positive or negative direction form the upper and lower warning limits. If the observation from the run is coming very close to the warning limit line, it means the process is nearing its statistical control limit. If the values go beyond three standard deviations from the mean, it means the process is out of control, and that certain errors other than the random variation are entering the process. At this time, the analysis for routine samples should be stopped, and the reason for the error

investigated. When the problem is solved, only then can routine testing begin. In Figure 100.2, an asterisk marks the point at which the method is out of statistical control.

EXAMPLE OF AN INTERLABORATORY (COLLABORATIVE) STUDY FOR THE VALIDATION OF THE SEMI-QUANTITATIVE METHOD

Any method must be fit for the purpose. Nitrate causes poisoning in ruminants. The nitrate-containing forages are usually responsible for this poisoning. The guidelines for feeding ruminants with nitrate-containing forages are as follows (on dry matter basis) (Guthrie, 1986):

- Forages with nitrate concentrations less than 1000 ppm are considered safe under all conditions.
- Forages with 1000–5000 ppm nitrate should be safe to feed to *nonpregnant animals* under all conditions.
- Forages containing more than 2500 ppm nitrate should be limited to 50% of the total ration for *pregnant and lactating* animals. Erratic and low milk production is expected when nitrate concentration in forages exceeds 2500 ppm.
- Forages containing 5000–10,000 ppm nitrate may be fed safely to *nonpregnant and nonlactating* animals if limited to 50% of the total ration. For *lactating and pregnant animals*, such forage should be limited to 25% of the total ration. Abortions and drop

in milk production should be expected if such forage is greater than 25% of the total ration.

- With forages containing greater than 10,000 ppm nitrate, abortions, acute symptoms and death should be expected. Thus, these forages should not be fed to ruminants.

Results of an intralaboratory study reported by Jain (1993) indicated that nitrate content of forage could be estimated using a test strip. Thus, a collaborative study was conducted to demonstrate the validity of the screening test for nitrate in forages.

Six forage samples were made for the collaborative study (Jain *et al.*, 1999). The nitrate concentration in forage samples ranged from 1000 ppm nitrate to 10,000 ppm nitrate. Five samples were made from field cases submitted to the Athens Veterinary Diagnostic Laboratory. Two of them were mixture of forages. The sixth specimen was also a mixture of forages, and was provided by the Veterinary Diagnostic Center, University of Nebraska, Lincoln. The forage specimens were dried overnight at 60°C in a convection oven, ground using a Wiley Mill to pass through a 2 mm screen, and then thoroughly mixed in a twin shell blender. Samples for each collaborator were prepared by placing 1.0 g of forage in a 50 ml plastic centrifuge tube labeled with a coded number. Five blind replicates of each of the six forage samples were prepared for each collaborator. The samples were labeled with numbers 1–30, and were sent to 20 different laboratories across the U.S.

Table 100.4 shows the results from various laboratories. The laboratory recorded the range number of a given sample. For example, for sample number 21,

TABLE 100.4 Response profiles of laboratory results for each range

The \* to the left of the number indicates that the range was incorrectly determined.  
<sup>a</sup>Results of laboratories I and M were deleted from statistical analysis as outliers based on *chi-square* test and inspection, McClure (1990).

which is in range number 1, all the laboratories, except laboratory U, identified the sample correctly in range number 1. The complete results were received from 19 laboratories. The statistical analysis of the data was conducted according to McClure (1990). The published collaborative report does not show how the calculations for statistical parameters were made; it only shows final results. The step-by-step calculations are shown in this chapter for the benefit of the reader.

### Outlier results

First, the results were tested for outlier values, if any, using *chi-square* statistics ( $Q$ ). The null hypothesis is that labs do not have significantly different proportions of correct results. Table 100.5 shows the recast of the data in Table 100.4 for statistical purposes to reflect correct (1) and incorrect (0) results, and is used for computation of the  $Q$  statistic, by Eqn (100.11):

$$Q = \frac{(L-1)(L\sum T_i^2 - (\sum T_i)^2)}{(L\sum S_j - \sum S_j^2)} \quad (100.11)$$

where  $L$  is the number of laboratories reporting the results,  $T_i$  is the number of correct results by the laboratory ( $i$ ) and  $S_j$  is the total number of correct results for sample ( $j$ ). Thus, referring to Table 100.5,

$$Q = \frac{(19-1)(19(16023) - (551)^2)}{19(551) - (10145)}$$

$$Q = \frac{18(836)}{324}$$

$$Q = 46.44$$

This calculated value of chi-square is greater than the critical value of 28.87 for 18 ( $L-1$ ) degrees of freedom. Thus, the null hypothesis is disapproved, and there are significantly different proportions of correct results. By inspection, the laboratories I and M appear to be outliers. After rejecting the outliers the test was repeated, and the calculated value of statistic ( $Q$ ) was found to be 15.775, which is less than the critical value of 26.29 for 16 degrees of freedom (note that the results of laboratories I and M were rejected).

### Sensitivity rate

The sensitivity rate ( $p_+$ ) is the probability that the method will classify a test sample in a "given range" provided that the sample is in that "given range." For example, samples 2, 4, 6, 10, 11, 12, 13, 16, 21 and 27 are range 1 samples; whereas all other samples are in "another range." For

statistical analysis, we are saying that all samples listed under range 1 in Table 100.4 are correctly identified if they are identified as 1 in the table. Any other number in the table for range 1 is considered as misidentification, and is considered a negative value for range 1. The data for the calculations of sensitivity rate and its standard error for various ranges are shown in Table 100.6.

$$(p_+) = \frac{\sum a_i}{\sum m_i} \quad (100.12)$$

where  $\sum a_i$  is the total number of correct results for a given range and  $\sum m_i$  is the total number of results for that range. Thus, the sensitivity for range 1,

$$(p_+) = \frac{169}{170} = 0.994$$

The standard error for sensitivity for each range can be calculated by the formula

$$s.e.(p_+) = \left\{ \frac{(\sum a_i^2 - (\sum a_i)^2/L)}{\sum (\bar{m})^2 L(L-1)} \right\}^{1/2} \quad (100.13)$$

Thus for range 1,

$$s.e.(p_+) = \sqrt{\frac{1681 - 1680.0588}{100 \times 17 \times 16}} = 0.006$$

This means that for range 1, if large numbers of observations were made, 6 out of 1000 observations will misidentify range 1 and 994 observations will correctly identify range 1.

The sensitivity rate and standard error for other ranges can be calculated similarly.

### Specificity rate ( $p_-$ )

The specificity ( $p_-$ ) for the "given range" is the probability that the method will classify the test sample in "any other range" provided the test sample was in "another range." For range 1, all samples that are not in range 1 are in "another range." The value of ( $p_-$ ) can be calculated by Eqn (100.12). For specificity rate calculations,  $m$  is 20 since there are 20 samples in ranges 2, 3 and 4. Thus the total of all  $m$  values is  $20 \times 17$  (340, since there were 17 laboratories). The total of correct values for specificity rate is 339, since only laboratory Q has a range 2, 3 or 4 samples identified as range 1 sample. The data for calculations of specificity rate and its standard error are shown in Table 100.7.

$$\text{Thus specificity rate for range 1 is } (p_-) = \frac{339}{340} = 0.997.$$

[illegible]

$\Sigma a_i^2$	1681		407		400		1662	
$\Sigma(a_i)^2$	28,561		6889		6724		28,224	
$(\bar{m})^2$	100		25		25		100	

<sup>a</sup> $m_j$  = number of "known" positive samples for a given range/lab;  $a_i$  = number of positive results obtained among "known" positive samples for a given range/lab.

The standard error for specificity rate using Eqn (100.13) is:

$$s.e.(p_-) = \sqrt{\frac{6741 - 6760.059}{400 \times 17 \times 16}} = 0.003$$

### False positive rate ( $p_{f+}$ )

The false positive rate is the probability that the test sample is in "another range" and has been classified in a "given range." The data for the calculations of false positive rate and its standard error is shown in Table 100.8. The equations for the calculations for false positive rate and its standard error are Eqns (100.14 and 100.15), respectively.

$$\text{False positive rate } (p_{f+}) = \frac{\sum a_i}{\sum m_j} \quad (100.14)$$

$$s.e.(p_{f+}) = \sqrt{\frac{(\sum a_i^2 - 2(p_{f+})\sum a_i m_j + (p_{f+})^2 \sum m_j^2)}{L(L-1)(\bar{m})^2}} \quad (100.15)$$

Thus, the false positive rate ( $p_{f+}$ ) for range 1 is  $1/170 = 0.0058823$  rounded to 0.006

$$s.e.(p_{f+}) = \sqrt{\frac{1 - 2(0.0058823) \times 11 + 0.0000346}{17 \times 16 \times 100}} = 0.0058395$$

<sup>a</sup> $m_j$  = number of "known" positive samples for a given range/lab;  $a_i$  = number of negative results obtained among "known" negative samples for a given range/lab.

### False negative rate ( $p_{f-}$ )

The false negative rate is the probability that a test sample is in a "given range" and the sample has been classified in "another range." The data for the calculations of false negative rate and its standard error are shown in Table 100.9. Thus, the false negative rate ( $p_{f-}$ ) and its standard error for various ranges can be calculated from the Eqns (100.14 and 100.15), respectively.

False negative rate ( $p_{f-}$ ) for range 1 =  $1/340 = 0.0029411 = 0.003$  and its standard error is

$$s.e.(p_{f-}) = \sqrt{\frac{1 - 2 \times (0.003) \times 21 + 0.0612}{17 \times 16 \times 400}} = 0.0029 = 0.003$$

### Performance parameters for the method

Various performance parameters are shown in Table 100.10.

## LABORATORY QUALITY MANAGEMENT

The integrity of a laboratory product depends on the quality system that is followed by the laboratory. Just what is quality and why is it so important? Quality system has a different meaning in different laboratories but

<sup>a</sup>The sensitivity rate ( $p_+$ ) is the probability that the method will classify a test sample in a "given range" provided the sample is in that "given range."

<sup>b</sup>The specificity rate ( $p_-$ ) is the probability that the method will classify the test sample in "another range" provided the test sample is in "another range."

<sup>c</sup>The false positive rate ( $p_{f+}$ ) is the probability that the test sample is in "another range" and has been classified in a "given range."

<sup>d</sup>The false negative rate ( $p_{f-}$ ) is the probability that a test sample is in given range, and the sample has been classified in "another range."

they share the same key elements to ensure the quality and integrity of the product. A quality system has elements that are of a quality assurance (QA) nature and others that are of a quality control (QC) nature. The quality system is also referred as QA/QC. Some laboratories work under the standards of a certain organization such as ISO, AOAC, or AAVLD, whereas some laboratories develop their own quality system customized to the needs of the laboratory (Tebbett, 2003).

### Quality assurance

ISO standard 9000:2000 defines QA as part of the quality management focused on providing the confidence that quality requirements will be fulfilled. All QA programs have similar elements: they are designed to ensure that (1) the sample is not contaminated, (2) is handled by personnel who are trained for that specific job and are using equipment that is properly calibrated and procedures that are validated, and (3) that everything is documented and that records can be accessed when needed (Tebbett, 2003). Good quality produces good results. It gives the laboratory an edge over competitors and makes the customers happy because they can rely on the integrity of the results produced. Poor quality wastes time, supplies and money (Archer, 2005). The accuracy of the result is questionable, which casts a shadow on everything that the laboratory produces.

### Quality control

Quality control refers to the steps taken during the analytical process to ensure that the process produces reliable measurements, data that are fit for the purpose.

## CONCLUSIONS

"Prove it!" What would be your response to that challenge to the data generated by your investigation or services? Can you prove the accuracy of your data? Yes, you can prove the integrity and accuracy of your results if the validated analytical method was used in conjunction with reference materials traceable to a recognized source, and you have at hand the validation data. Just saying that we use validated methods in our laboratory is not enough. The analysis of reference materials traceable to sources recognized by measurement bodies with client samples is essential to provide defensible data of such quality that is useful to the client. Even the validated methods must be repeated in the laboratory to confirm that the laboratory is able to get the performance parameters as reported in the validated method. The record keeping of the validation of performance parameters is part of the quality management plan. In order to ascertain that the method is performing under statistical control, a control sample should be run with each batch of samples. The value of the control sample gives the indication of the performance of the method on a given day. Analyzing control samples with each batch of samples is also part of the quality management program. Each laboratory must have a sound quality management (QA/QC) program.

## ACKNOWLEDGMENT

The authors would like to thank Teresa Morrison for the laboratory work used in this chapter.

# Sample submission for toxicological analysis

Beverly S. Arnold

## INTRODUCTION

Is this animal poisoned? This question arises in almost every veterinary practice. An accurate diagnosis is the single-most important factor in dealing with poisoned animals. The offending agent may be known or unknown. If the offending agent is known, specific treatment and prevention can be initiated. Often the toxic agent is unknown. In this instance, efforts are limited to supportive care and symptomatic therapeutic measures.

Chemical analysis is very important in diagnosing poisoning. This is usually done at veterinary diagnostic laboratories. In the U.S. there are 41 AAVLD accredited veterinary diagnostic laboratories. A list of accredited and allied laboratories is available at [www.aavld.org](http://www.aavld.org). Most of these laboratories are partially funded by the respective states, thus, the services of veterinary diagnostic laboratories are available at a reasonable price to the client. Familiarity with the chemical analysis services provided by the diagnostic laboratory in your area and its fee structure are extremely important in the effective use of the services provided by the laboratory.

The objective of this chapter is to provide guidelines for proper sample submission to diagnostic laboratories. Each diagnostic laboratory has a submission form, which should be completed in full to get the most efficient service for chemical analysis. All of the diagnostic laboratories require complete history, clinical signs and post-mortem findings. This information greatly aids the laboratory personnel to decide on the best course of chemical analysis.

## REQUIRED INFORMATION FOR SAMPLE SUBMISSION

### History

A detailed history of the circumstances associated with poisoning is the first step for a successful diagnosis. The investigation of a poisoning case is as much detective work as it is veterinary medicine and chemical analysis. Three detectives are partners in this endeavor – veterinarian, client and the analytical laboratory. The veterinarian must be ready to gather as many pieces of the puzzle together as possible. [Fitzgerald \(2001\)](#) described in detail various elements of a good history. [Osweiler \*et al.\* \(1985\)](#) and [Osweiler \(1996\)](#) provided a checklist for a good history.

### Clinical signs

Clinical signs are very important in reaching the diagnosis of a poisoning. Clinical signs can narrow the search for toxic agents. Ask the client for the sequence of clinical symptoms. Describe clinical signs in detail. It is not enough to say that the patient was observed with central nervous system (CNS) signs. It is essential to provide the complete sequence of events as to how the patient acted.

### Post-mortem findings

If the animal has died, send the body to a veterinary diagnostic laboratory. A pathologist qualified in

necropsy techniques will conduct the necropsy and collect the appropriate samples for histological as well as for toxicological testing. If it is poisoning then why worry about necropsy and histological examination? Simply test for toxicants and it should give us a diagnosis. Unfortunately, it is not that simple. There are thousands of chemicals that can cause poisoning in animals. *There is no simple test for all the poisons.* Some poisons produce extensive lesions, others only slight tissue alterations, and some produce no lesions at all. Based on this information the pathologist can provide assistance in the selection of toxicants to test for.

### Chemical analysis

Chemical evidence is often an indispensable aid in diagnosing toxicological problems. Used properly, chemical analysis can provide the most important evidence of poisoning. Analytical data should be used in conjunction with history, clinical signs, necropsy findings and histological examination. The importance of clinical signs, post-mortem findings and chemical analysis has been described in detail in previous reports (Osweiler *et al.*, 1985; Poppenga and Braselton, 1990; Gale, 2000, 2001, 2004; Puschner and Gale, 2001; Volmer and Meerdink, 2002).

## SAMPLE COLLECTION AND SUBMISSION FOR TOXICOLOGICAL ANALYSIS

A list of various types of samples which can be useful in the investigation of poisoning cases is given in Table 101.1.

Each sample should be stored in a separate container, and the container should be labeled with an indelible ink with animal and tissue identification. Place the sample container in a zip-lock bag, squeeze the air out of the bag, and seal and label it. *Do not add anything to the samples for chemical analysis: no antiseptic, no preservative, no fixative, unless otherwise noted (as for whole blood).* These instructions apply to all the samples which are collected. Lorgue *et al.* (1996) provides a detailed account for sample collection and dispatch to the laboratory with particular reference to United Kingdom.

### Whole blood

Whole blood should be collected in royal blue top (for trace elements) Vacutainer tubes with anticoagulant. At least 10ml of whole blood should be collected. If more

than one test is required, collect 20ml blood. Make sure the tube is properly sealed. Refrigerate the sample. *Do not freeze whole blood sample.*

### Serum

The blood for serum samples should be collected in royal blue top Vacutainer tubes (plain) which contain *no additives or anticoagulants*. After the clot forms, in usually less than 30min, the serum should be separated promptly, and transferred to a clean plastic tube and frozen.

### Urine

Urine should be collected in a screw cap plastic bottle (4oz.) and frozen.

### Liver biopsy specimen

Collect approximately 100–200mg of liver sample and immediately freeze; some laboratories may not be able to provide results for some metals due to small sample size. Contact the laboratory before proceeding with biopsy.

### Milk

Collect in a clean jar and refrigerate.

### Feces

Place feces in heavy duty aluminum foil, wrap it completely, place in zip-lock bag and freeze.

### Vomit or gastric aspirate

Place vomitus in a screw cap plastic bottle and freeze. In case of gastric aspirate make sure to submit first aspirate.

### Hair

Hair samples should be collected using clean scissors or clippers. Do not contaminate with other materials such as blood on gloves. Place the hair sample in a zip-lock bag. Keep it at room temperature.

### Brain, liver, kidney, fat and other tissue(s) with lesions

Collect appropriate amount of the particular sample (Table 101.1), place the sample on heavy duty aluminum

TABLE 101.1 Samples for toxicology testing

Sample	Amount	Tests for which sample can be used	Comments
<i>Ante-mortem samples</i>			
Blood	10–20 ml	Heavy metals, trace elements, anticoagulants, antifreeze, cholinesterase, cyanide, chlorinated hydrocarbon pesticides	Refrigerate sample. Use anticoagulant such as EDTA or heparin. Use royal blue tubes with anticoagulant
Serum	10–20 ml	Some metals like Cu, Zn, and nitrate/nitrite, ammonia, drugs (particularly sulfa drugs)	Separate clot from the serum. Refrigerate or freeze (if it will take long during shipping). Amount required for single test will be much less. Check with the testing laboratory. If Zn assay is desired use royal blue tubes without any additive or anticoagulant
Urine	50–100 ml	Alkaloids, some metals, antibiotics, cantharidin, drugs, sulfa drugs, oxalates and paraquat or diquat	Freeze. Especially useful for paraquat or diquat
Feces	250 g	Drugs, various poisons excreted mainly in bile	Freeze. Indicator of recent exposure
Biopsy specimen: liver		Metals	Freeze
Milk	250 ml	Antibiotics, chlorinated insecticides, polychlorinated biphenyls	
Vomitus or gastric	All available	Various poisons. Heavy metals, anticoagulants, antifreeze, pesticides (all chlorinated hydrocarbons organophosphates, carbamates)	Freeze. Indicator of recent exposure. In case of gastric aspirate make sure to submit first aspirate
Hair	5–10 g	Pesticides, and some metals such as As and Se	Indicator of recent exposure. Chronic accumulation of metals
<i>Post-mortem samples*</i>			
Brain	Half	Chlorinated pesticides, pyrethrins, cholinesterase, and metals like, Pb, Na, Hg	Brain should be separated by midline sagittal section. Collect frontal cortex for cholinesterase determination. Freeze
Fat	250 g	Chlorinated pesticides and dioxins	
Kidney	100 g or all available	Metals like As and Pb. Phenolic compounds, oxalates	Freeze
Liver	100 g or all available	Chlorinated pesticides, alkaloids, anticoagulants, aflatoxin M <sub>1</sub> and metals	Freeze
Ocular fluid	All available	Nitrate/nitrite electrolytes	Freeze
Rumen content	500 g	Various poisons. Heavy metals, pesticides (all chlorinated hydrocarbons organophosphates and carbamates)	Freeze. Sample should be collected from several locations in the rumen. Rumen content is not a good sample for nitrate/nitrite evaluation
Stomach content	500 g or all available	Various poisons. Heavy metals, anticoagulants, antifreeze, pesticides (all chlorinated hydrocarbons organophosphates and carbamates)	Freeze
<i>Environmental samples</i>			
Baits	All available	Various poisons. Heavy metals, anticoagulants, antifreeze, pesticides (all chlorinated hydrocarbons organophosphates and carbamates), anticoagulants	Any other information which is available about bait should be communicated to the testing laboratory
Feeds	2 kg	Various poisons. Heavy metals, pesticides (all chlorinated hydrocarbons organophosphates and carbamates), ionophores	Multiple representative samples should be taken from various places from the stock and mixed thoroughly for a composite sample or retained as individual samples to detect variability in the feed or both. Feed samples are required for ionophores screening
Forage (pasture)	2–5 kg	Various poisons. Usually used for evaluation of nitrate/nitrite	Samples should be taken from multiple locations in pasture and mixed thoroughly for composite sample. Avoid contamination from soil. Refrigerate sample
Forage (hay)	2–5 kg	Various poisons	Samples should be taken from multiple locations using a forage core sampler from baled hay or stacks and mixed thoroughly for composite sample
Forage (silage)	2–5 kg	Various poisons	Freeze
Mushrooms	Whole 100 g	Identification cyclic peptide hepatotoxin	Keep cool and dry in paper bag
Plants	Entire plant	Identification	Press between sheets of paper
Soil	1 kg	Various poisons	Samples should be taken from multiple locations using a soil core sampler and mixed thoroughly for composite sample
Water	1 l	Nitrate/nitrite, pesticides and metals	Use clean glass container. Refrigerate sample

foil, fold the corners of aluminum foil to seal the sample and place the foil with the sample in the appropriate size zip-lock bag. Handle one specimen at a time and avoid cross contamination. Freeze the tissue samples; fat may be refrigerated. Special attention is needed for brain samples. Brain should be separated by midline sagittal section. Collect the frontal cortex for cholinesterase assay (Gupta, 2004) and freeze the sample until analysis. It should be pointed out that caudate nucleus should not be used for cholinesterase assay, since frontal cortex is a better indicator of cholinesterase status (Gupta, 2004).

### Ocular fluid

Collect ocular fluid in a small plastic tube and freeze.

### Ingesta (rumen content and stomach content)

Carefully examine the contents of rumen or stomach for extraneous material. Make sure that the extraneous material is sampled for submission. Collect appropriate amount of the particular sample (Table 101.1), place the sample on heavy duty aluminum foil, fold the corners of aluminum foil to seal the sample and place the foil with the sample in the appropriate size zip-lock bag. Rumen contents should be collected from several locations in the rumen and mixed thoroughly. Rumen content is *not* a good sample for nitrate/nitrite evaluation.

### Baits

Collect all possible bait samples, wrap in heavy duty aluminum foil and place in a zip-lock bag. Gather all possible information regarding the bait, and forward the information to the testing laboratory along with the sample.

### Feedstuffs

Feedstuffs should be collected from several different locations in bin, crib, or silo. Many mycotoxins, for example, are found in isolated pockets of the feed and therefore could be missed if one sample is obtained. It is preferable to sample some feed from the troughs or bunks. If the ration is mixed on the premises, it is advisable to collect at least one pound each of the various components in the total ration. Samples of dry ration can be submitted in plastic bags, and the bag labeled with the identification of the sample.

### Forage (pasture)

Samples should be taken from multiple locations in pasture and mixed thoroughly for composite sample. Avoid contamination from soil. Refrigerate the sample.

### Forage (hay)

Ideally, hay samples should be taken from multiple locations using a forage core sampler from baled hay or stacks and mixed thoroughly for composite sample. Additional attention should be paid when sampling hay for nitrate/nitrite assay. Nitrate is water soluble. When a bale of hay is exposed to rain, nitrate leaches from the top of the bale and percolates through the bale. In this instance, it is preferable to sample hay in the area where the water line has stopped. This area usually has very high nitrate concentration. Since this sample is wet, freeze it promptly. Make a notation on the history sheet if the animals were observed to eat hay from this area. In addition, the samples from other parts of the bale should also be submitted.

### Forage (silage)

Silage samples should be taken from multiple locations and frozen promptly.

### Mushrooms

Samples of mushrooms are collected for two purposes: identification of mushroom species and chemical identification of cyclic peptide hepatotoxin. For identification, collect a whole mushroom, and keep it cool and dry in a paper bag. For the presence of cyclic peptide hepatotoxin, collect about 100g sample and freeze.

### Plants

Plant samples are collected for identification of the plant as well as the identification of plant toxins. It is desirable that the whole plant is collected intact, with roots and any flowers or buds for identification. Plants can be pressed between sheets of newspaper and sent for identification. Plants for chemical analysis should be wrapped in aluminum foil, placed in a labeled plastic bag and frozen.

### Soil

Samples of soil for chemical analysis should be taken from multiple locations using a soil core sampler and mixed thoroughly for composite sample.

## Water

Collect samples of water in clean glass containers.

## Samples for histological examination

In addition to samples for chemical analysis, samples of tissues fixed in formalin should also be submitted for histological examination. The importance of histological examination of tissue samples has already been discussed in an earlier section of this chapter.

## Samples for nutritional elemental analysis

Whole blood and serum are analyzed for this purpose. For elemental analysis, whole blood should be collected in royal blue top Vacutainer tubes. For serum samples, the blood should be collected in royal blue top tubes (plain), which contain *no additives or anticoagulants*. After the clot forms, in usually less than 30 min, the serum should be separated promptly and transferred to a clean plastic tube and frozen. The manuscript by [Hancock et al. \(1988\)](#) provides excellent information about the number of animals to be sampled for laboratory analysis for herd health management. It contains information tables for sample size required to estimate prevalence or attribute with a given confidence limit.

## Submission forms

All of the veterinary diagnostic laboratories have submission forms. Cases are not accepted without submission forms. Complete the submission form as thoroughly as possible. Include all the information as discussed in earlier sections. Remember that there are three detectives in solving the poisoning problem – the client, the practitioner and the analytical toxicologist at the diagnostic laboratory. It has been our experience that an accurate, fully completed submission form greatly helps laboratory colleagues to take the most appropriate analytical approach.

## SHIPPING REGULATIONS FOR DIAGNOSTIC SPECIMENS

Most countries have regulations for shipping diagnostic specimens. In the United States the rules are published in the “Code of Federal Regulations” (CFR) Part 49, sections 100–185. It is available on the internet at <http://ecfr.gpoaccess.gov/>.

## Packing diagnostic specimens for transport: summary

- You as the shipper – not the transport company – are responsible for the shipment until the package reaches the consignee.
- The diagnostic specimens should be packaged in triple packing, consisting of primary, secondary and the outer packing.
- *Primary packaging*: Primary receptacle(s) must be water tight, e.g., screw cap seal with Para film or adhesive tape or similar. Multiple primary receptacles must be wrapped individually to prevent breakage.
- *Secondary packaging*: Use enough absorbent material in the secondary container to absorb the entire contents of all primary receptacles in case of leakage or damage. Secondary packaging must meet IATA packaging requirements for diagnostic specimens including the 1.2 m (3.9 ft) drop test procedure.
- Secondary packaging must be watertight. Follow the packaging manufacturer’s or other authorized party’s packing instructions included with the secondary packaging. Secondary packaging must be at least 100 mm (4 in.) in the smallest overall external dimension. Must be large enough for shipping documents, e.g., air waybill.
- *Outer packaging*: The outer packaging should be rigid and of adequate strength for the intended use.
- Each package and the air waybill are labeled differently depending on whether the contents are infectious or non-infectious animal specimens. Infectious substances are considered dangerous or hazardous materials. National and international regulations require that the person involved in the packaging and shipping of hazardous materials be trained and certified in the proper handling of these materials.
- An itemized list of contents must be enclosed between the secondary packaging and the outer packaging. Place in a sealed plastic bag to protect from moisture.
- A shipper’s declaration for dangerous goods is *not* required if the sample was taken directly from the patient, it does not contain an infectious substance and the container is labeled “Exempt Animal Specimens.”
- *Fines and penalties*: According to 49 CFR Sec. 171.1 (c) “Any person who knowingly violates a requirement of the Federal hazardous material transportation law...Is liable for a civil penalty of not more than...\$27,500...and not less than \$250 for each violation...and shall be fined under Title 18, United States code, or imprisoned for not more than 5 years, or both.”

## Dispatch of samples

- Place one or two ice packs (as used for camping) in a polystyrene box. Place all frozen sample packets over

ice packs. If whole blood is shipped together, make sure that some insulating material is between the frozen samples and blood. Place the polystyrene box in a rigid box.

- Write the address of the receiving laboratory legibly on the center of the outside box. On the upper left-hand corner write the sender's address.
- The submission form should be attached to the outside of the secondary packing and sealed in a plastic sleeve.
- The parcel should be clearly marked "diagnostic specimen" on the outside packing, and sent either by U.S. parcel post, UPS, FedEx, or any other courier. Check with the courier for their special requirements.

## CONCLUSIONS

Great care should be taken during the collection and shipping of diagnostic specimens for chemical analysis. Remember that laboratory results are as good as the submitted specimen. Follow transportation rules carefully, or any violation will involve a fine. Diagnostic laboratories are not the enforcers of transportation rules. There was an incident of a shipping foul-up by a practitioner. The courier called the laboratory to say that they had a package for delivery to the laboratory. However, courier staff were unwilling to handle the package, since it was shaking and making funny noises. The laboratory was asked to retrieve the package right away. The senior member of the laboratory went to pick up the package, opened it and found a live piglet in the container. Fortunately, the laboratory was informed the day before by the practitioner that he was sending a euthanized piglet for examination. Apparently, the piglet was not given enough euthanasia solution. This incident happened about 10 or more years ago. Imagine what would happen today if a package like this arrived at the courier!

# Toxicoproteomics in diagnostic toxicology

Christina R. Wilson and Stephen B. Hooser

## INTRODUCTION

During the past decade, advances in genomics research have resulted in the completion of entire genome sequences for multiple species. This plethora of genetic information, compiled in genome sequence databases, has been used to characterize changes in gene expression in response to external stimuli, such as toxicants (toxicogenomics). Because genomic data reflects changes in gene expression at the mRNA level, DNA sequence databases can be queried to predict what proteins may be present in the cell. However, this approach is problematic because there is a poor correlation between mRNA levels and protein concentrations in cells (Gygi *et al.*, 1999a; Anderson and Seilhamer, 2005). Additionally, the biological activity of proteins is controlled by post-translational protein modifications or protein–protein interactions, both of which cannot be predicted by the genomic data. Therefore, characterizing the entire protein complement expressed by genes (proteome) in response to external stimuli serves as a better indicator of the response of an organism, tissue, or cell to toxic insult. This has given rise to the “proteomic” approach to toxicological evaluation. Toxicoproteomics can encompass global analysis of all of the proteins expressed, called “shotgun proteomics,” or can entail analyzing a subset of proteins of interest, often termed “targeted proteomics.” Regardless of the approach, proteomics-based research has created an analytical challenge, requiring sophisticated, high-throughput analytical techniques and complex computer algorithms.

## ANALYTICAL TOOLS FOR PROTEOMIC ANALYSES

### The proteome and sample complexity

The initial step in proteome analysis typically involves the separation of intact proteins or peptides generated from proteolytic digestion of protein mixtures. Analysis of these heterogeneous components has proven to be an analytical challenge due to the large dynamic range of proteins and the microheterogeneity of protein expression in biological samples. For instance, serum albumin concentrations can range from 35 to  $50 \times 10^9$  pg/mL and proteins of lower abundance, such as interleukin 6, can range in concentration from 0 to 5 pg/mL (Anderson and Anderson, 2002). This is also complicated by protein heterogeneity due to polymorphisms, alternative mRNA splicing, or variations in post-translational modifications. When analyzing global proteolytic digests of proteins (i.e., at the peptide level), the sample complexity is compounded further. Proteolytic digests of the serum proteome, which could contain as much as 20,000 proteins, can potentially result in 200,000 to 600,000 peptides (Anderson and Anderson, 2002; Issaq *et al.*, 2005). Therefore, one can appreciate the analytical challenges encountered when conducting proteomics research in complex biological systems. Attempts to overcome these drawbacks have imposed improvements in sample preparation and separation methodologies. Multidimensional levels of separation can be achieved when these techniques are combined affording increased resolution, sensitivity and accuracy of detection.

## Two-dimensional gel electrophoresis

Since its inception in 1975 (O'Farrell, 1975), two-dimensional gel electrophoresis (2-DGE) has become one of the most common platforms for separating and profiling complex protein mixtures. This technique is two dimensional in that there are two levels of protein separation. The first dimension uses immobilized pH gradient-isoelectric focusing, which separates proteins based on differences in net charge (Görg *et al.*, 2000). In the second dimension, proteins are resolved by electrophoresis and separated based on molecular weight. Visualization of resolved protein spots is achieved using universal stains such as Coomassie blue, Coomassie brilliant blue (SeePico™), silver, negative-reversible zinc, fluorescent, or radioisotope labeling dyes (Görg *et al.*, 2000; Lopez, *et al.*, 2000; Ong and Pandey, 2001; Kuramitsu *et al.*, 2010). If a particular subproteome is targeted for detection, more specific gel stains can be used. For example, detection of target proteins can be accomplished using stains containing antibodies for those proteins of interest or post-translationally modified proteins can be visualized using specialized stains for phosphorylated and glycosylated proteins (Görg *et al.*, 2004; Vlahou and Fountoulakis, 2005; Otani *et al.*, 2011).

After staining, the gel is digitized and protein concentrations quantitated using sophisticated 2-DGE image analysis software. Comparative analysis between control samples and samples of diagnostic interest can be accomplished using these image analyzers to superimpose the digitized data from multiple gel runs. However, due to the laborious nature of this procedure and the lack of gel reproducibility, comparative analysis is often difficult. In order to circumvent these limitations, fluorescent dyes, known as Cy dyes, have been developed permitting simultaneous analysis of two samples on one gel (Ünlü *et al.*, 1997; Hamdan and Righetti, 2002). This technique, called two-dimensional differential in-gel electrophoresis (2-D DIGE), involves labeling each sample with one of two different Cy dye fluorophores, mixing the two samples together, and analyzing them using 2-DGE and fluorescent gel imaging.

While the gel-staining techniques used to visualize and quantitate proteins may vary, in all instances protein identification is commonly accomplished using tandem mass spectrometry (MS/MS). Excised protein spots are digested into peptides using proteolytic enzymes and subjected, offline, to MS/MS analysis. The peptide mass fingerprints generated and peptide sequence data are then compared to theoretical peptide masses in protein or genome sequence databases using specialized bioinformatics algorithms.

Despite the fact that improvements in 2-DGE technology have enabled high resolution of separated proteins and enhanced protein identification, some intrinsic

problems remain. Limited throughput capabilities, inability to measure low and high molecular mass proteins, inter-gel variability and inefficient detection of basic and hydrophobic proteins are still inherent limitations of this proteomics platform. Regardless of these limitations, 2-DGE is still a powerful tool for the separation of intact proteins and is the most widely used technique in comparative toxicoproteomic analyses.

## High performance liquid chromatography

Attempts to improve protein separations have warranted the development of gel-free systems for large-scale analyses. Chromatographic strategies used to fractionate proteins and peptides have proven to be a successful alternative to 2-DGE. The chromatographic techniques commonly employed in proteomics research include affinity chromatography, capillary electrophoresis (CE), hydrophobic interaction chromatography, hydrophilic interaction chromatography, ion exchange chromatography (IEX), reversed-phase chromatography (RPC) and size exclusion chromatography (SEC) (Goheen and Gibbins, 2000; Levison, 2003; Goetz, *et al.*, 2004; Mahn and Asenjo, 2005; Mirzaei and Regnier, 2005; Babu *et al.*, 2006; Mondal and Gupta, 2006; Wilson *et al.*, 2008; Di Palma *et al.*, 2011). These modes of chromatography fractionate proteins and peptides based on their adsorption and desorption on stationary phase supports through mobile phase manipulation. On the protein level, they are commonly used to pre-fractionate samples in order to simplify complexity prior to analysis by 2-DGE or high performance liquid chromatography (HPLC). Fractionation of proteins using these methods can also be accomplished online using high throughput HPLC techniques. While this approach has proven to be a successful initial step in protein purification, HPLC fractionation of intact proteins is uncommon in proteomics.

HPLC is, however, the most widely used analytical tool for separating proteolytic digests of complex protein mixtures. In this approach, all of the proteins in the sample are digested into peptides using a proteolytic enzyme. After digestion, the peptides are separated using HPLC with UV detection. When interfaced with a mass spectrometer, the amino acid sequences of these peptides can be determined and their respective parent proteins identified using bioinformatics software.

Large-scale analysis of proteolytic digests can compromise the resolving power of HPLC when only one chromatographic fractionation technique is used (Davis and Giddings, 1985a,b). Therefore, orthogonal approaches using multidimensional chromatographic separations are preferred, affording greater peptide resolution and accuracy of detection. The most widely used high throughput separation technique is the coupling of IEX

and RPC with MS instrumentation. Other examples of multidimensional HPLC/MS techniques can also include RPC/CE chromatography, affinity chromatography/RP chromatography, SEC/IEX/RPC and SEC/RPC/CE (Issaq *et al.*, 2005; Zhang *et al.*, 2010a).

HPLC has also been used for quantitative analysis of protein expression. Relative quantitation of proteins by HPLC is based on the theory that the concentration of the parent protein can be determined by the relative peak areas of UV-detected peptides observed from that protein (Chelius and Bondarenko, 2002). Another HPLC-based approach for relative protein quantitation involves the use of internal protein standards (Bondarenko *et al.*, 2002). In this technique, biological samples are spiked with an internal standard protein prior to enzymatic digestion of the proteins into peptides. The chromatographic peaks observed can be normalized to the peak area of the internal standard and the relative concentrations of the proteins are inferred.

Unlike 2-DGE/MS tools, multidimensional HPLC/MS is amenable to high throughput analyses and has the ability to resolve peptide mixtures regardless of molecular mass or hydrophobicity. This is important because resolving peptide mixtures by 2-DGE is impractical due to their narrow isoelectric points and molecular weight ranges and because 2-DGE tools cannot be directly interfaced with MS instrumentation. Even though 2-DGE is superior when separating intact proteins, methods based on pairing multidimensional HPLC and MS technology are becoming more refined and continue to advance proteomics research.

## Protein and peptide microarrays

Protein and peptide microarray technologies offer a complimentary approach to traditional separation methodologies and mass spectrometry. This technology incorporates the use of a variety of high throughput microarray platforms to probe protein function, abundance and to globally analyze protein expression in biological systems. The platforms commonly used in proteomics include proteome, antibody, reverse-phase protein and lectin microarrays (Lina *et al.*, 2011).

Protein function microarrays use immobilized capture ligands to screen for protein–drug, protein–enzyme, protein–protein interactions (Kawahashi *et al.*, 2003; Nielsen *et al.*, 2003; Zhu *et al.*, 2003; Cretich *et al.*, 2006). Analytical microarrays, such as those used in surface-enhanced laser desorption (SELDI)/TOF MS, use retention chromatography for protein profiling and detection (Merchant and Weinberger, 2000; Cretich *et al.*, 2006). This technique is capable of on-chip sample fractionation utilizing various chromatographic surface chemistries

and can probe for chemical properties in proteins such as phosphorylation, glycosylation, hydrophobicity, or anionic–cationic properties.

Microarrays require immobilization of a capture ligand or chromatographic media onto a planar solid support, often resulting in thousands of spots per slide (MacBeath and Schreiber, 2000; Kumble, 2003). Samples of interest are added to the microarray and the entire array is scanned to detect proteins or peptides that interact with the ligand or chromatographic media.

Detection strategies for protein or peptide microarrays entail either label-free or labeled probe methods (Espina *et al.*, 2004; Cretich *et al.*, 2006). The label-free strategy is a direct detection method that includes MS, surface plasmon resonance, or atomic force microscopy. SELDI microarray chips commonly use MS-based detection of proteins or peptides. Labeled probe methods of detection include utilizing chromagens (similar to ELISA protocols), chemiluminescence, fluorescence, or radioactive decay-based detection techniques.

Microarray technology is progressively becoming a versatile platform for its potential use in diagnostic toxicology. Although efforts to standardize array analyses have been challenging, microarrays make it possible to simultaneously screen thousands of samples and profile large numbers of proteins from biological samples.

## Mass spectrometry

Recent developments in hybrid mass spectrometers have revolutionized the ability to analyze proteins and peptides, providing high throughput automation combined with high sensitivity and resolving power. In general, mass spectrometers have three components, an ion source, a mass analyzer and a detector. The ion source is the component in which protein and peptide ions are produced; the mass analyzer separates or resolves these ions based on their mass-to-charge ( $m/z$ ); and the detector detects the selected ions from the mass analyzer. One stage mass analysis is commonly used to measure the molecular weights of intact proteins or peptides. However, in order to obtain peptide sequence information, hybrid mass spectrometers must be employed. MS/MS, or tandem mass spectrometry, detects intact peptide ions in the first mass analyzer. Once selected, the peptide ion enters the collision cell where it is fragmented into secondary ions by collision-induced dissociation (CID). These ions are then separated in the second mass analyzer, their  $m/z$  ratios detected and MS/MS spectra are generated. Bioinformatics database tools use the MS/MS data to generate peptide amino acid sequence information and compare them with theoretical sequences in protein or genome databases to identify proteins.

There are two major types of hybrid mass analyzers used in proteomics research, matrix-assisted laser desorption ionization/time-of-flight (MALDI-TOF/TOF) instruments and electrospray ionization/tandem MS instruments (ESI/MS/MS) (Karas and Hillenkamp, 1988; Fenn *et al.*, 1989; Hillenkamp *et al.*, 1991). The MS technology chosen depends on the type of MS data that needs to be generated from toxicoproteomic experiments. For example, MALDI-TOF/TOF instruments are fast, robust mass analyzers, have a large dynamic range and do not require labor-intensive sample preparation. MALDI-TOF/TOF instruments have high resolution, making them the instruments of choice when using mass spectrometry for quantitative proteomic analyses. ESI/MS/MS instruments, including those containing hybrid combinations of quadrupole, 3-D ion trap, linear ion trap, Orbitrap, TOF and Fourier transform-ion cyclotron resonance mass analyzers (FTICR) have approximately four times less peak capacity than MALDI-TOF/TOF; however, they have higher mass accuracy affording more accurate protein identification (Hopfgartner *et al.*, 2004; Hu *et al.*, 2005; O'Connor *et al.*, 2006; Yates *et al.*, 2006; Merchant, 2010). Additionally, they are capable of analyzing low molecular weight peptides and can be directly interfaced with HPLC instrumentation.

Innovative approaches to advance protein identification strategies have spurred the development of new MS technologies. Improvements in ion activation using electron capture dissociation (ECD) or infrared multiphoton dissociation technologies have been shown to yield more extensive peptide sequence coverage when compared to CID, resulting in significant improvements in protein identification (Wysocki, *et al.*, 2005; Bakhtiar and Guan, 2006). Although once thought to be impossible, characterization of intact, large proteins can be accomplished using ECD combined with FTICR (Sze *et al.*, 2003; Zhang *et al.*, 2010b). Developments in MALDI imaging mass spectrometry have paved the way to simultaneously map peptides and proteins by direct MS analysis of thin tissue sections, providing a means to correlate and monitor changes in protein patterns associated with regions of the tissue that are histologically significant (Mange *et al.*, 2009; Stauber *et al.*, 2010). Other significant technological advances in large biomolecule ionization and data analysis have enabled the development of miniaturized, portable mass spectrometers capable of direct analysis of complex biological samples (Laughlin *et al.*, 2005; Cooks *et al.*, 2006).

In addition to being essential for protein identification, MS technology is being used for quantitative proteomic profiling. Through the use of stable isotope-coded mass tags, differential quantitation of changes in peptides from control and experimental samples is possible. Quantitation of changes in global protein expression

TABLE 102.1 Isotope-coded reagents used for chemical labeling of peptides

Reagent	Labeling technique	Reference
ALICE	Thiol modification of cysteines	Qui <i>et al.</i> (2002)
AQUA	Synthetic internal standard peptide	Gerber <i>et al.</i> (2003)
ICAT	Iodoacetylation of cysteine	Gygi <i>et al.</i> (1999b)
iTRAQ™	Modification of primary amines	Zieske (2006)
GIST	Acylation of primary amines	Ji <i>et al.</i> (2000)
MCAT	Guanidination of C-terminal lysine	Cagney and Emili (2002)
QUEST	Amidation of N-terminal lysine	Beardsley and Reilly (2003)

involves proteolytic or chemical labeling of peptides with isotope-coded mass tags prior to separation by HPLC. These labeling reagents are chemically identical; however, one label contains light isotope atoms and the other heavy isotope atoms. During proteolysis, enzymatic cleavage results in the incorporation of oxygen at the peptide carboxy-terminus. Exploiting this reaction, <sup>18</sup>O (heavy) and <sup>16</sup>O (light) isotopic oxygen labels can be used to differentially label two samples (Stewart *et al.*, 2001; Ye *et al.*, 2010). Other examples of isotope-coded reagents and their labeling strategies are listed in Table 102.1. In isotope tagging, peptides from a control sample are labeled with the light isotope and the peptides from the treated sample are labeled with the heavy isotope. After labeling, both samples are mixed together and fractionated using HPLC. When subjected to MS analysis, the mass spectrometer can distinguish between the two isotope-labeled peptide samples because a predictable mass difference will be observed between the control and experimental peptides. MS-based quantitation is then achieved by calculating the difference between the ion intensities of the light-labeled control peptide and the heavy-labeled experimental peptide samples (Figure 102.1). From this data, differential displays of peptides that increase or decrease in response to a stimulus can be generated. These differential displays are commonly used to generate protein expression profiles or protein signature patterns that can be used in comparative toxicoproteomic investigations.

## Bioinformatics tools

Protein identification is accomplished by using computer search algorithms that correlate MS and MS/MS data with predicted amino acid sequences contained in protein or genome sequence databases. Even though several types of MS and MS/MS search engines have been created, databases that are used more frequently include MASCOT, SEQUEST, Spectrum Mill, X!Tandem and Protein Prospector (Eng *et al.*, 1994; Clauser *et al.*, 1995;

**FIGURE 102.1** MALDI-TOF MS spectrum of GIST isotopically labeled peptides from control and experimental serum samples. Comparison of the relative ion intensities between the two peptides indicate that the peptide present in the experimental sample (at 1222.43  $m/z$ ) was present at a higher concentration when compared to the control sample (at 1219.40  $m/z$ ).

Perkins *et al.*, 1999; Robertson and Beavis, 2004; Kapp *et al.*, 2005). Database resources have also been created to probe for post-translational modifications on proteins and peptides. These database search engines include UniCarb-DB, for glycomics, and PHOSIDA 201, for common post-translational modifications (Gnad *et al.*, 2011; Hayes *et al.*, 2011). Tox-Prot, a searchable toxin protein database, has been created that can be queried for most known animal protein toxins (Jungo and Bairoch, 2005).

Even though the computer algorithms designed for most bioinformatics databases are slightly different, their general approach to protein identification is similar. Database search engines compare the experimental precursor  $m/z$  ions from each MS/MS scan with hypothetical peptide  $m/z$  values from the database. Hypothetical peptide masses from the database that correspond with the experimental mass values are assigned probability scores. The proteins recognized with the highest scores are indicative of the best probable protein match to the experimental MS/MS data. Some bioinformatics tools assign  $p$ -values to the correlation scores, providing an additional means for evaluating credibility of protein matches.

Integrating MS technology with bioinformatics tools has become an indispensable tool in proteomics research. However, due to the overwhelming amounts of MS and MS/MS data generated from typical proteomics experiments, creating bioinformatics tools that adequately identify and characterize the data has been a tremendous

challenge. Credible protein identification is reliant on successful interpretation of MS and MS/MS data. Unfortunately, data interpretation is often complicated by ion suppression, atypical MS/MS peptide fragmentation patterns, ill-defined universal standards for evaluating credible database matches and inability to define a single protein from one peptide spectrum (Kearney and Thibault, 2003). Additionally, variants of MS instrumentation are developing rapidly and the computer algorithms necessary to correlate the data from these next generation mass spectrometers with information contained in protein or genome sequence databases will continue to be a challenge.

## PROTEOMICS APPLICATIONS IN DIAGNOSTIC TOXICOLOGY

The current objectives of toxicoproteomics in diagnostic toxicology is to define molecular mechanisms of toxicity, screen for drug toxicities and elucidate biomarkers or signature protein profiles in order to more accurately assess, predict and diagnose toxicities (Kennedy, 2002; Guerreiro *et al.*, 2003; Wetmore and Merrick, 2004). For decades, laboratories have relied on individual protein markers for assessing toxicity. However, some of these single biomarkers can be non-specific and reflect protein

leakage from tissues, as opposed to the direct effects of toxicants on the tissues alone (Plebani, 2005). Toxicities in biological systems are multifactorial and complex, emphasizing identification of multiple biomarkers for accurately diagnosing and classifying toxicity. This makes proteomics research in toxicologic evaluation appealing because these technologies are capable of globally profiling multiple proteins. Hence, the potential to better define molecular signatures of toxicity for clinical and diagnostic toxicology is becoming increasingly possible. Several proteomic applications have been applied to gain a better understanding of target organ toxicities, mechanisms of toxicity and biomarkers of exposure for a variety of toxicants.

### Aquatic toxicology and pesticides

In veterinary toxicology, pesticide use and potential non-target toxicity in aquatic organisms is always a concern. In order to gain a better understanding of the mechanisms of toxicity, changes in protein expression have been assessed in fish exposed to single or multiple pesticides. For example, proteomic analyses of proteins in brain responsive to methyl parathion in zebrafish (*Danio rerio*) have been investigated. In this study, it was found that six proteins, which were predominantly cytoplasmic proteins, significantly changed with methyl parathion exposure (Huang *et al.*, 2011). The proteins most affected by methyl parathion are known to be involved in catalysis, binding, cell structure and metabolic regulation. In another study in brains from male, flathead minnows (*Pimephales promelas*), protein expression was compared in fish exposed to permethrin, terbufos, or a binary mixture of both pesticides (Biales *et al.*, 2011). In this study, 24 proteins changed with exposure to these pesticides when compared to controls. Some of the proteins identified are known to be associated with the cytoskeleton, glycolysis, hypoxia and the ubiquitin–proteasome system. The investigators also compared protein expression patterns in treated fish versus control fish. Interestingly, the permethrin protein expression pattern was distinguishable from that in the controls, enabling them to discriminate between the two treatment groups with 87.5% accuracy. When comparing the proteins identified in the aforementioned studies, the protein dihydropyrimidase-like 3 was down-regulated in zebrafish exposed to methyl parathion; however, this protein was up-regulated in the flathead minnows exposed to permethrin.

### Hepatotoxicity

Monitoring liver function is crucial in toxicologic evaluation. Hence, it is no surprise that toxicoproteomic

experiments have been conducted to gain a better understanding of proteins that change with hepatotoxicity. For example, toxicoproteomics has been used to identify metabolic pathways affected by drug-induced cirrhosis in rat models. In these studies, thioacetamide and ethanol have both been shown to down-regulate proteins involved in oxidative stress and fatty acid  $\beta$ -oxidation pathways during early phases of cirrhosis (Low *et al.*, 2004; Venkatraman *et al.*, 2004). Ivermectin hepatotoxicity has been investigated in gilthead sea bream fish (*Sparus aurata*). Of the proteins that significantly changed, 30 proteins decreased and six proteins increased with exposure to ivermectin (Varo *et al.*, 2010). The major hepatic proteins that changed were apoA-1 (lipid metabolism),  $\beta$ -globin and ATP synthase subunit beta (oxidative stress response and regulation of energy).

### Toxins

Valuable information regarding toxicological evaluation of venom (“venomics”) has also been made possible through toxicoproteomic investigations. These investigations have been used to identify protein toxin components in venom, assess geographic venom variability and evaluate antivenin efficacy. In one study conducted in venom from the Asian forest scorpion (*Heterometrus petersii*), 10 families of venom peptides and proteins were identified. The proteins identified in the venom were potassium channel toxins, antimicrobial and cytolytic peptides, calcium channel toxins, La1-like peptides, phospholipase A2, serum proteases, acid phosphatases and diuretic peptides (Ma *et al.*, 2010). Comparative proteomic analysis of pit viper venom (*Bothrops atrox*) has been used to show geographic variation in venom phenotypes and to assess antivenin reactivity. The protein toxin phenotype in pit vipers from Colombia and Venezuela were recognized to be typical of the adult phenotype; whereas the toxin phenotype from Brazil resembled that of the juvenile snake (Calvette *et al.*, 2011). The significance of this finding was relevant to the treatment of envenomation by this type of snake, as it was shown that the antivenins used for pit viper snake bites in these regions were more immunoreactive against the venom in the pit vipers with toxin phenotypes similar to juvenile snakes (Brazil region).

Other natural toxins examined using proteomics include mycotoxins. It is known that drought stress and high temperatures provide opportunistic conditions for fungal growth in corn and other susceptible crops (Guo *et al.*, 2008). In an attempt to gain a better understanding of what makes certain corn crops more susceptible to aflatoxin contamination from *Aspergillus flavus*, a proteomic comparison of corn kernel proteins in resistant and susceptible crops was evaluated. Using 2-DGE and

ESI/MS/MS, proteins were identified in corn kernels resistant to *Aspergillus flavus* that included proteins related to stress-tolerance (aldose reductase and glyoxalase 1 protein) and antifungal proteins T1 and PR10 (Chen *et al.*, 2002).

## CONCLUSIONS

Recognition of the diagnostic accuracy of proteomics data and standardization of methodologies remain a challenge to proteomics researchers. Despite these concerns, toxicoproteomics has the potential to better define molecular mechanisms of toxicity and elucidate biomarkers or signature protein profiles for clinical and diagnostic toxicology. This technology promises to establish new guidelines for preventive and predictive toxicity, ultimately revolutionizing and redefining our future understanding of toxicology.

# Microscopic analysis of toxic substances in feeds and ingesta

Lynn S. Bates

## INTRODUCTION

Feed microscopy is the scientific discipline and technology for the identification and evaluation of feed ingredients and formula feeds. Basically there are three essential components to a successful microscopic identification. These include an aid to the eye, a trained mind and a collection of reference standards. The feed microscopist uses both the stereomicroscope and the compound microscope to identify unknown particles by comparisons to known reference standards. The experience and training of the microscopist determine the efficacy and speed of the identification. A microscopic analysis can be applied to any type or size of particles but commonly observations range from the macroscopic level for the initial gross examinations to the stereoscopic level for centimeter- to millimeter-sized opaque to translucent particles. Translucent and transparent fine particles are examined with the compound microscope to confirm the particle identity at the cellular and sub-cellular levels. In addition, due to the ability of the human mind to sort and classify a wide range of different materials rapidly, the feed microscopist can accomplish a subjective analysis of a feed ingredient in just a few minutes that might take a chemist several hours to accomplish.

It is important to understand from the beginning that feed microscopy is subjective and visual in nature. It is not an objective technology that generates hard numbers. It is designed to identify the feed resources and their inherent quality visually but not to determine the quantity of the individual nutrients within those feed

resources. Therein is the real essential value of feed microscopy to the feed manufacturer, quality assurance laboratory, veterinary toxicologist or anyone concerned about feed ingredient quality and its effects on the consuming animal. Feed microscopy is the entire other half of the quality assurance picture that is often discounted because it involves an opinion. It is, however, a powerful technology that plays an important role in the evaluation of any feed or toxicant analysis and an understanding of what microscopy can do needs to be introduced into every general veterinary and toxicology curriculum.

Microscopy is critical to the toxicological examination of feeds because it is the most rapid and practical way to define problems and focus on potential solutions. Although feed microscopy has not generally been a part of veterinary school curricula, feed microscopists have been part of the diagnostic picture for many years. Veterinary diagnostic laboratories and poison control centers, often located in universities or in a state chemist's office, have utilized feed microscopists as part of their rapid response teams. Unfortunately the number of feed microscopists that are trained and available for veterinary diagnostic work today has declined dramatically to the point that integrating a feed microscopist into the initial toxicological examination is now very difficult. Because the microscopist can sort through more seemingly unrelated but potentially pertinent information about a feed than any other type of analyst and handle more complex situations in feeds than a chemist using standard methods, we need to reinsert a feed microscopist back into the modern veterinary fast response diagnostic team.

For example, there are absolutely no rapid chemical assays to locate blister beetles or their fragments in alfalfa samples and the analysis of the cantharidin toxicant would take several hours. In contrast, a feed microscopist should be able to locate specific evidence of the beetles in a few minutes without any sample preparation. The knowledge of how and where to look for potential problems in feeds is also a critical part of defining a problem. Although it is more specific to look for the toxin itself, the low concentrations of toxins in feeds make them difficult to detect. It is often more efficacious to find an indicator of the toxin and take appropriate remedial action than spend the time in sample preparation and detailed confirmatory analysis.

## THE SEARCH FOR CLUES

Feed ingredients and finished feeds come in a bewildering array of sources, particle sizes, mixtures and forms. Added to that the other natural materials that are fed, or that animals consume, and the task of identifying toxicological problems appear totally impossible. Certainly that would be the case if we did not have an organized way of identifying and classifying all the potential ingredients in a feed. Basically the majority of feed ingredients and formula feeds are byproducts from the food industry. Because they are materials processed out of foods, they are often wet and require drying to be safely stored prior to use. They may also be relatively dry but hygroscopic and difficult to store. They could also be dry but susceptible to oxidation or rancidity due to having been removed from their cellular compartmentalization in nature. For these and numerous other reasons, they are all potential problems for the toxicologist if they are not handled or stored properly. Nevertheless, the clues to identifying which ingredient(s) or feeds are or are not a problem in any situation is right in front of the toxicologist and available to be interpreted. The clues for feed quality are inherent in the visible appearance of each ingredient.

## BACKGROUND: PRINCIPLES OF FEED MICROSCOPY

Feed microscopy is founded on the most basic descriptive aspects of biology and the wide diversity of cellular structures found in natural organisms that are genetically controlled and that do not change from year to year. It is also based on the fact that many of these unique tissues, cellular traits and sub-cellular

characteristics are not greatly affected by the moisture, heat, pressure and shear commonly used to manufacture formula feeds. Therefore, not only are these cellular characteristics inherently good identifiers of individual feed ingredients and mixtures, they are equally good for finished formula feed identifications because they maintain their characteristics after they have been intimately mixed, conditioned, pelleted, extruded, or otherwise manufactured into finished feeds. Consequently, feed microscopists can trust these characteristics to make accurate identifications of ingredients and confirm them to the cellular and sometimes the sub-cellular levels. If a micro-chemical or micro-biochemical test is applied to the sample, the feed microscopist can confirm ingredients to the molecular level and watch the reaction in real time in the cells. In addition, they can evaluate feed ingredients, finished formula feeds and, in special instances, the ingesta and fecal wastes from feeds and forages. The latter is a specialized part of the feed microscopy field but one that is particularly important for the toxicologist. In all these situations, the feed microscopist is very much like a medical examiner or a veterinary toxicologist who uses the unique visual characteristics of organ or tissue morphology, red or white blood cell characteristics or sub-cellular tissue sections to diagnose diseases or other pertinent problems.

Feed microscopy is, in concept, a simple subjective science. It is sometimes further defined as being both art and science due to the need to have steady hands and to develop very good manipulative skills under the microscope. Therefore, if we build on the basic three essentials and add a few hand tools to the well-trained mind, the microscopes and the numerous reference standards mentioned above, we can produce a complete analytical system.

Feed microscopy, due to its conceptual simplicity, is a rapid and relatively accurate technology for identifying materials and problems for which no other direct tests or scientific instruments exist. It is also a relatively rapid way to identify animal problems and it can become an essential complement to objective laboratory analyses. For example, a feed microscopist can identify the residues in a feed bunker that had been rejected by cattle, the contents of dog vomit to identify a feed source or a problem, or perhaps locate evidence of mold growth or mites hidden in a pelleted feed. Subsequently the microscopist can, after locating evidence of a potential feed problem, advise the analytical or toxicology laboratory staff to select appropriate methods to confirm, negate or quantify the extent of the problem. Thus, the feed microscopist is very much like a diagnostician who examines an animal and, based on multiple observed criteria, concludes subjectively that certain definitive laboratory tests should be run to confirm the diagnosis and potential cure.

The feed microscopist, like the diagnostician and toxicologist, must be well versed in the significance of tiny observed differences from the expected norms. Toxicants are not visible at light microscope resolution and feed microscopists are not trained to evaluate tissue samples, organ morphology or animal behavior. However, the particles and structures associated with toxicity such as yew leaves, mold growth or moldy feed, a blister beetle wing fragment, castor bean seed coat fragments and many others can be detected and identified using common feed microscopy methods. These are the keys to both the identification of potential feed problems and the selection of suitable chemical testing plus the evidence to correlate with the findings of the diagnostician.

Because there are often no specific tests for the small differences that must be detected to ascertain a particular problem, the feed microscopist uses all possible senses to evaluate the feeds. For example, although there is no single instrument that can identify an unknown sample as fish meal or ground corn without a lot of work, a feed microscopist can make those qualitative determinations in a matter of minutes. Thus, organoleptic observations, color of particles, breakage lines, presence of caramelized and charred particles and many other seemingly insignificant details may offer clues to the quality of a feedstuff or help to explain a suspected toxicant situation. An objective laboratory test would be necessary to confirm or deny the actual presence of the suspected toxicant.

Another very important facet of feed microscopy is to detect natural contaminants that are similar to the feed ingredients and particularly for adulterants that are deliberately selected to deceive and not be detected by standard methods. An example of a classical adulterant would be urea used in an ingredient for a monogastric animal ration. The ingredient could command a premium price due to the apparent superior protein content. It would not be detected by the feed manufacturer testing for crude protein. Unless non-protein nitrogen testing was routinely run to detect this type of protein spiking or if a microscopist spotted the urea particles and ordered a non-protein nitrogen test, this adulteration would escape detection.

It should have become obvious by this point that a feed microscopist familiar with the structural characteristics of plants, animals and microbial materials and trained in the proper use of the microscope or other aid to the eye can not only solve certain difficult to solve types of problems such as those of feed quality, but can often aid the chemist or other laboratory analyst to select appropriate tests to solve increasingly more complex problems that we often encounter today. Feed microscopy is particularly well suited for solving complex multifaceted contaminant, adulterant and toxicological problems and should be part of any rapid response team.

## THE APPLICATIONS OF FEED MICROSCOPY

Although the concepts of feed microscopy are quite simple, there are numerous ways to achieve accurate results. The more techniques and methods the microscopist masters, the easier it will be to handle the wide range of sample matrices and problem samples that will be encountered. Some techniques require essentially no sample preparation whereas others might require flotation, sieving or other separations to assist the analyst. There are no absolutes in feed microscopy as is the case with most subjective examinations. Therefore, it is essential that the microscopist have a full understanding of the available techniques and methods so that the most appropriate tests are applied and the most scientifically accurate information can be established from the available evidence in any sample. If the sample size is limited, then certain tests might have to be run before others so that the reagents of the first test will not confound the results of subsequent tests. Thus, the feed microscopist should be well versed in chemistry and biochemistry to be a key member of a rapid response team.

The trained mind of the feed microscopist may also be thought of as a computer with a massive hard drive and an extreme logic program to sort through the hundreds of facts and "what if" possibilities. That would be true also of any diagnostician dealing with complex situations. One way to understand and appreciate the capabilities of feed microscopy and some of the variables that should be considered in the sorting process to the most applicable methods and techniques for a particular sample is to consider what can be seen at various magnifications.

Feed microscopy is often defined by the level of magnification used. The initial examination would be analogous to a gross morphological description to establish the general direction of each later stage of an analysis. The stereomicroscope or dissecting microscope is the basic workhorse for most feed microscopists just as it is for the veterinary diagnostician or toxicologist. It would be used to aid the eye in a general review of the surfaces of pelleted feed, for example, although a lighted magnifier could be used as well. An examination of a feed ingredient or finished feed generally requires at least 7× magnification to see particles ground through a typical 2mm hammermill screen. On site, field work can be done with a folding 6× linen tester or a battery operated 10× hand lens but more detailed laboratory work would require at least 7× to 10× magnification. The finer particles in the same hammermilled feed would require 30× to 75× magnification. The color, luster, particle shape, particle size, effects of processing, etc. would be visible at the magnification of the stereomicroscope.

Seed coat particles, ground yew leaves, insects and insect fragments, mineral particles and many other particles associated with toxicants could also be examined and confirmed with the stereomicroscope. It is important to keep in mind the relative sizes of structures to be examined and the type of information one can obtain from each. For example, a macroscopic feed examination would involve those characteristics that can be defined by minimal magnification. The naked eye aided by a hand lens or magnifying glass provides sufficient magnification to determine the feed ingredient or formula feed color, shapes of particles and other very obvious physical characteristics. A finished feed might be described as a densified, polished feed pellet, an extruded star-shaped petfood form, a floating fish particle, a granular crumble of a relatively soft pelleted feed for chickens or perhaps a mixture of silage, whole corn and a concentrated protein pellet for feeder cattle. All of these could be done with a hand lens and a needle probe. Similarly, a suspected feed ingredient or material that accidentally got into a feed might be described by its source. A description could be "weeds along a confinement area with potential toxic seeds," or a note that an on-farm feed mill was using roasted soybeans recovered from a sunken barge. Perhaps late harvested corn with extreme weather damage or restaurant cooking oil with floor sweepings was being used. Every piece of the puzzle needs to be collected and considered because when toxicants get into feeds the situation becomes a forensic analysis.

The higher magnifications of a stereomicroscope would be needed to complete the above examinations. The shift from macroscopic to stereoscopic would allow a more detailed picture of the weathered corn, any potential mold contamination of the recovered waterlogged soybeans and the seed characteristics from the ingesta of a free roaming animal. The compound microscope plus some careful sample preparation would be needed to jump up to a cellular or histological analysis. The higher magnification would permit a visible examination of mold mycelia invading the seed structure, the cell types and sub-cellular calcium oxalate crystal inclusions of certain leaves and other definitive structures used for identification. The compound microscope permits the unique cellular characteristics of all the ingredients to be used for the analysis.

## CLASSIFICATION OF FEED INGREDIENTS BY SOURCES

Feed microscopy can also be sorted, studied and examined by the ingredient sources. This allows parallel

comparisons of similar structures which are related uniquely to each species. Each level of detail opens new opportunities for confirming an analysis.

*Processed feed grains, legumes and oilseeds* are whole seed sources that are minimally processed for feeds. Corn (maize) is one of the most common feed grains in the world. It is fed whole, ground or flaked. Grinding and steam flaking enhance the nutrient availability particularly of carbohydrates because corn is primarily a starchy energy source. The extent of starch gelatinization can be observed with polarized light. Grain sorghum and the several millets are smaller seeds that are fed in the same manner. Wheat, barley, rye, oats and rice are more typically food grains but lesser grades are used directly in feeds. The feed microscopist can identify ground particles from each of these sources by their inherent structural characteristics. For example, an examination of an unknown flat particle associated with intact starch could be compared to the modified leaf tissue that in grains is considered as chaff or hull. Wheat chaff is left in the field and is not in direct contact with starch in the seed. Therefore, logically the microscopist would search inwardly to the next flat layer under the hull which is pericarp. The outer pericarp, when ground, often remains attached to other layers of the original ovary wall plus the testa and aleurone layers and is called bran in commercial channels. The unknown would be compared to reference standards of the pericarp or bran for each cereal. If the initial observations that the particle was associated with starch were true, the particle would likely match the cell types and be confirmed as a bran particle of one of the cereals. Knowledge of the structure of all the seeds commonly used in feeds allows a logical comparative examination of any cereal or other feed ingredient.

An example of a confirmed minimal processed legume is cracked or whole fed soybeans. The soybean is the only major feed legume that is fed whole but it is usually roasted to minimize trypsin inhibitors. When whole soybeans are roasted, the seed coat splits transversely to the embryonic axis and remains on the seed. It is a unique characteristic associated with roasting. The extent of roasting could be measured by the residual urease activity. Other legumes such as lentils, lupine, dry beans and peas are found in feeds but not as mainline ingredients and they have no significant trypsin inhibitors that would require heat treatment. Each of these clues leads to a confirmed analysis.

Cottonseed is one of the few oilseeds fed whole as a fiber source in cattle. The seeds are very fuzzy and can be easily identified by the attached cotton fibers that rotate polarized light, have a dumbbell-shaped cross-section and exhibit a slow twist. In addition, the hull is a three-layered achene that is multicolored and unique to cottonseeds. Many of the characteristics exhibited by

oilseeds are similarly so specific that tiny particles of the oilseeds can be identified even after they have been hammermilled and processed into finished feeds.

*Processed feed grain, legume and oilseed byproducts* are food byproducts on which the entire feed industry is based. A wide range of ingredients from the production of foods are available. These include corn bran, corn gluten feed, corn gluten, hominy feed, wheat middlings, wheat bran, barley hulls, rice hulls, oat hulls, just to list a few. Legume and oilseed byproducts include soybean hulls, peanut meal and hulls, canola meal, linseed meal, sunflower meal and hulls, safflower meal and hulls, cottonseed meal and hulls, and many less common meals. Each ingredient has specific characteristics at each level of magnification to identify it with confirmation at the cellular level. These structures can be found in the listed references of this chapter or created by careful dissection of authenticated reference standards.

*Processed byproducts from other plants* include citrus pulp, bagasse from sugar cane and beet pulp from sugar beets, fruit pomaces, tomato pomace, potato meal, food gum meals and other food byproducts. Almost everything that is not designated human food finds its way into feeds.

*Processed plant products from industrial sources* include distiller's grains and solubles from the power alcohol and distillery industries, fats and oils from off-grade edible and detergent oil sources, *Aspergillus* meal from food and industrial enzyme production, and many others. The oils are particularly problematic because they have no visible cellular structures and can get mixed accidentally with miscible industrial liquids and pesticides.

*Processed animal products and byproducts* include whole animal meals such as chopped beef, fish meal or poultry, lamb or venison meat. Examples of meat meals include blended meat meal (beef and pork), fish meal from larger trimmed out or canned fish, and all manner of rendered meat products. Feed microscopy is currently the major firewall against BSE (Bovine Spongiform Encephalopathy) or mad cow disease tissues getting into cattle feed.

*Processed natural mineral products and metallic wastes* are the minerals in feed. On rare occasions, ground circuit boards and other electronic and industrial waste that contains metallic components get into feeds. Cadmium, arsenic, lead and other toxicants also find their way into feeds. These can be detected by the microscopist and suitable chemical testing initiated to determine the extent of the problems.

*Processed aquatic products and byproducts* include fish meals, shellfish meal, oyster shells, shrimp meal, shrimp shell meal and shrimp head meal, squid meal and other specialized products. Of all the byproduct meals, the aquatic ones are the most variable and potentially the most adulterated because they lack specific standard descriptions for trading. The feed microscopist is often quite challenged by these meals in feeds.

## CLASSIFICATION OF FINISHED FORMULA FEEDS BY PROCESSING

We can also classify finished feeds by the type of agglomeration and cooking processes used as an aid to understanding the effects of processing on the feed ingredients. Although the key identifiers will not change dramatically, it is important to understand that the extent of conditioning and moisture incorporation during processing will (1) affect the starch gelatinization and other binding reactions and (2) affect the methods used in the microscopic examination to reverse the hydrothermal bonds and permit easier examinations. Some of the common processes and applications are as follows.

*Pelleted and crumbled feeds* are used to maintain uniform nutritional distribution in feeds. The pelleting operation increases the bulk density and fixes the nutrients so that no segregation occurs during shipment and handling. The pellets are crumbled to make it easier for poultry and small animals to feed. Crumbling increases the surface areas for saliva or other digestive juices to be absorbed and to speed digestion. Crumbling also increases the available surface area for moisture absorption and in humid areas can lead to mold growth. Pelleted feeds have relatively friable structures due to minimum starch gelatinization. They can be readily hand ground in a mortar and pestle. The particles will usually separate adequately to conduct an analysis when aided by solvent flotation and sieving to separate fine particles and fat, and ease the identification of fine particles.

*Expanded and extruded feeds* enhance nutrient availability and feeding efficacy primarily by increased gelatinization during conditioning and the ability of the extruder to process higher moisture feed mixtures. The extruder combined with the expander, particularly when the feed is re-ground or re-extruded for aquaculture feeds and some pet foods, reduces the sizes of the individual feed particles to the point that the feed microscopist can barely identify the sources of the ingredients. The extent of gelatinization is much greater for extruded matrices and they do not separate easily even after mortar and pestle grinding, flotation and sieving. They are a much more difficult matrix to separate and examine.

*Steam conditioned and rolled feeds* have enhanced cell disruption and nutrient availability. The process is used primarily for whole grain corn and sorghum that are to be fermented or reconstituted and fed with silage and other rations. Unless flaked grain has been mixed with other ingredients, no additional separations are needed prior to the microscopic examination.

*Canned pet foods* are specialty soft and wet products with unique attractants and flavors. They require thermal processing to maintain shelf life stability and palatability. They are particularly difficult to analyze but are

commercially sterile and not prone to microbial growth or related toxicant problems.

### CLASSIFICATION OF FORAGES BY POINTS OF CONTACT OR POTENTIAL TOXICANTS

Lastly, we can classify feed resources by their natural habitats and their potential for toxicological problems. These plants and toxicant situations are not commonly seen by the feed microscopist but a good broad knowledge of plant structures makes the feed microscopist particularly well suited to examine them. These include native forages and pasture plants that may be consumed due to animals roaming free on pasture and via casual contacts. Some cut and stored forages and silages that are fed to confined animals may be weathered and spoiled. Exotic and introduced plants may be consumed due to invasive growth in pastures or by accidental cuttings and unknowledgeable feedings. Finally, decorative house plants and some garden materials may be consumed by pets. All these types of forage samples are examined as they are taken. That is, no specific methods are used to reduce the particle size because the evidence will be compromised by additional processing. Instead the particles are separated by hand into appropriate classes to be examined. For example, a whole kernel corn, silage and concentrate pellet feed would be separated on a large tray by hand or with minimal sieving depending on the particle size classes involved. Hand separations are generally easiest, although time consuming. The corn and pelleted concentrate would be dried and each examined separately. The pellet would be handled like any other pelleted feed and analyzed for its component parts. The silage would also be dried and, if a toxicant was suspected, the examination would focus on the purity of the silage including weedy and herbaceous forages, evidence of wild fermentation, mold growth and the extent of uniformity and the presence of additives. Identifications would be based on collected forages from the farm or ranch or keyed to range and pasture plant references. Unknown forages could also be identified through herbarium collections.

### IDENTIFICATION OF INGESTA PARTICLES

The identification of fecal and ingesta samples is very similar to the routine examinations of feeds and forages. Sometimes particles can be isolated directly from the samples. Otherwise the samples require pre-analysis

preparation for biological safety for the microscopist. A standard fume hood or air handling unit to isolate aromas and filter out dried dusty particles would also be needed for biological safety.

Digestion, even through a rumen, is similar to the feed manufacturing process and does not destroy the cellular characteristics used for identifications. Thus, the identification of yew or hemlock leaves, cockleburrs, crotalaria and other toxic weed seeds and most other plant toxin sources is the same as for forage examinations. Reference standards of the seeds and plant tissues are the key to the identifications, although having some ingesta samples for comparisons is always helpful. Medical laboratory manuals also provide routine methods for the safe handling of fecal sample examinations that can be applied to feed microscopy.

### THE ROLE OF THE ATTENDING VETERINARIAN

Because few feed microscopists are available for on-site examinations, the attending veterinarian should have an understanding of feed microscopy and what it can provide for an investigation. The veterinarian should be aware of the sampling requirements for microscopy, the need to secure both the feed ingredients and the finished feeds from bagged storage, from feed bunkers, from augers and feed mixing, handling and feeding systems, and from any other on-farm or confinement locations. Samples from baled hays or forages, silage bunkers, fence rows, pastures and other waste areas available to animals should be retained. In the case of pets and small animals, representative samples should include house plants, decorative plantings and garden areas around the house. Too often the feed microscopist is given only a sample of a suspect feed or ingredient which may or may not be related to the toxicant problem. A more encompassing view should be encouraged. Because sampling is one of the most critical aspects of any toxicant situation, samples representing the earliest possible point in time should be secured as quickly as possible and retained for microscopic examinations.

If an ingesta or fecal sample is available, it should be processed immediately or frozen (iced for short-time transport) at  $-10^{\circ}\text{C}$  or below to limit microbial activity. The following is a simplified analytical scheme to handle these samples.

*Ingesta or fecal samples* should be separated into the portion for chemical testing and the microscopy aliquot. A 5 or 10g wet weight aliquot can be rinsed and washed thoroughly through a 260 or 400 mesh stainless steel sieve to retain essentially all particulates but remove all the

solubles (assuming no chemical or biochemical testing will be needed on that sample aliquot for extra-cellular constituents). The particulate residues should be transferred from the sieve to a hard surfaced but porous filter paper (standard pleated coffee filters work well) and the sample air dried. Do not heat the sample if any enzyme-based testing will be required. The dried particles, particularly the fibrous cellulosic particles, may be gently rolled in a mortar with the pestle to cause the fibrous particles to separate. Do not attempt to grind them. If the sample is too fatty to separate and the particles cannot be identified due to a coating of fat, flotation on chloroform (observe the current laboratory safety procedures for the solvent) may be necessary as both a defatting step and a separation of mineral constituents and particulate fines. Defatting will take about three rinses using 2–3 times the volume of the fatty aliquot. When the chloroform has evaporated, the examination can proceed with standard feed microscopy methods comparing the unknown particles with reference standards and confirming the observations at the cellular level. Remember, most of the digestible nutrients will have been removed from the cellulosic cell matrix debris. This may change the appearance slightly but the cellulosic structures will not have changed, depending on passage time, and can be compared to reference standards of ingesta and feces if they are available. Animal tissues would have been digested and would not generally be available for examination.

## FEED MICROSCOPY TRAINING AND AVAILABLE LITERATURE

Although this chapter has briefly introduced feed microscopy and what it can do for toxicological examinations, some mention of where training is available, how one organizes a reference sample collection and sets up a laboratory may be of interest. Because feed microscopy is a “hands-on” practical technology, it is not easily learned from a book. It is instead taught as an intensive short course. An Internet search is currently the best way to locate feed microscopy short courses.

Feed microscopy draws on all the scientific disciplines and information exists but is widely scattered and often out of print and not readily available. The interpretive drawings of [Winton and Winton \(1932\)](#) still stand as one of the best reference sources ever published for food and feed structures. [Vaughan \(1970\)](#) updated the oilseeds with excellent interpretive drawings and some photographs. *The Manual of Microscopic Analysis of Feedstuffs* ([Bates et al., 1992](#)) draws the most important technical information together into a single reference book specifically for feed microscopy but it is not a textbook or a training manual. [Klein and Marquard \(2005\)](#) put

together an extensive *Atlas of Feed Microscopy* which provides many line drawings that had not been previously available in English. *The Aquaculture Feed Microscopy Manual* ([Bates et al., 1995](#)) explored the ingredients commonly used in fish, shrimp and other confined aquatic organisms. *Introduction to Food-Borne Fungi* ([Samson et al., 1995](#)) is one of the best references for detailed photos and interpretive drawings of the common molds attacking foods and feeds. What is most notable about the feed microscopy literature is the lack of a single treatise or detailed text for the feed microscopist that covers everything including the cellular keys for identification of forages and pasture plants and the identification of ingesta and fecal particles. Reference standard collections are critical to feed microscopy and ingesta identifications. Typically microscopists share samples or hard-to-find materials at professional meetings or via mailings. Sample collections of authentic materials are usually provided at feed microscopy short courses.

## THE FEED MICROSCOPY LABORATORY

Feed microscopists generally work alone, not in groups, and their laboratories are reflections of their work habits in whatever space is available. An ideal feed microscopy laboratory work station is centered in a “U” configuration with sinks, hoods, preparation areas, etc. located nearby but not in the immediate microscope area where fumes or solvents might damage the microscopes. [Figure 103.1](#) shows a laboratory with shallow drawer cabinets full of reference standards supporting the work surfaces holding the microscopes. A boom stand stereomicroscope is at the right side, a large research stereomicroscope is in the center equipped with video and

**FIGURE 103.1** An efficient “U”-shaped feed microscopy laboratory configuration.

still camera ports and a large frame compound microscope is seen on the left side. A microscope and a second compound microscope are just outside the picture borders along the legs of the "U." A balance, hand tools, reagents, reference materials and many other small items used in the analyses can be seen in the photo along with small cabinets for all types of reference standards.

## THE EQUIPMENT

The following equipment list details briefly the essential items plus many that are useful but may not be available in most laboratories. In all cases, purchase the best equipment that can be justified. Remember, many extremely fine used microscopes are available for the starting microscopist:

- *Stereoscope*: Research grade, zoom microscope equipped with a brightfield/darkfield base and trinocular head. The newer models provide more options for digital photomicrography, videography, illumination and depth of field than the older, more simplified microscopes. Because the stereomicroscope is the heart and soul of the equipment used, it should be selected carefully to do all the types of examinations that are anticipated.
- *Compound microscope*: Large frame research model. Many excellent used Leitz, Zeiss and other brands from the mid-1980s are still available and serviceable. Most microscopy laboratories cannot justify purchasing the latest research models.
- *Dual compound microscopes*: Bridged for side-by-side comparisons of unknowns and authentic reference standards.
- *Documentation*: Digital cameras can be readily interfaced with microscopes to provide a digital record of observations, reference standards, side-by-side comparisons, etc.
- *Hand tools*: This should include tweezers, needles and probes for manipulating samples, small cutting instruments (scalpel, micro-scissors), glassware and sieves for flotation separations, measuring tools (manual or digital calipers, optical and stage micrometers and measuring cells for particulates). Many microscopists fabricate their own tools or adapt and modify tools from other disciplines. Dentistry picks and probes, tools for clay sculptors, model builder's scissors, micro-soldering torches and many other small tools have been adopted for use under the microscope.
- *Reference standards set*: The collection of reference standards (authentic) is a critical aspect of feed microscopy. The reference collection is one of the central three requirements for microscopy and maintaining a collection is a career-long endeavor. Every effort

should be made to collect multiple samples of each feed ingredient to represent the variations from different parts of a country or different appearances due to heating, drying and other processing variations of manufactured byproducts. The underlying cellular structures will remain essentially the same (except for agglomerated and co-mingled byproducts) but the appearances may differ.

The reference collection should be preserved in glass or plastic containers that can be well sealed and maintained free of insects. Freeze potentially contaminated samples for 10–15 days before placing them in the collection. No pesticides or other chemicals should be used for preserving a reference collection because natural aromas are an inherent part of the ingredients.

## CONCLUSIONS AND FUTURE EXPECTATIONS

Feed microscopy offers a wide range of applications for the analysis of feed ingredients, finished feeds, ingesta and fecal samples. Although the classical applications of feed microscopy in the feed industry and state compliance laboratories have become relatively static due to a series of events and decisions ranging from load cell technology to least cost formulations to collective terms for labeling, the needs for microscopists in BSE screening and bio-security issues, toxicology and forensic applications have dramatically increased. Thus, this is a time of transition. This chapter illustrates just a fraction of the applications and opportunities for feed microscopists. The identification and evaluation of particulates from foods, feed ingredients, formula feeds, forages, weed seeds and all manner of other sources will continue to expand for many years if the current demand can be interpolated correctly into the future.

## Prevention and treatment of poisoning

Camille DeClementi

### PREVENTION OF POISONING

Prevention of poisoning in household pets consists of controlling the animals' environment to decrease exposure to potentially dangerous substances. This requires animal caretakers to be diligent and knowledgeable of potential risks. While much of the advice offered to prevent poisoning will seem like common sense to many veterinarians, these guidelines are often unfamiliar to animal caretakers. Veterinarians are therefore encouraged to share this information with their clients.

Clients should be reminded to keep all veterinary and human medications, both prescription and over-the-counter (OTC), out of the reach of animals. Since some pets are able to climb onto high surfaces and open cabinets, medications are not adequately "out of reach" in those places. Owners should be instructed not to give their pets any medication, including their own, unless directed by their veterinarian. Clients may not realize that giving an OTC medication that they consider safe, like acetaminophen, could cause life-threatening illness in their pet. For example, treatment of alopecia in cats with topical minoxidil solution has led to pleural effusion, pulmonary edema and death (DeClementi *et al.*, 2004). Clients should also store all other potentially hazardous products, including cleaning products, auto-care products, pesticides and insecticides, out of the reach of their animals. Garbage cans should be sealed with tamper-proof lids.

Animal caretakers should be urged to read all label information before using a product on an animal or in the animal's environment and to follow the label instructions exactly. Veterinarians should mention that it is

often not safe to use a product on an animal species for which it is not intended. For example, using a concentrated permethrin flea product labeled for dogs could prove deadly if used on a cat (Richardson, 2000a).

Since many plants are poisonous, clients will want to be aware of the plants in an animal's environment, including those in outside areas. Additionally, they should be alert to any fluids leaking from vehicles and clean up leaks immediately. If a rodenticide or other bait is necessary in the home or yard, the product should be placed in an area that is completely inaccessible to non-target animals. The bait should be removed as soon as it is no longer needed. An animal's enclosure should be routinely checked, and unfamiliar or questionable items removed. Companion animals should be supervised, when possible, if they are outdoors, and a securely gated, confined area should be provided when animals are left unattended.

The guidelines for keeping household pets safe from poisoning are very similar to those for children, especially toddlers. Some pets may even be more at risk than children because, unlike children, they are commonly left unattended. They are also likely to chew open some containers, including those considered child-safe. The ASPCA website has additional information regarding poison prevention ([www.asPCA.org](http://www.asPCA.org)).

Decreasing the risk of exposure to toxicants is also important in large animals. Caretakers should be urged to purchase hay and feed from reputable suppliers, to examine the feed for recognizable contamination, and to verify cleanliness and high quality. Feed should be stored in a clean, insect-free area at the appropriate moisture level to prevent damage and lessen the risk of contamination or mycotoxin growth (Osweiler, 2001).

Learning to identify poisonous plants and their potential effects is critical for large animal clients. Once poisonous plants have been recognized in an area, many strategies can be employed to limit exposure. The most effective strategy is to remove animals from poisonous plant-infested areas either by herding or fencing off those areas. If this is impossible, attempts should be made to reduce the poisonous plant populations via mechanical (burning or pulling), chemical (herbicides), biological (such as using the larvae of the cinnabar moth to control tansy ragwort), or other control methods. Since treatment with herbicides may increase palatability or toxicity in some plants, animals should not be allowed access to herbicide-treated areas until all treated plant material is dead and removed. Once the plant populations are controlled, good grazing management can be used to maintain the area in a condition that limits regrowth of the plants (Cheeke, 1998).

Large animal enclosures and barns should also be kept free of other potential toxicants, including insecticides, pesticides, petroleum products and medicated feeds. Following label instructions is just as important for large animals as household pets. Medicated feeds, medications and insecticides should be used only on the labeled species. If a pour-on amitraz product intended for cattle is instead used on horses, fatal ileus may result (Gwaltney-Brant, 2004).

## STABILIZATION AND MONITORING

Toxicant exposures often require immediate or urgent attention. Television and movies have led the public to believe that every toxicant has an antidote; consequently animal caretakers may expect their veterinarian to provide one. Unfortunately, this expectation is far from reality. There are very few antidotes and when they do exist, they may be cost prohibitive or difficult to obtain. Therefore, it is critical for the clinician to concentrate on *treating the patient and not the poison*. Poisoning cases should be managed following the same principles of triage and patient stabilization as other emergencies. Decontamination and antidote administration, if available, should follow initial stabilization.

A detailed history should be taken after the patient is stabilized, but the following questions should be asked on presentation. To what toxicant was the animal exposed? What amount? When did the exposure occur? Has the patient shown any effects? Have any treatments been performed (for example, dilution, emesis or bathing)? Have other animals also been exposed?

As in any emergency case, initial evaluation and stabilization of the patient should address the basic ABCs (airway, breathing, bleeding, cardiovascular, circulation

and level of consciousness). The clinician must assure that the patient has an adequate airway and is not having difficulty breathing. If needed, an endotracheal tube should be placed or a tracheostomy performed to establish a patent airway. If the patient is dyspneic, 100% oxygen should be delivered via oxygen cage, mask or nasal cannula (Mathews, 2006). Oxygen supplementation is contraindicated in a paraquat exposure (Oehme and Mannala, 2006). Stress and handling should be minimized in a dyspneic patient.

The patient should be checked for bruising and for signs of active bleeding from the nose, mouth, anus and vulva or penis. The mucous membrane color and capillary refill time should be evaluated. Pulse rate, rhythm and strength should be assessed. Electrocardiogram (ECG) and blood pressure monitoring should also be performed. If needed, an intravenous (IV) catheter should be placed and fluid therapy initiated. Attempts should be made to control life-threatening arrhythmias (Mathews, 2006).

The patient's level of consciousness should be determined. If the patient is actively seizing, diazepam, given as an IV bolus at a dosage of 0.5–1 mg/kg, is often the initial drug used for dogs and cats. If this is not effective, other medications including phenobarbital, pentobarbital and propofol may be useful. Inhalant anesthesia may also be used to control the seizure activity (Mathews, 2006). The reader is referred to a formulary or reference on emergency seizure control for recommendations on doses and drug choices for the species being treated. Since some diagnostic tests, including that for ethylene glycol, may give false results once injectable medications are administered, the clinician should obtain blood samples prior to administering these medications. Body temperature should be checked and thermoregulation initiated if needed.

Once the patient has been stabilized, a more thorough clinical evaluation can be completed including complete history, physical examination and appropriate diagnostic testing (Cantilena, 2001), and a treatment plan developed. The signalment and health history of the patient is important in developing a treatment plan. If the patient is a nursing or pregnant female, for example, precautions will need to be taken to prevent exposure to the fetus or young. Or if the patient is taking a highly protein-bound medication, it is more at risk from an overdose of another protein-bound drug. If there is no known exposure to a toxicant but poisoning is suspected based on presentation and clinical findings, the questions in Table 104.1 may be helpful to reveal a cause.

Next, a complete treatment plan should be developed. It should include what method, if any, will be used to prevent further toxin absorption and if an antidotal therapy will be used. The plan should address any clinical signs not addressed in the initial stabilization. It should

TABLE 104.1 History gathering questions

- 
- When was the patient last normal?
  - How long have the signs been present?
  - Were there any initial signs that are no longer present?
  - Was the onset of the signs gradual or sudden?
  - Are there other pets in the area? Are they affected?
  - What was the location of the animal in the last few hours prior to development of signs? Was the animal supervised?
  - Is the animal indoors or outdoors mostly?
  - If the animal is outdoors, is it confined or does it roam?
  - To what areas of the home or garage does the animal have access?
  - Have any new foods or treats been introduced to the animal's diet?
  - Any access to sugar-free products?
  - Has there been any recent access to garbage?
  - Has the animal chewed or destroyed anything recently?
  - Are there any medications in the house (human, veterinary, prescription, OTC)?
  - Could the animal have been exposed to illicit drugs?
  - Are there children or teenagers in the household?
  - Have there been any recent visitors who may have dropped medication?
  - Are there any rodenticides or other baits being used in the home or yard?
  - Could the animal have ingested any plants (indoors or outdoors)?
  - Have any medications, herbal products or insecticides been administered to this or any other animals in the household recently?
  - Are there any mushrooms growing in the yard?
  - Is there a compost pile in the yard?
  - Have any yard treatments been applied recently?
  - Are there any livestock in the animal's environment?
  - Have any livestock been recently euthanized or buried on the property?
- 

list what additional findings may yet develop and a plan of action for each. The plan should define how often the patient will be monitored and what indices will be evaluated. And it should determine what diagnostic tests are appropriate for the situation. The treatment plan may need to be updated as the case progresses.

Diagnostic testing will be governed by clinical findings, history and, in a known exposure, expected effects. The clinician should perform baseline testing and repeat as required throughout the course of the treatment. Appropriate testing may include a packed cell volume (PCV) and total solids (TS) to identify dehydration or blood loss in cases of anticoagulant exposure or agents that may cause gastrointestinal (GI) ulceration. A complete blood count (CBC) may be needed to check for inflammation or secondary infections in cases where GI ulceration and perforation are possible, such as in exposures to cationic detergents, corrosive materials or non-steroidal anti-inflammatory medications (NSAIDs). Monitoring the CBC is also indicated in exposures that may cause bone marrow suppression such as estrogen overdoses.

A full chemistry panel is often appropriate. Blood glucose should be monitored closely with exposures to sulfonyleurea hypoglycemic agents and in exposures to the sugar-free sweetener xylitol in dogs. Monitoring the renal values, blood urea nitrogen (BUN) and serum creatinine is important in many exposures to identify dehydration and renal alterations if the patient was exposed to potential renal toxicants such as lilies in cats, grapes and raisins in dogs, NSAIDs and ethylene glycol. In these cases, urinalysis is also indicated. Electrolytes should be monitored in cases where IV fluid therapy is required and in cases where the toxicant may lead to electrolyte abnormalities. For example, hypokalemia is a common effect in dogs that puncture albuterol inhalers (Vite and Gfeller, 1994).

Monitoring of acid-base status is important in some cases, such as exposures to aspirin and ethylene glycol. The cardiovascular system will need to be monitored, via ECG and evaluating blood pressure in exposures to certain agents such as pseudoephedrine and the methylxanthines in chocolate. Other general testing including pulse oximetry, radiographs and ultrasound may be required depending on the toxicant. Specific tests, such as an ethylene glycol test or serum iron panel, may also be suitable depending on the situation.

In addition to these physiological parameters, the patient's clinical signs, vitals, behavior and mentation should be monitored frequently for the duration of the treatment and abnormalities addressed. The frequency and degree of monitoring will depend on the situation. The patient's attitude should be noted regularly. Respiratory and cardiovascular status should also be checked at regular intervals, especially in cases where these systems may be affected by the toxicant. Capillary refill time and mucous membrane color can be used to assess peripheral perfusion. Body temperature should be monitored if the toxicant, clinical findings or treatments may cause abnormalities. Appetite, hydration status, bowel movements and urinary output should also be noted.

## DECONTAMINATION

Once the patient has been stabilized, decontamination should be considered to prevent additional exposure to the toxicant. Although the basics of decontamination are similar among species, the specific method of decontamination that is chosen in each case must be guided by the exposure circumstances and the species exposed. For all decontamination methods, consider sedation or anesthesia if the procedure will be very stressful for the patient, but only if the health of the patient will allow. The handler should wear appropriate protective clothing

including gloves, mask and eye gear to prevent personal exposure. Most exposures to toxicants can be broken down into ocular, dermal and oral exposures. The following are methods of decontamination for each of these exposure types.

### Ocular exposure

Ocular exposures may cause effects ranging from mild irritation to corrosive injury and blindness depending on the substance, the concentration, the exposure time and the sensitivity of the patient. With any ocular exposure, the eyes should be flushed repeatedly with tepid tap water or saline solution for a minimum of 20–30 minutes (Rosendale, 2002). An eyedropper can be used for smaller patients like birds or reptiles. With a larger patient, fill a plastic cup and slowly pour the contents over the ocular area. Patients can be given a mild sedative prior to flushing if needed and if the health of the patient will allow. If not sedated, the patient should be allowed to rest at regular intervals during the flushing to minimize stress. Fluorescein staining should be performed after flushing and again at 12–24 hours post-exposure to check for corneal ulceration. Additional treatment with ophthalmic and systemic medications may be necessary.

### Dermal exposure

Dermal exposure to a large variety of substances, including petroleum products, pesticides and insecticides, corrosive or irritating materials and substances that are sticky (tar, asphalt, sap and glue), may occur. Removal of such substances may be less stressful for the patient and safer for the handler if sedation is used. Sedatives should only be used if the health of the patient will allow. If not sedated, the patient should be allowed to rest at regular intervals to minimize stress.

In birds, dermal substances can be removed by using a water bottle to spritz the bird lightly with room temperature water. This procedure should be done in a warm environment to prevent chilling. The bird should be misted until the feathers no longer smell or feel of the product. If misting alone does not remove the product, and soap is needed, a liquid dishwashing detergent (e.g., Dawn™) may be diluted in the bottle and applied. After removal of the substance, the bird should be rinsed via misting with plain water until all soap is removed. In cases of heavy exposure, birds may be bathed with liquid dishwashing detergent and rinsed well. After misting or bathing, the bird should be wiped with a dry towel and kept in a warm environment away from drafts until completely dry. The procedure for reptiles is similar.

For dermal exposures in mammals, bathing in a mild liquid dishwashing detergent and warm water is recommended. Baths may be repeated in order to remove the toxicant completely (Rosendale, 2002). The animal should then be rinsed well with warm water and towel dried, then kept in a warm environment until completely dry. For smaller patients, like cats, that resent being sprayed with water, the bucket technique may be helpful. Fill a bucket with warm soapy water and, while supporting the hind legs, immerse the patient up to the neck. Remove the patient and continue washing. Use a fresh bucket with plain warm water to rinse well.

If the patient has a sticky substance on its fur, feathers or skin, do not use solvents to remove it since these may be irritating or corrosive to the patient. Instead, to remove sticky substances from mammals, remove as much of the substance as possible by trimming the fur. Then work a small amount of vegetable oil, mineral oil, mayonnaise or peanut butter through the rest of the substance until it breaks down into “gummy balls.” Afterwards, wash with liquid dishwashing detergent as described above (Rosendale, 2002). For birds, do not trim the feathers, just use vegetable oil, mineral oil, mayonnaise or peanut butter and then mist as described above.

### Oral exposure

When a patient is exposed to a potentially dangerous substance by ingestion, the clinician has many options for decontamination including dilution, induction of emesis, lavage, removal via endoscopy or gastrotomy, use of adsorbents, cathartics and administration of enemas. Often, the best treatment plan will include more than one of these methods.

#### Dilution

Dilution with a small amount of milk or water is recommended in cases where irritants or corrosive materials have been ingested. A suggested dose is 2–6 ml/kg (Mathews, 2006) which would be approximately only 1–2 teaspoons in an average-sized cat. It is important to use only a small amount of liquid for dilution. Using excessive amounts could lead to vomiting and re-exposure of the esophagus to the damaging material. For birds and reptiles, juicy fruits and vegetables can be fed to accomplish dilution. Dilution is not recommended in patients who are at an increased risk for aspiration, including those who are obtunded (Rosendale, 2002) or actively seizing. Additionally, milk, yogurt and cottage cheese have been useful as demulcents in cases of oral irritation following ingestion of plants containing insoluble calcium oxalate crystals (Philodendron species, for example) (Means, 2004b).

## Emetics

Emetics are usually most effective if used within 2–3 hours post-ingestion (Rosendale, 2002) but in some instances emesis may be effective even after that time frame. For instance, if a timed-released medication was ingested or if the substance ingested could coalesce to form a bezoar in the stomach, emesis may be effective later than 3 hours after the ingestion. Chocolate (Albretsen, 2004) and chewable medications may form bezoars. If the patient has not eaten in the previous 2 hours, feeding a small moist meal before inducing vomiting can increase chances of an adequate emesis. Emetics generally empty 40–60% of the stomach contents (Beasley and Dorman, 1990).

Dogs, cats, ferrets and potbelly pigs are examples of domestic animals that are able to vomit safely. Emetics should not be used in rodents, rabbits, birds, horses and ruminants. Rodents are unable to vomit (Plumb, 2005) and rabbits have a thin-walled stomach putting them at risk for gastric rupture if they vomit (Donnelly, 2004). It is not safe to induce emesis in birds, horses or cattle.

Induction of emesis is contraindicated with ingestion of alkalis, acids or other corrosive agents. When one of these products is swallowed, the protective epithelial lining of the esophagus may be damaged. This damage can leave the muscular layer of the esophagus exposed and at risk for ulceration, perforation and scarring if vomiting does occur (Beasley and Dorman, 1990). Emesis is not recommended after ingestion of petroleum distillates due to the risk of aspiration. Pre-existing conditions of the patient that can cause vomiting to be hazardous, such as severe cardiac disease or seizure disorder, must also be taken into account by the clinician when deciding whether to induce emesis. In all instances, the attending veterinarian must weigh the benefits of emesis against the risks. Emesis should not be attempted if the animal has already vomited or is exhibiting clinical signs such as coma, seizures or recumbency, which make emesis hazardous. Additionally, if the patient has ingested a CNS stimulant and is already agitated, the additional stimulation of vomiting could elicit seizures (Rosendale, 2002).

Hydrogen peroxide, apomorphine hydrochloride and xylazine hydrochloride are commonly used emetics in the veterinary clinical setting. Preliminary data obtained from the ASPCA Animal Poison Control's toxicology database indicate that hydrogen peroxide and apomorphine are effective emetics in dogs. Emesis was successful in 92% of dogs when administered either 3% hydrogen peroxide or apomorphine. No significant adverse effects were reported in dogs after emetic use. Apomorphine was poorly effective as an emetic in cats. Xylazine was an effective emetic in 57% of cats. When emesis was successfully induced, 68% of patients vomited some portion of the ingested toxicant (Khan *et al.*, 2009).

*Hydrogen peroxide*, at a 3% concentration, is a useful emetic when given orally. It is an ideal emetic for household use because the 3% concentration is used in many households for cuts and scrapes. Additionally, it is inexpensive and easy to administer. Hydrogen peroxide is thought to induce emesis via gastric irritation (Peterson, 2006). The dosage is 1–2 ml/kg (Beasley and Dorman, 1990) generally not to exceed 50 ml for dogs and potbelly pigs and 10 ml for cats and ferrets (Peterson, 2006). The dose can be administered with a syringe or turkey baster or can be mixed with a small amount of milk or ice cream to entice voluntary ingestion. Vomiting usually occurs within 10–15 minutes and the dose can be repeated once more if emesis is not initially successful. Walking or other gentle movement may be beneficial in initiating emesis.

*Apomorphine hydrochloride* is often used in the clinical setting to induce emesis in dogs. Use of apomorphine is considered controversial in cats since a safe dose has not been established (Plumb, 2005) and it is not very effective (Khan *et al.*, 2009). Apomorphine hydrochloride is a synthetic opiate that stimulates the dopamine receptors in the chemoreceptor trigger zone to cause emesis. The dosage is 0.04 mg/kg intravenously (IV) or intramuscularly (IM). Emesis is expected rapidly following IV administration, but may take 5 minutes with IM administration. Apomorphine can also be used conjunctivally by crushing and dissolving a portion of a tablet in a few drops of water. The solution is then administered into the conjunctival sac at a dose of 0.25 mg/kg (Plumb, 2005). This route may be preferred since the eye can be rinsed after emesis has occurred to prevent additional systemic absorption and decrease the likelihood of adverse events. At doses used to induce emesis, adverse effects may include central nervous system (CNS) depression and protracted vomiting. CNS stimulation and respiratory and cardiac depression may be seen with excessive doses (Plumb, 2005). The opiate antagonist naloxone can be used to reverse the CNS and respiratory effects, but will not block the emetic effect (Rosendale, 2002).

*Xylazine hydrochloride* is a potent  $\alpha_2$ -adrenergic agonist used in the veterinary clinic setting primarily as a sedative. It has also been used, with some success, as an emetic in cats (Beasley and Dorman, 1990; Khan *et al.*, 2009). Xylazine does not produce predictable emesis in dogs (Plumb, 2005). The recommended emetic dose in cats is 0.44 mg/kg IM. This is lower than the dose used for sedation in cats. Emesis is expected within 5 minutes of administration. Possible adverse effects include CNS and respiratory depression, hypotension and bradycardia. These effects, as well as the emetic effects (Beasley and Dorman, 1990), can be reversed by giving an  $\alpha_2$ -adrenergic antagonist, either yohimbine at a dosage of 0.5 mg/kg IV or atipamezole at a dosage of 50 mcg/kg IM (Plumb, 2005).

### Lavage

Lavage is sometimes used in cases where emesis is contraindicated, not possible or has been unsuccessful. If the patient is agitated, seizing or recumbent or has other health concerns, such as recent abdominal surgery, that increase the risks associated with induction of emesis, lavage is an option. Lavage should also be considered in species, like rabbits and rodents, which are unable to vomit safely. Lavage is unlikely to remove as much ingested toxicant as emesis (Beasley and Dorman, 1990) and is associated with significant potential risks. For these reasons, it should not be chosen haphazardly as a decontamination method over emesis. Lavage should also not be used to remove caustic substances or volatile hydrocarbons for the same reasons emesis is contraindicated in such cases (Rosendale, 2002).

Gastric lavage can be used in mammals to remove recently ingested toxicants. If the patient is a species with cheek pouches, the cheek pouches should be emptied gently with a finger or swab prior to the lavage. In all instances, a cuffed endotracheal tube should be in place to prevent aspiration, therefore general anesthesia must be performed unless the patient is comatose. Body temperature water (5–10 ml/kg) should be instilled via a large bore gastric tube with a fenestrated end, inserted to a length equal to the distance from the nose to the xiphoid cartilage (Beasley and Dorman, 1990). The head of the patient should be kept lower than the chest throughout the procedure. Gravity should be used to instill the water by holding the tube higher than the patient and then drained by moving the tube lower than the patient. The flushing process should be repeated multiple times (15–40) until the lavage fluid runs clear. With each flush, approximately the same amount of fluid instilled should be removed. The free end of the tube should be occluded before removal to prevent aspiration (Rosendale, 2002). The initial washings should be saved for toxicological testing if needed (Peterson, 2006).

In humans, hypernatremia following lavage with normal saline and hyponatremia following lavage with water have been reported. Additionally, one human study showed that as much as 25% of the fluid used for lavage passed into the small intestine. Thus, there is a concern that lavage may actually propel a toxicant into the small intestine where the absorptive surface area is greater. These risks should be limited by allowing the entire amount of fluid to drain out after each flush and by using only gravity to instill the water. Other risks associated with gastric lavage include esophageal or stomach damage or perforation, hypothermia and the accidental placement of the tube in the trachea and the instillation of fluid into the lungs (Rosendale, 2002).

A lavage technique can also be used in birds to remove recently ingested toxicants from the crop. To prevent

injury to the patient and handlers, anxious and fractious birds should be anesthetized prior to the procedure. If the patient is under general anesthesia, an endotracheal tube should be placed to protect the airway (Richardson *et al.*, 2001). The patient should be held with the head up and the mouth held open. The bird's head and neck should be extended to minimize esophageal damage. An appropriately sized feeding tube (soft plastic or rubber) is then passed into the crop. The crop should be palpated to assure correct placement. Then 10–20 ml/kg of warm saline is infused into the crop, the crop is massaged gently and the liquid is aspirated. The first washing can be kept for toxicological evaluation if needed. The cycle is repeated three or four times (Echols, 2005).

### Adsorbents

Adsorbents may be utilized in addition to or instead of emesis or lavage to prevent further systemic absorption of a toxicant. These agents act by adsorbing to a chemical or toxicant in the upper gastrointestinal tract and facilitating its excretion via the feces. The most commonly used adsorbent is activated charcoal. In the past, kaolin-pectin (Kaopectate®) had also been recommended as an adsorbent and demulcent in some instances. However, Kaopectate®, and most generic kaolin-pectin combinations, now contain bismuth subsalicylate as the active ingredient instead of kaolin and pectin. Some commercial-activated charcoal products also contain kaolin (Vet-A-Mix, Toxiban®).

Activated charcoal is composed of large porous particles that are able to adsorb and therefore trap a wide range of organic compounds within the gastrointestinal tract. The surface binding area of these products is quite large, in the range of 900–1500 m<sup>2</sup>/g (Rosendale, 2002). Charcoal tablets and capsules, found in pharmacies and used to control flatulence and bloating, are not likely to be as effective as the commercially prepared products (Buck and Bratich, 1986) as the concentration of the charcoal is often low and may have a smaller binding area.

The recommended dose of activated charcoal for all species of animals is 1–3 g/kg (or 1–3 mg/g) body weight (Buck and Bratich, 1986). There are many products on the market, including both liquid and powder forms. If using the powder formulation in dogs and cats, the total calculated dose of activated charcoal is mixed with 50–200 ml of warm tap water to make a slurry (Rosendale, 2002). In horses and ruminants, each gram of activated charcoal powder is mixed with 3–5 ml of water (Plumb, 2005). In symptomatic small animal patients and large animals, the activated charcoal liquid or prepared slurry is administered via stomach tube (Bailey and Garland, 1992). Small animals receiving activated charcoal via stomach tube should be sedated and have a cuffed endotracheal tube in place to prevent aspiration.

In small animal patients where no clinical effects are present, activated charcoal can be given orally with a large syringe or can be mixed with a small amount of canned food or chicken broth and offered to the patient (Rosendale, 2002). Some patients, especially dogs, will voluntarily ingest the mixture. Many birds will regurgitate a portion of the activated charcoal dose given and some dogs and cats will vomit after administration.

Repeated doses of activated charcoal may be indicated in some instances, such as cases where toxicants undergo enterohepatic recirculation. The first step in this process involves the toxicant being carried to the liver by either the portal vein after absorption from the gastrointestinal tract or via the systemic circulation. Once in the liver, the toxicant then enters the bile and is excreted into the gastrointestinal tract where it is again available for absorption. Many toxicants are known to undergo this type of recycling, including ibuprofen, marijuana and digoxin.

When repeated doses are indicated, half the original dose should be given at 4 to 8 hour intervals, often for 2–3 days (Peterson, 2006). It is important to mention that with medications that are excreted in the bile, activated charcoal can be of benefit regardless of the route the medication was administered. Thus, if a patient received an overdose of injectable ivermectin subcutaneously, activated charcoal will still be a very valuable decontamination option. The ivermectin molecules will be carried to the gastrointestinal tract by the bile.

The use of activated charcoal does carry some risks and it does not bind all compounds equally. Some chemicals that are not effectively adsorbed include: ethanol, methanol, fertilizer, fluoride, petroleum distillates, most heavy metals, iodides, nitrates, nitrites, sodium chloride and chlorate. Activated charcoal should not be given to animals that have ingested caustic materials since it is unlikely to bind them, it can be additionally irritating to the mucosal surfaces and make visualization of oral and esophageal burns difficult (Buck and Bratich, 1986). If ethylene glycol testing will be performed, activated charcoal should be administered after blood is collected, since propylene glycol found in many formulations can cause a false positive on some of these tests. Additionally, the timing of the activated charcoal administration should be taken into account when deciding on dosing of other oral medications since the charcoal can also bind them. In acetaminophen overdose in humans, for example, it is recommended that *n*-acetylcysteine not be administered orally until 3 hours after activated charcoal (Plumb, 2005).

Administration of activated charcoal carries a significant risk of aspiration. If the patient does aspirate the charcoal, the prognosis is poor. Hence proper placement of the stomach tube and a protected airway is a must in symptomatic patients. The patient may also experience constipation and black bowel movements, making

it difficult to determine if melena is present. If the activated charcoal sits within the gastrointestinal tract for a significant period of time, it may release the compound it has adsorbed, leading to systemic absorption and recurrence of the clinical signs. It is for this reason that activated charcoal is frequently administered with a cathartic. In fact, many commercially available preparations do contain a cathartic such as sorbitol.

Another possible adverse effect of activated charcoal administration is the development of hypernatremia. In humans, hypernatremia has been reported primarily in children when multiple doses of a charcoal-sorbitol mixture were administered. The hypernatremia is attributed to a water shift from the intracellular and extracellular spaces into the gastrointestinal tract as a result of the osmotic pull of the sorbitol cathartic (Allerton and Strom, 1991). The ASPCA Animal Poison Control Center (APCC) has also received reports of elevated serum sodium following activated charcoal administration in dogs. Hypernatremia seems to be more often reported in small dogs receiving multiple doses of activated charcoal, but it has also been reported in large dogs and in cases receiving only a single dose. Furthermore, unlike the human reports, hypernatremia has also been noted in cases where no cathartic was present in the charcoal product given (APCC unpublished data). Perhaps one of the other components of the product is also osmotically active. In these cases, the APCC has found that administration of a warm water enema is very effective at lowering the serum sodium and easing the resultant central nervous system effects.

### Cathartics

Cathartics enhance elimination of substances, including activated charcoal, by promoting their movement through the gastrointestinal tract. Since activated charcoal only binds to toxicants by weak chemical forces, without cathartics, the bound toxicant can eventually be released and reabsorbed (Rosendale, 2002). When used with activated charcoal, the cathartic should be given immediately following or mixed with the charcoal. Cathartics are contraindicated if the animal has diarrhea, is dehydrated, if ileus is present, or if intestinal obstruction or perforation are possible (Peterson, 2006).

There are bulk, osmotic and lubricant cathartics. The most commonly used bulk cathartic is psyllium hydrophilic mucilloid (e.g., Metamucil®). Psyllium is found in the ripe seed coatings of *Plantago* species. It absorbs water and swells in the intestine increasing bulk to induce peristalsis and decrease gastrointestinal transit time. The dose in dogs is 1 teaspoon to 2 tablespoons, and the dose in cats is 1–4 teaspoons (Plumb, 2005). Psyllium can also be used in birds by mixing one-half teaspoon with 60ml of baby food to form a gruel,

then administering by a dosing syringe or eyedropper (Richardson *et al.*, 2001).

Another bulking cathartic that can be used in dogs and cats is unspiced canned pumpkin. Dilute peanut butter, fruit or vegetables can also be used as bulking cathartic agents in birds and reptiles. Timothy hay can be utilized in rabbits. Bulking cathartics are also used to assist the passage of physical agents through the gastrointestinal tract (Beasley and Dorman, 1990). Examples include small pieces of plastic, coins, button batteries and sand in horses (Plumb, 2005).

Osmotic cathartics have limited absorption from the gastrointestinal tract so they are able to pull electrolyte-free water into the gastrointestinal tract, thereby increasing the fluid volume and stimulating motility to hasten expulsion in the feces. There are saline and saccharide osmotic cathartics. Sorbitol is the most commonly used saccharide osmotic cathartic; it is the cathartic of choice and is frequently combined with activated charcoal in commercially prepared charcoal products. The dose is 1–2 ml/kg of a 70% solution (Peterson, 2006). Sorbitol can be utilized in mammals, birds and reptiles.

The saline cathartics include sodium sulfate (Glauber's salts) and magnesium sulfate (Epsom salts). The recommended dose is 250 mg/kg. The use of magnesium sulfate has led to hypermagnesemia in some cases, which presents as depression of the central nervous and cardiovascular systems (Rosendale, 2002). Saline cathartics should not be used in patients with renal insufficiency or in birds or reptiles.

Of the lubricant cathartics, mineral oil is the most often used. Heavy mineral oil is preferred to light mineral oil since it is thought to carry less of a chance of systemic absorption and aspiration following oral administration. Mineral oil lubricates fecal material and the intestinal mucosa easing elimination and reduces absorption of water from the gastrointestinal tract, increasing fecal bulk and cutting transit time (Plumb, 2005). Mineral oil is not recommended as a cathartic following activated charcoal administration as the mineral oil may render the charcoal less adsorptive (Buck and Bratich, 1986; Galey, 1992). Mineral oil has been recommended to bind lipid-soluble toxicants including metaldehyde, nitrate and cantharidin (Stair and Plumlee, 2004; Plumb, 2005) and is used to treat impaction in horses (Buck and Bratich, 1986). The recommended dose in horses is 2–4 L per 500 kg body weight (Brown and Bertone, 2001). Possible adverse effects include diarrhea and aspiration of the oil leading to lipid pneumonitis. Ensuring proper placement of the stomach tube and slow administration lessen the risk of aspiration (Plumb, 2005).

As mentioned above, hypernatremia attributed to sorbitol administration has been reported in humans. Because all cathartics alter the water balance in the gastrointestinal tract, electrolyte abnormalities, especially hypernatremia,

are a potential risk to their use. A patient's hydration status should be monitored frequently and fluids administered, intravenously or via an enema, as needed.

### Enemas

Enemas are also appropriate when elimination of toxicants from the lower gastrointestinal tract is desired (Beasley and Dorman, 1990). Many extended-release or controlled-release medications are absorbed from the entire gastrointestinal tract, including significant absorption from the colon (Buckley *et al.*, 1995). Enemas can be used to move those medications quickly through the colon and lessen additional systemic effects. The general technique is to use plain warm water or warm soapy water. Commercial phosphate enema solutions should be avoided due to the risk of electrolyte and acid-base disturbances (Beasley and Dorman, 1990). Enemas are not recommended for birds since they already have a rapid gastrointestinal transit time. In reptiles, enemas may be useful since ingested materials often lag for prolonged periods in the colon.

### Endoscopy/Gastrotomy

In some cases, endoscopy or gastrotomy may be indicated to prevent further clinical effects. Endoscopy can be used to remove small objects, such as pennies, lead paint chips and small batteries. These objects can also be removed via gastrotomy if endoscopy is not available. Gastrotomy is also used to prevent obstruction from expanding foreign objects. Expandable isocyanate-containing glues (i.e., Gorilla Glue™) can swell once ingested to fill the entire volume of the stomach. A gastrotomy is needed in these cases to remove the mass (Horstman *et al.*, 2003).

## ANTIDOTAL THERAPIES

If an antidote to the toxicant a patient has been exposed to exists, the appropriate time to administer it will depend on the situation. In some instances, the antidote will be crucial in stabilizing the patient. For example, atropine should be used immediately in cases of organophosphate toxicosis in which the patient has life-threatening bradycardia and bronchial secretions (Gwaltney-Brant and Rumbeiha, 2002). On the other hand, in some cases, administration of the antidote is best done later. This is true for vitamin K<sub>1</sub> being used in anticoagulant rodenticide exposures. In a recent exposure, decontamination first would be the most appropriate course of action. In an anticoagulant patient that is symptomatic, supportive measures like a blood transfusion should be started first

since the vitamin K<sub>1</sub> will not be immediately life-saving (Merola, 2002).

Unfortunately, few antidotes exist. There is little economic incentive for pharmaceutical companies to seek approval for antidotal medications with only a small projected market (Post and Keller, 1999). Additionally, organizing clinical trials for antidotal medications is uniquely problematic. The U.S. Food and Drug Administration (FDA) has offered incentives to develop antidotal therapies through the Orphan Drug Act. As a result, at least one antidotal therapy was released for veterinary patients: fomepizole was approved for use in treating ethylene glycol intoxication (Cantilena, 2001). In situations where an antidote does exist, its use may be limited by its expense or availability.

Antidotes are generally divided into three groups, based on the mechanism by which they are protective. The groups are chemical antidotes, pharmacological antidotes and functional antidotes. Chemical antidotes act directly on the toxicant. They may decrease the toxicity of the agent or increase its excretion. Pralidoxime chloride, for example, does both; it binds to organophosphate insecticide molecules making them unable to bind to their target, and the pralidoxime–insecticide complex is then readily excreted (Mowry *et al.*, 1994).

Pharmacological antidotes antagonize the poison at the target site. Flumazenil, for example, has a high affinity for benzodiazepine receptors, thus it competes with benzodiazepines to reverse their depressive effects (Gwaltney-Brant and Rumbeih, 2002). Functional antidotes act to lessen the symptoms of the poisoning. They have no interaction with the toxicant. An example of a functional antidote is the use of methocarbamol to control fasciculations and tremors associated with tremorgenic mycotoxins (Schell, 2000). Below are some examples of antidotal therapies available for use in veterinary medicine.

### Antidotes for amitraz: atipamezole and yohimbine

Amitraz, a synthetic formamidine pesticide, is used topically to control ticks, mites and lice on cattle, pigs and dogs, as well as to treat demodectic mange in dogs (Grossman, 1993). It is also available in a collar form for tick control in dogs. The acaricide action of amitraz is not well understood, but it may have effects on the central nervous system of susceptible organisms. It also exhibits significant alpha-2 adrenergic agonist activity (Plumb, 2005). This activity is believed to be responsible for the clinical signs associated with amitraz toxicosis including ataxia, central nervous system depression, hypotension, hyperglycemia, mydriasis, hypothermia, gastrointestinal stasis and bradycardia. In dogs, toxicosis can occasionally result from exposure to a topical product but is more

commonly due to ingestion of an amitraz-containing collar (Grossman, 1993; Gwaltney-Brant, 2004).

*Atipamezole* (Antisedan®) is alpha-2 adrenergic antagonist labeled for use as a reversal agent for the sedative medetomidine. It has been used successfully in the treatment of amitraz toxicosis to reverse the central nervous system depression, bradycardia, gastrointestinal stasis and hyperglycemia (Grossman, 1993; Gwaltney-Brant, 2004). The recommended dose in dogs is 50 µg/kg IM. The drug has a good margin of safety; dogs injected with 10 times the therapeutic dose did not have significant effects. Potential adverse effects of atipamezole administration include vomiting, diarrhea, hypersalivation, a brief period of excitation or apprehensiveness and tremors (Plumb, 2005). In cases where an amitraz collar was ingested and has not been retrieved from the gastrointestinal tract, the atipamezole dose may need to be repeated each time signs recur until the collar is passed through the gastrointestinal tract.

*Yohimbine* is another alpha-2 adrenergic antagonist that has been used to counter the toxic effects of amitraz. The recommended dose in dogs is 0.1 mg/kg IV. Yohimbine has a short half-life (1.5–2 hours in dogs); consequently, the dose may need to be repeated. Potential adverse effects include temporary apprehension or central nervous system excitation, tremors, hypersalivation, elevated respiratory rate and hyperemic mucous membranes. Careful dosing is recommended, because tremors and seizures have been reported in dogs receiving five times the therapeutic dose (Plumb, 2005).

### Antidotes for anticholinesterase agents: atropine and pralidoxime

*Atropine* is used to counter the muscarinic effects of anticholinesterase agents. Acetylcholine (ACh) is a neurotransmitter that transmits impulses at cholinergic nerve synapses and neuromuscular junctions. The enzyme anticholinesterase (AChE) is responsible for the hydrolysis of ACh. Anticholinesterase agents, which include the carbamate and organophosphate (OP) insecticides, produce their effects by binding with AChE to disrupt the breakdown of ACh. The ACh accumulates within the synapse leading to overstimulation of the end organ (Meerdink, 2004). There are two basic cholinergic receptor types: muscarinic and nicotinic. The muscarinic are the postganglionic parasympathetic receptors in smooth muscle, the heart and endocrine glands. Overstimulation of these receptors leads to a complex of signs, often described as SLUDGE, which includes salivation, lacrimation, urinary incontinence, increased peristalsis and diarrhea, increased bronchial secretions and dyspnea, miosis, nausea, emesis and abdominal discomfort. Excessive stimulation of the nicotinic receptors, which are found in the

skeletal muscles and autonomic ganglia, leads to tremors, and possibly seizures, potentially followed by muscle fatigue, weakness and paralysis (Meerdink, 1989).

Atropine competes with the accumulated ACh in the synapse to block only the muscarinic effects. Atropine does not block the nicotinic effects. The dosage used to counter anticholinesterase agents is: dogs and cats 0.2–2 mg/kg; cattle 0.5 mg/kg; horses 0.22 mg/kg. In all of those species, one-quarter of the dose is given IV and the remainder intramuscularly (IM) or subcutaneously (SC) (Plumb, 2005). In some cases, administration of atropine may need to be repeated, but great care should be exercised to prevent over-atropinization. Auscultation should be performed to monitor the patient for bradycardia and continued bronchial secretions, since these are the most life-threatening of the muscarinic signs. Additional atropine should only be given if these signs are present. The patient will not die from miosis or hypersalivation. Horses are quite susceptible to ileus caused by atropine administration, and a total dose of no more than 65 mg is recommended for a horse of average weight (Meerdink, 2004).

Atropine is not an effective antidote for other types of insecticides including pyrethroids. When presented with a suspected case of anticholinesterase exposure, the clinician can use a test dose of atropine to assist in making a preliminary diagnosis. The patient should be given the preanesthetic dose of atropine (0.02 mg/kg) IV. If this dose is able to produce typical anticholinergic signs such as mydriasis and tachycardia, then the patient has likely *not* been poisoned by an anticholinesterase agent (Fikes, 1990). If the patient truly had been poisoned by an anticholinesterase agent, the dose of atropine required to produce those effects would be at least 10 times higher (0.2 mg/kg).

*Pralidoxime chloride* (2-PAM) is used with atropine in the treatment of OP poisoning to relieve nicotinic signs such as tremors and muscle weakness (Fikes, 1990). 2-PAM reactivates the acetylcholinesterase enzyme (AChE) that has been inactivated by the OP. Normally, acetylcholine (ACh) binds to the enzyme at the anionic binding site. OPs and carbamates bind nearby on the esteric site, thus physically blocking the anionic site from ACh and inactivating the enzyme. 2-PAM is able to squeeze in via nucleophilic attack and bind to the anionic binding site. It then attaches to the OP forming a pralidoxime–OP complex. This complex detaches from the enzyme reactivating it and is then excreted in the urine (Fikes, 1990; Mowry *et al.*, 1994; Plumb, 2005).

Administration of 2-PAM is most effective if given within 24 hours of exposure (Plumb, 2005). If the OP remains attached to the AChE much longer, aging of the bond may occur so that it can no longer be broken by 2-PAM (Meerdink, 1989; Mowry *et al.*, 1994). There are instances when later administration is warranted. For example, in large OP exposures, pralidoxime may still

be of some benefit if given within 36–48 hours (Plumb, 2005). And 2-PAM may still be indicated even later if clinical signs have been present for an extended period of time (Fikes, 1992). Please see Table 104.2 for dosing information.

Treatment with 2-PAM should continue until the animal is asymptomatic. If no improvement is seen after 24–36 hours following initiation of treatment, 2-PAM should be discontinued (Fikes, 1990). In acute feline chlorpyrifos toxicosis, cats with persistent tremors can be maintained on 1–2 times daily treatment for up to 4 weeks. The typical presentation in these cats differs from the classical signs expected from other OPs. The onset may be delayed 1–5 days and the cats have neurological signs, including tremors, especially of the muscles of the back, neck and top of head, ataxia and seizures in addition to non-specific depression and anorexia which can persist for 2–4 weeks (Fikes, 1992).

As indicated in Table 104.2, when given IV, administration of 2-PAM should be slow. Rapid IV administration can cause tachycardia, muscle rigidity, transient neuromuscular blockade and laryngospasm. At therapeutic doses, 2-PAM is generally safe and has no significant adverse effects. However, careful dosing is recommended. At high doses, 2-PAM may exhibit anticholinesterase activity including muscle weakness, ataxia, vomiting, hyperventilation, seizures, respiratory arrest and death. The LD<sub>50</sub> in dogs is 190 mg/kg (Plumb, 2005).

Patients receiving 2-PAM should be monitored for hypersensitivity reactions. 2-PAM is generally not recommended for carbamate toxicosis because AChE inhibition due to carbamates is rapidly reversible (Plumb, 2005), and 2-PAM has less affinity for carbamates than OPs (Meerdink, 2004). In addition, there is evidence that 2-PAM can reduce the protective effects of atropine in the treatment of one carbamate, carbaryl (Fikes, 1990). Since the drug is excreted by the kidneys, patients with underlying renal impairment should receive a decreased dose and be monitored closely for signs of toxicity (Plumb, 2005).

TABLE 104.2 Pralidoxime dosing in OP treatment

Species	Dosing instructions
Dogs and cats	Pralidoxime works best when combined with atropine. Pralidoxime at 20 mg/kg, 2–3 times a day. Initial dose may be given either IM or slow IV. Subsequent doses may be given IM or SQ.
Cattle	25–50 mg/kg as a 20% solution IV over 6 minutes or as a maximum of 100 mg/kg/day as a CRI IV infusion.
Horses	20 mg/kg (may require up to 35 mg/kg) slow IV and repeat every 4–6 hours.

## Cyproheptadine HCl

Cyproheptadine HCl has been successful in treating serotonin syndrome in dogs and people (Gwaltney-Brant and Rumbelha, 2002). Cyproheptadine is an antihistamine that is most commonly utilized in veterinary practice as an appetite stimulant for cats. It also is a potent serotonin antagonist (Plumb, 2005).

Serotonin is a neurotransmitter in the central nervous system. It also acts to promote platelet aggregation and as a stimulant on the smooth muscle of the respiratory, gastrointestinal and cardiovascular systems. The term serotonin syndrome is used to describe the characteristic signs which develop from excessive serotonin including autonomic, neuromuscular, behavioral and cognitive abnormalities (Gwaltney-Brant *et al.*, 2000). Excess serotonin may result from use or accidental overdose of medications that increase brain serotonin levels. These medications include selective serotonin reuptake inhibitors (SSRIs), like venlafaxine (Effexor®), paroxetine HCl (Paxil®) and fluoxetine HCl (Prozac®), as well as 5-hydroxytryptophan which is a serotonin precursor sold over-the-counter as a dietary supplement (Gwaltney-Brant and Rumbelha, 2002). See Table 104.3 for a list of medications that carry a high potential of increasing brain serotonin levels.

Dogs with serotonin syndrome typically have hyperthermia, central nervous abnormalities including tremors, seizures, ataxia, excitation or depression and hyperesthesia, and gastrointestinal effects of vomiting, diarrhea and abdominal discomfort (Gwaltney-Brant and Rumbelha, 2002). Death is possible if the signs are not controlled quickly. When used as a serotonin antagonist, the recommended dose of cyproheptadine in dogs is 1.1 mg/kg up to every 8 hours until signs do not recur (Gwaltney-Brant, 2006 personal communication). The dose can be given orally if the patient is alert, not vomiting and activated charcoal was not given within 2 hours. In those instances, the dose can be crushed, mixed with a small amount of saline and given per rectum. The drug should be discontinued after the first two doses if little or no improvement

is noted (Gwaltney-Brant *et al.*, 2000). A similar dose of cyproheptadine has also been of some benefit in controlling vocalization and disorientation in some cases of baclofen toxicosis (Wismer, 2004).

## Digoxin immune Fab

Digoxin immune Fab fragments (e.g., Digibind® from GlaxoSmithKline) are a promising treatment for life-threatening digoxin toxicosis. The Fab fragments are used as a specific antidote for digoxin since they inactivate the drug by directly binding to it. The fragments are produced by first immunizing sheep with digoxin-human albumin complexes. In response, the sheep produce antibodies that are collected, purified and cleaved with papain into Fab fragments and Fc portions (Kittleson and Kienle, 1998). Digoxin immune Fab fragments are quite expensive, so their use may be cost prohibitive and they may be difficult to obtain. A local human hospital pharmacy may be willing to sell the product to the veterinary clinic if needed.

Digoxin and other digitalis glycosides are thought to cause their effects by inhibition of the sodium-potassium ATPase pump ( $\text{Na}^+/\text{K}^+$ -ATPase) through competition with potassium for binding sites (Kittleson and Kienle, 1998). Fab fragments can actually remove a digoxin molecule that is bound to the ATPase since their affinity for digoxin is much stronger than the affinity of digoxin for the  $\text{Na}^+/\text{K}^+$ -ATPase target (Gwaltney-Brant and Rumbelha, 2002). Fab fragments may also be used as an effective antidote for digitoxin toxicosis since they bind to it, though with less affinity than for digoxin. Moreover, sufficient cross-reactivity exists with cardiac glycosides derived from *Bufo* toads and a wide variety of plants; consequently, Fab fragments may be effective at controlling toxicoses from these agents as well (Clark *et al.*, 1991; Gwaltney-Brant and Rumbelha, 2002). See Table 104.4 for a list of plants containing cardiac glycosides that Fab fragments may be effective against.

TABLE 104.3 Drugs with high serotonergic potential

Amitriptyline (e.g., Elavil®)	Lithium
Amphetamines (e.g., Adderall®)	Meperidine (e.g., Demerol®)
Clomipramine (e.g., Clomicalm®)	Moclobemide
Dexfenfluramine	Paroxetine (e.g., Paxil®)
Fenfluramine (e.g., Ponderal®)	Phenelzine
Fluoxetine (e.g., Prozac®)	Selegiline (e.g., Anipryl®)
Hydroxytryptophan	Sertraline (e.g., Zoloft®)
Imipramine (Tofranil®)	Tranlycypromine
Isocarboxazid	Tryptophan
	Venlafaxine (e.g., Effexor®)

TABLE 104.4 Plants containing cardiac glycosides

Plant species	Common name
<i>Acodkanthera oblongifolia</i>	
<i>Adonis microcarpa</i>	Pheasant's eye
<i>Asclepias physocarpa</i>	Balloon cotton bush
<i>Byrophyllum tubiflorum</i>	Mother of millions
<i>Calotropis procera</i>	King's crown
<i>Carissa laxiflora</i>	
<i>Cerbera manghas</i>	Sea mango
<i>Convallaria majalis</i>	Lily of the valley
<i>Cryptostegia grandiflora</i>	Rubber vine
<i>Helleboros.</i>	
<i>Nerium oleander</i>	Oleander
<i>Thevetia neriifolia</i>	Yellow oleander

The antidotal use of Fab fragments is indicated for treatment of potentially life-threatening cardiac glycoside toxicoses. Fab fragments should be considered when the patient has developed cardiac arrhythmias that are unresponsive to other antiarrhythmic therapy. Ideally, the appropriate dose of Fab fragments is determined by using the patient's serum digoxin level. In some cases, the laboratory at a local human hospital may be willing to perform serum levels for the veterinarian. If a serum level can be obtained, the following formula is used to calculate the number of vials (Gwaltney-Brant and Rumbeiha, 2002). This formula assumes each vial will bind 0.5 mg of digoxin:

$$\text{Dose (number of vials)} = \frac{\text{Serum digoxin concentration (ng/ml)} \times \text{Body weight (kg)}}{100}$$

In cases where the cost of the calculated number of vials is prohibitive, if digoxin levels cannot be measured, or if the Fab fragments are being used to treat another cardiac glycoside, treatment can be initiated with one to two vials and the patient observed for improvement. The reconstituted Fab fragments are administered intravenously over approximately 30 minutes. If the clinician feels the patient's clinical signs are immediately life-threatening, the product can instead be given as a bolus. Fab fragments act quickly and dramatically. The patient's cardiac status is expected to begin improving within 20–90 minutes of administration and complete resolution of the clinical effects is usually seen within 4 hours (Gwaltney-Brant and Rumbeiha, 2002). If significant improvement does not occur, additional vials may need to be given.

While monitoring the patient, it is important to note that the total serum digoxin concentration will be markedly increased with most commercial assays after Fab fragment administration. This occurs because previously tissue-bound digoxin binds to the Fab fragments, and the Fab–digoxin complexes then move into the blood to be excreted by the kidneys (Ward *et al.*, 1999). Since these patients have a compromised cardiovascular system as a result of the toxicosis, it is likely that renal perfusion is also compromised. These animals should be monitored carefully because decreased renal clearance of Fab–digoxin complexes may allow for dissociation of the toxin and recurrence of signs (Gwaltney-Brant and Rumbeiha, 2002).

The patient should also be monitored for hypokalemia. Elevated serum potassium is expected with cardiac glycoside toxicosis due to interference with the Na<sup>+</sup>/K<sup>+</sup>-ATPase pumps. After administration of the Fab fragments, potassium moves quickly back into the cells leading to a significant drop in serum potassium levels. Serum potassium levels should be checked frequently within the first few hours and hypokalemia treated if

needed (Gwaltney-Brant and Rumbeiha, 2002). The patient should also be monitored for anaphylaxis, fever and hypersensitivity reactions (Ward *et al.*, 1999).

### Antidotes for ethylene glycol: ethanol and fomepizole

*Ethanol* can be used as an antidote for ethylene glycol poisoning. Ethylene glycol is found in many products at many concentrations. Most animal intoxications occur from ingestion of antifreeze since these products may have concentrations of ethylene glycol exceeding 90%. With intoxication, the gastrointestinal, central nervous, cardiopulmonary and renal systems can be affected. Death is usually due to acute renal failure. The ethylene glycol itself does not cause the life-threatening clinical findings. It must be converted, primarily in the liver, to its more toxic metabolites including glycolic, glyoxalic and oxalic acids (Dalefield, 2004). The first step in the metabolism is conversion of the parent ethylene glycol molecule to glycoaldehyde via the enzyme alcohol dehydrogenase (ADH). Ethanol is also metabolized by alcohol dehydrogenase, therefore it competes for the enzyme, allowing time for ethylene glycol to be excreted unchanged in the urine (Mathews, 2006). Early intervention is very important to prevent the conversion to toxic metabolites. If a toxic dose was ingested and treatment is not initiated within a few hours of exposure, the patient's prognosis is grave.

The dosing recommendations for ethanol vary among authors. Intermittent dosing is possible, but a constant rate infusion (CRI) is preferred to avoid high blood concentrations of the ethanol which can exacerbate the potential clinical effects (Mathews, 2006). See Table 104.5 for examples of intermittent and CRI dosing recommendations for dogs and cats.

Ethanol is easy to obtain and is inexpensive. However, significant adverse effects will likely develop at the high doses required for treatment of ethylene glycol toxicosis, including severe respiratory and central nervous system depression and metabolic acidosis. Since the signs of ethylene glycol intoxication mirror those effects, gauging patient progress can be challenging (Plumb, 2005).

*Fomepizole*, also called 4-methylpyrazole (4MP), is marketed as Antizol-Vet<sup>®</sup> as an antidote for ethylene glycol toxicosis in dogs. Studies have found that 4MP can also be used in cats, but must be used at higher doses to be effective (Connally *et al.*, 2002). 4MP is a synthetic ADH inhibitor that works similarly to ethanol to prevent the conversion of ethylene glycol to its toxic metabolites. However, while ethanol acts by competing for the enzyme, 4MP forms a complex with ADH and its coenzyme (Connally *et al.*, 1996). Fomepizole is significantly more expensive than ethanol, but has a therapeutic advantage because it causes fewer serious side effects

TABLE 104.5 Ethanol dosing in EG treatment

	Intermittent dosing	CRI
<b>Dogs</b>	<ul style="list-style-type: none"> <li>Start with a 20% solution</li> <li>Give 5.5 ml/kg IV q4hrs for 5 treatments</li> <li>Then give 5.5 ml/kg IV q6hrs for 4 additional treatments</li> </ul>	<ul style="list-style-type: none"> <li>Start with a 5% solution</li> <li>Give at CRI rate of 5.5 ml/kg/h</li> </ul>
<b>Cats</b>	<ul style="list-style-type: none"> <li>Start with a 20% solution</li> <li>Give 5 ml/kg IV q6hrs for 5 treatments</li> <li>Then give 5 ml/kg IV q8hrs for 4 additional treatments</li> </ul>	<ul style="list-style-type: none"> <li>Start with a 5% solution</li> <li>Give at CRI rate of 5 ml/kg/h</li> </ul>

(Gaddy, 2001). Dose-related central nervous system depression is the only adverse effect expected and tends to be mild if it develops. Cats are more at risk, because they require higher doses. Since 4MP has few serious risks, treatment is recommended in cases where exposure to ethylene glycol is suspected but not confirmed (Gwaltney-Brant and Rumbeiha, 2002).

4MP is excreted in the urine and accumulates over time depending on the dosage amount and frequency of administration. Since the drug accumulates, lower doses are given following the initial dose (Gaddy, 2001). In dogs, an initial dose of 20 mg/kg of the 5% reconstituted solution is given IV. At 12 and 24 hours after the first dose, additional doses of 15 mg/kg are given. Finally, at 36 hours after the first dose, a dose of 5 mg/kg is given. In cases where the patient has not fully recovered following the above doses, additional dosing of 3 mg/kg every 12 hours is recommended (Gwaltney-Brant and Rumbeiha, 2002).

The dosing schedule in cats is an initial dose of 125 mg/kg IV, then subsequent doses at 12, 24 and 36 hours with 31.25 mg/kg (Plumb, 2005). Treatment in cats with either 4MP or ethanol must begin within 3 hours post-ingestion of ethylene glycol or prognosis is grave. In dogs, fomepizole is most effective if given within 3–6 hours of ethylene glycol ingestion; however, some benefit was seen as late as 36 hours post-ingestion. A late dose may prevent additional injury to the kidneys (Gwaltney-Brant and Rumbeiha, 2002).

## Flumazenil

Flumazenil, 1,4-imidazobenzodiazepine, is a benzodiazepine antagonist (Plumb, 2005). It is derived from the antibiotic anthramycin (Gwaltney-Brant and Rumbeiha, 2002) and blocks benzodiazepines by competition for the benzodiazepine receptor in the central nervous system

(Plumb, 2005). Flumazenil has a higher affinity for the receptor than that of the benzodiazepines; as a result, it displaces receptor-bound benzodiazepines to reverse their depressive effects (Gwaltney-Brant and Rumbeiha, 2002).

Flumazenil has been used as a successful therapy for benzodiazepine toxicosis in dogs and cats (Wisner, 2002; Plumb, 2005). It is also used to improve neurological signs in dogs with severe hepatic encephalopathy (Plumb, 2005). Flumazenil has been used in humans, with some success, to reverse ethanol and tegretol-induced central nervous system depression. Consequently, it is reasonable to assume flumazenil also could be effective in small animal patients in such cases (Gwaltney-Brant and Rumbeiha, 2002).

The recommended flumazenil dose in dogs and cats is 0.01–0.02 mg/kg administered by rapid IV injection (Plumb, 2005). The medication rapidly crosses the blood–brain barrier and a swift reversal of benzodiazepine-induced sedation is expected within 1–2 minutes (Gwaltney-Brant and Rumbeiha, 2002). The dose may need to be repeated multiple times, since flumazenil's half-life is shorter than most of the benzodiazepines. The half-life of flumazenil is only 1 hour in humans (Plumb, 2005), but the half-life of diazepam in the dog is 6 hours. The patient should be monitored carefully for recurrence of signs and additional doses of flumazenil given as needed. Repeat doses should not be given in asymptomatic patients. Flumazenil may act as a benzodiazepine agonist if administered at high doses despite its antagonist action at therapeutic doses (Gwaltney-Brant and Rumbeiha, 2002).

Flumazenil is a costly medication and carries the risk of significant adverse effects. It should be reserved for cases where the patient has life-threatening benzodiazepine-induced clinical signs. The drug should be given through a patent IV catheter, because extravascular leakage can cause extensive local tissue irritation and necrosis (Gwaltney-Brant and Rumbeiha, 2002). In humans, vomiting, cutaneous vasodilation, vertigo, ataxia and blurred vision have been reported following flumazenil administration (Plumb, 2005). Seizures and death are also rarely reported in humans after treatment with flumazenil (ASHSP, 2003).

Flumazenil may lower the seizure threshold and is contraindicated in cases when seizures are anticipated. It also may increase intracranial pressure and should not be used in patients with head trauma (Gwaltney-Brant and Rumbeiha, 2002). Additionally, flumazenil is contraindicated in patients with life-threatening tricyclic antidepressant toxicosis and should be used only after careful consideration in cases of multiple drug overdose (Plumb, 2005). Most human deaths and seizures associated with flumazenil followed use in cases of tricyclic antidepressant toxicosis (ASHSP, 2003) and mixed overdoses (Plumb, 2005).

## Lipid emulsion

Intravenous infusion of a lipid emulsion (ILE) has been used successfully in humans to treat intoxication with local anesthetic medications and the antidepressant bupropion (Crandell and Weinberg, 2009; O'Brien *et al.*, 2010). Research studies in dogs, rats and rabbits have shown ILE to be effective in managing bupivacaine, verapamil, propranolol and clomipramine toxicosis. ILE has also been used in the treatment of companion animal intoxications as shown in two recent case reports. In one, ILE was used to treat lidocaine intoxication in a cat and in the other it was used to treat moxidectin toxicosis in a puppy.

Lipid emulsions are made from purified soybean oil in water, are commonly used in medicine to provide intravenous (parenteral) nutrition and are the delivery mechanism for certain hydrophobic drugs like propofol. The mechanism by which ILE is effective at treating toxicoses is not yet fully understood. However, the fact that ILE seems to be most effective in treating overdosage of lipid-soluble medications suggests that the infusion expands the amount of plasma lipid which acts as a sink in which the offending drug can gather reducing free drug concentrations. In theory, the drug is trapped in the plasma lipid so it is not available to act on other tissues (Crandell and Weinberg, 2009; O'Brien *et al.*, 2010).

The APCC uses the following dosing protocol. Using a 20% product, give an initial bolus of 1.5ml/kg slowly then start a continuous rate infusion (CRI) of 0.25ml/kg/min for 30–60 minutes. Four hours after the CRI is finished, check the serum for hyperlipemia and to see if the serum is orange or yellow. If the serum looks normal, repeat the initial bolus and CRI again. If hyperlipemia or a color change is present, check the serum for resolution every 2 hours. Repeat the initial bolus and CRI once the hyperlipemia or color change resolves. If a third dose is needed, follow the above directions beginning 4 hours after the second CRI finishes. Do not give more than three doses if there has been no significant response.

ILE may be effective in treating intoxications with many lipid-soluble medications including lidocaine, moxidectin, bupropion, bupivacaine, levobupivacaine, ropivacaine, verapamil, propranolol and clomipramine. Possible side effects of administering ILE include induction of pancreatitis, creation of a fat embolism, immunosuppression, phlebitis, thrombosis, hypertriglyceridemia and hepatic lipidosis (Crandell and Weinberg, 2009; O'Brien *et al.*, 2010).

## Methocarbamol

The skeletal muscle relaxant methocarbamol has proved to be very useful in the management of severe muscle

fasciculations, tremors and seizures associated with a variety of toxicologic agents. The exact mechanism by which methocarbamol works is unknown, but it is thought to act centrally to block nerve impulses in the brain stem, spinal cord and subcortical levels of the brain (Gwaltney-Brant and Rumbeiha, 2002; Plumb, 2005).

Methocarbamol has been used successfully in veterinary medicine to treat the following types of toxicoses: permethrin in cats (Richardson, 2000a), metaldehyde (Richardson *et al.*, 2003), strychnine (Gwaltney-Brant and Rumbeiha, 2002; Plumb, 2005) and tremorgenic mycotoxins (Schell, 2000). It is able to reduce the severity of tremors without causing the severe CNS depression often encountered when using a barbiturate medication (Gwaltney-Brant and Rumbeiha, 2002).

The dosage for dogs and cats is 55–220mg/kg administered slowly IV at a rate of no more than 2ml/min (Schell, 2000). Methocarbamol administration should be repeated if the signs recur; however, the total dose should not exceed 330mg/kg in a 24-hour period to avoid central nervous system and respiratory depression (Gwaltney-Brant and Rumbeiha, 2002; Richardson *et al.*, 2003). The dosage for horses is 15–25mg/kg by slow infusion (Plumb, 2005). The drug should not be given SQ and extravasation of methocarbamol should be avoided as the solution can be irritating (Plumb, 2005).

In dogs and cats, adverse effects may include sedation, salivation, emesis, lethargy, weakness and ataxia. Slow administration of the drug can help to avoid salivation and emesis. Sedation and ataxia can be seen in horses following methocarbamol administration. This medication is contraindicated in animals intended for food purposes and in patients hypersensitive to it. The manufacturer lists known or suspected renal insufficiency as a contraindication to injectable methocarbamol therapy since the injectable product contains polyethylene glycol 300, which has been found to increase acidosis and urea retention in renal-impaired humans (Plumb, 2005). For this reason, veterinary patients treated with injectable methocarbamol should receive IV fluid support and have kidney values monitored if renal impairment is suspected or is a possible outcome of their clinical signs. For example, patients with prolonged tremors or seizures can release muscular myoglobin. The myoglobin is excreted by the kidneys and can lead to renal damage (Volmer, 2004).

## Naloxone HCl

Naloxone HCl (Narcan®) is an injectable opiate antagonist used to reverse the effects of opiate medications. It is able to reverse opioid agonist/antagonists such as butorphanol as well. This drug is also being investigated for treatment of other conditions like septic, hypovolemic and cardiogenic shock (Plumb, 2005).

Naloxone is a pure opiate antagonist, and it has no analgesic activity or other agonist effects. Although the exact mechanism for its activity is not fully understood, it is thought the drug acts as a competitive antagonist by binding to multiple opioid receptor sites. The drug apparently has its highest affinity for the *mu* receptor which makes it an ideal antagonist since most of the clinically useful opioids work by binding to the *mu* receptor (Plumb, 2005; Volmer, 2006).

Naloxone reverses most of the effects of opioids including analgesia and respiratory and central nervous system depression (Plumb, 2005). It does not reverse the emetic actions of apomorphine in dogs (Volmer, 2006). At high doses, naloxone increases dopamine levels and acts as a GABA antagonist (Plumb, 2005).

Because orally administered naloxone is only minimally absorbed and the drug is destroyed rapidly in the digestive tract, an injectable formulation is preferred. The onset of action is normally within 1 to 2 minutes when given IV and within 5 minutes when given IM. The duration of action is usually 45–90 minutes but may be as long as 3 hours. Since the duration of action of naloxone may be shorter than the medication being reversed, additional doses may be required (Plumb, 2005).

The recommended dosage for dogs is 0.04 mg/kg IV, IM or SC; for cats, 0.02–0.04 mg/kg IV and for horses, 0.01–0.02 mg/kg IV (Plumb, 2005). In patients that have been intentionally given an opioid to treat a painful condition, abrupt reversal can lead to tachycardia, vasoconstriction and hypertension. In these cases, the unwanted central nervous system and respiratory depression can be reversed without reversing the analgesia. To achieve this, dilute 0.04–0.1 mg of naloxone in 5–10 ml of normal saline and give slowly to effect by dosing 0.5–1 ml each minute (Mathews, 2006).

Naloxone is considered quite safe at therapeutic doses. Very high doses have been associated with seizures in a few patients perhaps due to GABA inhibition. It is contraindicated in patients that are hypersensitive to it and should be used with caution in animals with pre-existing cardiac abnormalities due to the potential cardiovascular adverse effects (Plumb, 2005).

## N-acetylcysteine

N-acetylcysteine (NAC) is used to prevent methemoglobinemia and hepatic necrosis in acetaminophen (APAP) toxicosis. APAP is metabolized in the liver primarily via glucuronidation and sulfation to non-toxic metabolites. However, other pathways of metabolism exist which yield the toxic metabolites N-acetyl-para-benzoquinoneimine (NAPQI) and para-aminophenol (PAP) (Aronson and Drobatz, 1996; McConkey *et al.*, 2009). In a significant APAP exposure, the glucuronidation and sulfation

pathways become saturated, leading to increased production of NAPQI and PAP. NAPQI is produced through the P450 mixed function oxidase system and is normally inactivated through conjugation with glutathione (Richardson, 2000b). PAP is produced by deacetylation and is removed both through conjugation with glutathione and by *N*-acetylation. Dogs and cats are deficient in the enzymes needed for *N*-acetylation (McConkey *et al.*, 2009).

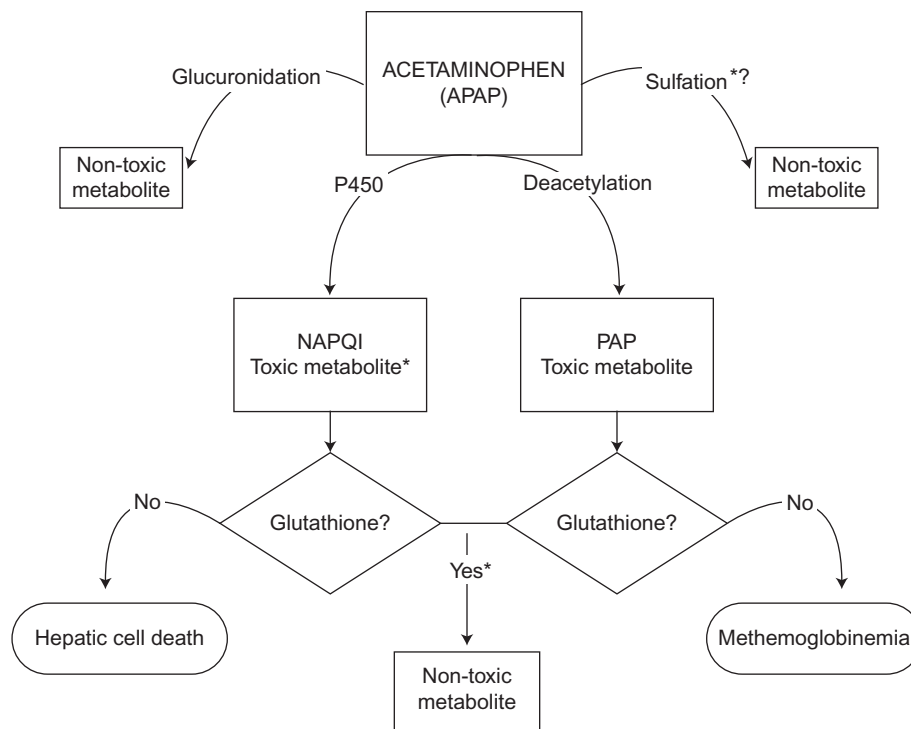

Initially the excess NAPQI and PAP will be detoxified through conjugation with glutathione. However, once glutathione stores are depleted, the NAPQI metabolite can lead to liver necrosis and the PAP metabolite can lead to methemoglobinemia. NAPQI binds to hepatic cell membranes causing oxidative injury to the bi-lipid layer and potential cellular death and necrosis (Richardson, 2000b). PAP causes redox cycling in the red blood cells (RBCs) leading to oxidation of the hemoglobin to methemoglobin which is unable to carry oxygen (McConkey *et al.*, 2009). While all species can develop both hepatic and RBC effects, dogs more commonly develop hepatic necrosis, whereas cats more commonly develop methemoglobinemia and Heinz body anemia (Taylor and Dhupa, 2000).

There are at least two mechanisms by which NAC prevents methemoglobinemia and hepatic necrosis from APAP. NAC binds directly with NAPQI rendering it inactive and therefore non-toxic. NAC is a precursor for glutathione production. It restores and maintains glutathione levels by increasing synthesis (Richardson, 2000b). NAC administration may also lead to increased serum sulfate which could re-establish the sulfation pathway to non-toxic metabolites (Aronson and Drobatz, 1996) (Figure 104.1).

The therapeutic dose of NAC for dogs and cats is a loading dose of 140 mg/kg PO or IV (as a 5% solution), then 70 mg/kg PO or IV every 6 hours for seven treatments. The number of additional treatments varies between authors; some recommend up to 17 treatments (Plumb, 2005). Presently, both an injectable form and oral solution are on the market. When given orally, NAC can cause gastrointestinal irritation so proper dilution is important.

## Pamidronate disodium

Pamidronate disodium (Aredia®) is a biphosphonate used in the treatment of hypercalcemia associated with malignancy and vitamin D<sub>3</sub> toxicity in dogs (Plumb, 2005). Vitamin D<sub>3</sub>, also called cholecalciferol, is found in some rodenticides. Calcipotriene, which is an analog of cholecalciferol, is found in some human prescription topical antipsoriasis medications (e.g., Dovonex®) (Pesillo *et al.*, 2002). Since vitamin D<sub>3</sub> plays an important role

**FIGURE 104.1** The metabolism of acetaminophen (APAP). Areas of *N*-acetylcysteine (NAC) action are indicated with an \*.

in calcium and phosphorus homeostasis, oral exposure to these rodenticides or topical medications can lead to significant elevations in serum calcium and phosphorus levels. Vitamin D<sub>3</sub> enhances calcium and phosphorus absorption from the GI tract. In addition, it works with parathyroid hormone to promote calcium reabsorption in the kidney and mobilization of calcium from the bone via osteoclastic-mediated bone resorption (Rumbeiha *et al.*, 2000; Morrow, 2001).

Calcium maintains cell membrane stability and is a second messenger in several cellular responses (Pesillo *et al.*, 2002). Therefore, increasing serum calcium can cause many cellular effects including altered cell membrane permeability, a decrease in cellular energy production and cellular necrosis (Morrow, 2001). Patients poisoned by vitamin D<sub>3</sub> and its analogs often present with polyuria, polydipsia, vomiting, anorexia, lethargy, hypercalcemia and hyperphosphatemia (Pesillo *et al.*, 2002). If elevations in serum calcium and phosphorus concentrations go unchecked, the plasma calcium phosphorus product (Ca X P) can rise above 60, leading to soft tissue mineralization (Morrow, 2001). Mineralization of the kidneys and heart can lead to a life-threatening decrease in function of these organs.

Pamidronate acts to decrease serum calcium levels by binding to hydroxyapatite crystals in the bone to prevent their dissolution and bone resorption. It also interrupts osteoclast activity and induces osteoclast apoptosis (Plumb, 2005). Some authors suggest pamidronate may

decrease intestinal absorption of calcium as well (Pesillo *et al.*, 2002).

The recommended dose of pamidronate is 1.3–2 mg/kg given as a slow IV infusion over several hours (Plumb, 2005). Pamidronate must be given in saline and should not mix with any IV fluid containing calcium (e.g., Ringer's). In most cases, a single dose will be effective in lowering calcium levels back to normal (Gwaltney-Brant and Rumbeiha, 2002). However, some patients may require an additional dose 5–7 days after the initial treatment (Morrow, 2001). Calcium levels should be monitored once daily for at least 10 days after they have returned to normal. Pamidronate is most effective if given within 24–36 hours of the exposure, prior to development of soft tissue mineralization (Gwaltney-Brant and Rumbeiha, 2002).

Anemia, thrombocytopenia and granulocytosis have been reported in humans following pamidronate administration. In dogs, hypersensitivity reactions, electrolyte abnormalities including hypomagnesemia and hypocalcemia, arrhythmias and renal toxicity are possible (Plumb, 2005). Slow infusion of the drug over at least 2 hours may help in avoiding renal effects. Use of pamidronate in dogs with impaired renal function is controversial since it may confound renal injury (Gwaltney-Brant and Rumbeiha, 2002).

Pamidronate is expensive, but its use may be more cost effective than using salmon calcitonin in vitamin D<sub>3</sub> toxicosis. Pamidronate lowers plasma calcium

concentrations within 24–48 hours of a single IV dose. Calcitonin requires dosing several times daily due to its short half-life. Additionally, with calcitonin therapy, saline diuresis and treatment with diuretics and corticosteroids must also be performed, requiring many days, sometimes multiple weeks, of hospitalization. In most cases treated with pamidronate, treatment can be performed on an out-patient basis once the calcium has returned to the normal range (Morrow, 2001; Pesillo *et al.*, 2002). Pamidronate is also preferred to calcitonin since patients may become refractory to calcitonin treatment after 10 days of therapy (Rumbeiha *et al.*, 2000; Morrow, 2001).

### Phytonadione (vitamin K<sub>1</sub>)

Phytonadione, a naphthoquinone derivative identical to naturally occurring vitamin K<sub>1</sub>, is used in the treatment of anticoagulant toxicosis resulting from anticoagulant rodenticides, the medication warfarin or moldy sweet clover (Plumb, 2005). All household pets, including pocket pets, may be exposed to anticoagulant rodenticides and the medication warfarin. Livestock and horses are more likely to be poisoned by the dicoumarol in moldy sweet clover, but they can also be exposed to rodenticides (Knight, 2004).

Anticoagulants block clotting factor activation. Vitamin K<sub>1</sub> is involved in the activation of precursor clotting factors into functional factors. During the activation, vitamin K<sub>1</sub> is converted to inactive vitamin K<sub>1</sub> epoxide. Normally, vitamin K<sub>1</sub> epoxide is reactivated by vitamin K<sub>1</sub> epoxide reductase. Anticoagulants work by inhibiting this enzyme and halting the recycling of vitamin K<sub>1</sub> (Merola, 2002). As a result, the number of active clotting factors decreases.

The vitamin K<sub>1</sub>-dependent clotting factors are II, VII, IX and X. These factors are involved in all three pathways of the coagulation system: the extrinsic, intrinsic and common (Means, 2004a). Active bleeding is not expected for 3 to 7 days after the ingestion because the body has a reserve of active clotting factors. When these degrade naturally or are consumed, clinical signs are possible. If an external source of vitamin K<sub>1</sub> is provided, the factors will be activated normally (Merola, 2002).

Bleeding can occur anywhere within the body and the presenting clinical signs will relate to where the bleeding has occurred. The signs may be vague and non-specific. In dogs, dyspnea, coughing, lethargy and hemoptysis are commonly reported due to bleeding into the chest cavity (Merola, 2002). With moldy sweet clover poisoning in livestock, prolonged bleeding in some members following routine surgical procedures, like castration or dehorning, is often the first indication of a problem within the herd (Knight, 2004).

The dose for vitamin K<sub>1</sub> in household pets is 1.5–2.5 mg/kg orally twice daily. Pocket pets and other small patients can be given the injectable formulation orally if a suitable tablet size is not available. Small patients should be dosed at the high end of the range and larger patients (e.g., large breed dogs) should be started at the low end (Means, 2004a). Vitamin K<sub>1</sub> should be given with a fatty meal to enhance absorption. In dogs, giving the medication with canned food caused a 4–5-fold increase in bioavailability (Plumb, 2005).

Oral administration is preferred since the vitamin K<sub>1</sub> will be carried, via the portal circulation, directly to the liver where the activation of clotting factors occurs (Merola, 2002). Additionally, vitamin K<sub>1</sub> injections have been associated with anaphylactic reactions and hematoma formation (Plumb, 2005). However, IM administration is recommended by many authors for livestock, perhaps for ease of administration. The recommended dose for cattle, horses, swine, sheep and goats is 0.5–2.5 mg/kg IM (Knight, 2004; Plumb, 2005).

The length of vitamin K<sub>1</sub> administration depends on the toxicant. Warfarin exposures generally require a 14-day course. Second generation anticoagulant rodenticides should be treated for 30 days, except for bromadiolone which should be treated for 21 days (Means, 2004a). Moldy sweet clover poisoning should be treated for 1–2 weeks (Knight, 2004). In all cases, a prothrombin time (PT) should be checked 48–72 hours after the course of vitamin K<sub>1</sub> is complete. If this test is abnormal, resume vitamin K<sub>1</sub> therapy for an additional 7 days (Merola, 2002).

Blood transfusions may be required in severely symptomatic patients, since it may take 6–12 hours for the liver to produce active clotting factors following initiation of vitamin K<sub>1</sub> therapy (Plumb, 2005). Exercise restriction is indicated in all patients during this lag time to prevent active bleeding (Merola, 2002). Substituting vitamin K<sub>3</sub> (menadione) for vitamin K<sub>1</sub> is not recommended, as it is not as effective and is nephrotoxic in horses (Merola, 2002; Knight, 2004).

## CONCLUSION

Proper client education is crucial to poison prevention. However, when poisonings do occur, the clinician should concentrate on treating the patient and not the poison. The same principles of history collection, physical examination and patient monitoring that are used in other cases should be applied when managing a poisoning patient. Appropriate decontamination and antidotal therapies should be decided on after initial patient stabilization.
